Lambdas 272

Annotation use-site targets 272

Java annotations 274

Repeatable annotations 276

Visibility modifiers 277

Packages 277

Class members 277

Modules 279

Coding conventions 279

Configure style in IDE 279

Source code organization 279

Naming rules 281

Formatting 283

Documentation comments 292

Avoid redundant constructs 293

Idiomatic use of language features 294

Coding conventions for libraries 298

Idioms 299

Create DTOs (POJOs/POCOs) 299

Default values for function parameters 299
Filter a list 299
Check the presence of an element in a collection 299
String interpolation 300
Read standard input safely 300
Instance checks 300
Read-only list 300
Read-only map 300
Access a map entry 300
Traverse a map or a list of pairs 300
Iterate over a range 301
Lazy property 301
Extension functions 301
Create a singleton 301
Use inline value classes for type-safe values 301
Instantiate an abstract class 302
If-not-null shorthand 302
If-not-null-else shorthand 302
Execute an expression if null 302
Get first item of a possibly empty collection 302
Execute if not null 303
Map nullable value if not null 303
Return on when statement 303
try-catch expression 303
if expression 303
Builder-style usage of methods that return Unit 304
Single-expression functions 304
Call multiple methods on an object instance (with) 304
Configure properties of an object (apply) 304
Java 7's try-with-resources 305

Generic function that requires the generic type information 305
Swap two variables 305
Mark code as incomplete (TODO) 305
What's next? 305

Types overview 306

Numbers 306

Choose a number type 306
Integer types 307
Floating-point types 308
Arithmetic operations 309
Type conversion 309
Data overflow 312
Bitwise operations 313
Floating-point number comparison 313
Boxing and caching numbers on the JVM 314

Unsigned integer types 314

Unsigned arrays and ranges 315
Unsigned integers literals 315
Use cases 316

Booleans 316

Declare a Boolean variable 317
Produce Boolean values 317
Boolean operations 317
Operator precedence 318
Boolean in conditions 319

Characters 320

Syntax 320
Unicode support 321
Escape sequences 321

Operations 322

Strings 323

Declare strings 324

String templates 325

Basic string operations 326

String conversion 330

Arrays 331

When to use arrays 331

Create arrays 332

Work with arrays 335

Convert to collections 338

What's next? 339

Type checks and casts 340

Checks with is and !is operators 340

Type casts 341

Smart casts 342

as and as? cast operators 347

Type aliases 350

Declare type aliases 351

Conditions and loops 353

If expression 353

When expressions and statements 354

For loops 360

While loops 363

Break and continue in loops 364

Returns and jumps 364

Break and continue labels 364

Return to labels 365

Exception and error handling 366

Throw exceptions 366
Handle exceptions using try-catch blocks 369
Create custom exceptions 373
The Nothing type 375
Exception classes 376
Stack trace 379
Exception interoperability with Java, Swift, and Objective-C 380

Functions 380
Function usage 380
Function scope 388
Generic functions 390
Tail recursive functions 390

Higher-order functions and lambdas 391
Higher-order functions 391
Function types 392
Lambda expressions and anonymous functions 394

Type-safe builders 397
How it works 401
Scope control: @DslMarker 403

Using builders with builder type inference 407
Writing your own builders 408
How builder inference works 409

Context parameters 412
Context parameters resolution 413
Restrictions 415

Inline functions 415
noinline 416
Non-local jump expressions 416
Reified type parameters 418

Inline properties 419
Restrictions for public API inline functions 419

Operator overloading 419

Unary operations 420
Binary operations 421
Infix calls for named functions 424

ExperimentalUnused return value checker 425

Configure the unused return value checker 425
Mark functions to check ignored results 426
Suppress reports for ignored results 427
Check for unused results in higher-order functions 428
Interoperability with Java annotations 429

Classes 429

Creating instances 430
Constructors and initializer blocks 431
Inheritance 437
Abstract classes 437
Companion objects 438

Data classes 439

Properties declared in the class body 440
Copying 440
Data classes and destructuring declarations 441
Standard data classes 441

Extensions 441

Receivers 442
Extension functions 442
Extension properties 446
Companion object extensions 447
Declaring extensions as members 448

Extensions and visibility modifiers 450
Scope of extensions 451

Interfaces 452
Implementing interfaces 452
Properties in interfaces 452
Interfaces Inheritance 453
Resolving overriding conflicts 453
JVM default method generation for interface functions 454

Delegation 455
Overriding a member of an interface implemented by delegation 455

Inheritance 456
Open keyword 457
Overriding methods 458
Overriding properties 458
Derived class initialization order 459
Calling the superclass implementation 459
Overriding rules 460

Object declarations and expressions 461
Object declarations 461
Object expressions 467
Behavior difference between object declarations and expressions 471

This expressions 471
Qualified this 472
Implicit this 475

Sealed classes and interfaces 475
Declare a sealed class or interface 476
Inheritance 478
Use sealed classes with when expression 479
Use case scenarios 480

What's next 483

Enum classes 483

Anonymous classes 483

Implementing interfaces in enum classes 484

Working with enum constants 484

Inline value classes 485

Members 486

Inheritance 487

Representation 487

Inline classes vs type aliases 488

Inline classes and delegation 489

Nested and inner classes 489

Inner classes 490

Anonymous inner classes 490

Functional (SAM) interfaces 491

SAM conversions 491

Migration from an interface with constructor function to a functional interface 492

Functional interfaces vs. type aliases 492

Properties 493

Declaring properties 493

Custom getters and setters 495

Backing fields 497

Compile-time constants 500

Late-initialized properties and variables 501

Overriding properties 502

Delegated properties 502

Delegated properties 502

Standard delegates 504

Delegating to another property 504

Storing properties in a map 505
Local delegated properties 506
Property delegate requirements 506
Translation rules for delegated properties 508
Providing a delegate 509

Null safety 511
Nullable types and non-nullable types 512
Check for null with the if conditional 513
Safe call operator 514
Elvis operator 515
Not-null assertion operator 515
Nullable receiver 516
Let function 517
Safe casts 517
Collections of a nullable type 518
What's next? 518

Equality 518
Structural equality 518
Referential equality 520
Floating-point numbers equality 520
Array equality 520

Generics: in, out, where 521
Variance 521
Type projections 524
Generic functions 526
Generic constraints 526
Definitely non-nullable types 527
Type erasure 527
Underscore operator for type arguments 529

Asynchronous programming techniques 530

Threading 530

Callbacks 531

Futures, promises, and others 532

Reactive extensions 532

Coroutines 533

Coroutines 533

Coroutine concepts 534

What's next 535

Reflection 535

JVM dependency 535

Class references 536

Callable references 537

Destructuring declarations 540

Example: returning two values from a function 541

Example: destructuring declarations and maps 541

Underscore for unused variables 542

Destructuring in lambdas 542

ExperimentalName-based destructuring 543

Backend development with Kotlin 544

Get started 545

Explore frameworks 545

Deploy your applications 546

Join the community 546

Next steps 546

Adding Kotlin to a Java project – tutorial 546

Project configuration 547

Project structure 549

Convert Java files to Kotlin 549

Explore compiler plugins 550
Next step 550

Test Java code using Kotlin and JUnit – tutorial....551
Configure the project 551
Add your first Kotlin test....555
Run tests 557
What's next....559

Test Kotlin projects with Maven 559
Create tests with JUnit 559
Run tests....561
Get detailed failure messages....562
Explore other testing frameworks 564
What's next....565

Use annotation processors in Kotlin projects 565
Use kapt with Java annotation processors 565
Use KSP in Gradle projects....567
What's next....569

Code quality tools in Kotlin projects 569
Code formatting with ktlint 569
Code analysis with detekt 571
Code quality with SonarSource 573
Code coverage with Kover....575
Other tools....577
What's next 578

Get started with Spring Boot and Kotlin 578
Next step....578

Create a Spring Boot project with Kotlin 579
Before you start 579
Create a Spring Boot project 579

Explore the project Gradle build file....582
Explore the generated Spring Boot application....584
Create a controller....584
Run the application....585
Next step....587

Add a data class to Spring Boot project....587

Update your application....587
Run the application....590
Next step....590

Add database support for Spring Boot project....590

Add database support....590
Update the MessageController class....592
Update the MessageService class....592
Configure the database....593
Add messages to database via HTTP request....594
Retrieve messages by id....596
Run the application....600
Next step....601

Use Spring Data CrudRepository for database access....601

Update your application....601
Run the application....604
What's next....605

Create a task manager app with Spring Boot and Claude....605

Set up the environment....605
Create a project....605
Create a development plan....607
Review the commits....609
Run the app....609
Test the app....610

Make refinements 611

Kotlin/Native FAQ 757
How do I run my program? 757
What is Kotlin/Native memory management model? 757
How do I create a shared library? 757
How do I create a static library or an object file? 757
How do I run Kotlin/Native behind a corporate proxy? 757
How do I specify a custom Objective-C prefix/name for my Kotlin framework? 758
How do I rename the iOS framework? 758
How do I enable bitcode for my Kotlin framework? 758
How do I get better crash reports for iOS? 759
How do I reference objects safely from different coroutines? 759
How can I compile my project with unreleased versions of Kotlin/Native? 759

Kotlin for Android 759

Introduction to library authors' guidelines 760
What's next 761

Minimizing mental complexity overview 761
Next step 762

Simplicity 762
Use explicit API mode 762
Reuse existing concepts 762
Define and build on top of core API 762
Next step 763

Readability 763
Prefer Explicit Composability 763
Use DSLs 764
Use extension functions and properties 765
Avoid using the boolean type as an argument 765
Use numeric types appropriately 766
Next step 766

Consistency **766**

Preserve parameter order, naming and usage 767

Use Object-Oriented design for data and state 767

Choose the appropriate error handling mechanism 767

Maintain conventions and quality 768

Next step 768

Predictability **768**

Do the right thing by default 768

Allow opportunities for extension 769

Prevent unwanted and invalid extensions 769

Avoid exposing mutable state 770

Validate inputs and state 770

Next step 771

Debuggability **771**

Provide a toString method for stateful types 771

Adopt and document a policy for handling exceptions 774

ExperimentalSupport coroutine stack trace recovery for custom exceptions 774

Next step 775

Testability **775**

Avoid global state and stateful top-level functions 775

What's next 776

Backward compatibility guidelines for library authors **776**

Compatibility types 776

Choose compatible language and API versions 777

Use the Binary compatibility validator 777

Specify return types explicitly 778

Avoid adding arguments to existing API functions 778

Avoid widening or narrowing return types 779

Avoid using data classes in your API 780

Avoid changing annotation targets 781
Considerations for using the PublishedApi annotation 782
Evolve APIs pragmatically....782
Use the RequiresOptIn mechanism....782
What's next 783

Best practices for library authors to create informative documentation 783

Provide comprehensive documentation 784
Create personas for your users 784
Document by example whenever possible 784
Thoroughly document your API 785
Document lambda parameters....785
Use explicit links in documentation 786
Be self-contained where possible....786
Use simple English....786
What's next....786

Building a Kotlin library for multiplatform....786

Maximize your reach....787
Design APIs for use from common code 787
Ensure consistent behavior across platforms 787
Test on all platforms 788
Consider non-Kotlin users 788
Promote your library 788

Get started with Kotlin custom scripting – tutorial 788

Project structure 789
Before you start 789
Create a project....789
Add scripting modules....790
Create a script definition....792
Create a scripting host....794
Run scripts....796

What's next? 797

IDEs for Kotlin development 797

IntelliJ IDEA 797

Android Studio 797

Visual Studio Code 798

Other IDEs support 798

Compatibility with the Kotlin language versions 798

What's next? 798

Java synthetic property references 901

Methods returning void 902

Escaping for Java identifiers that are keywords in Kotlin 902

Null-safety and platform types 902
Mapped types 910
Java generics in Kotlin 912
Java arrays 913
Java varargs 913
Operators 914
Checked exceptions 914
Object methods 914
Inheritance from Java classes 916
Accessing static members 916
Java reflection 916
SAM conversions 917
Using JNI with Kotlin 917
Using Lombok-generated declarations in Kotlin 917

Calling Kotlin from Java 918

Properties 918
Package-level functions 918
Instance fields 919
Static fields 920
Static methods 921
Default methods in interfaces 922
Visibility 923
KClass 924
Handling signature clashes with @JvmName 924
Overloads generation 925
Checked exceptions 926
Null-safety 927
Variant generics 927
ExperimentalInline value classes 929

Using Java records in Kotlin 930

Using Java records from Kotlin code 930
Declare records in Kotlin 930
ExperimentalAnnotate record components in Kotlin 931
Make annotations work with record components 932
Further discussion 932

Strings in Java and Kotlin 932
Concatenate strings 932
Build a string 932
Create a string from collection items 933
Set default value if the string is blank 934
Replace characters at the beginning and end of a string 934
Replace occurrences 934
Split a string 935
Take a substring 935
Use multiline strings 936
What's next? 937

Collections in Java and Kotlin 937
Operations that are the same in Java and Kotlin 938
Operations that differ a bit 940
Operations that don't exist in Java's standard library 941
Mutability 941
Covariance 942
Ranges and progressions 943
Comparison by several criteria 944
Sequences 945
Removal of elements from a list 945
Traverse a map 946
Get the first and the last items of a possibly empty collection 946
Create a set from a list 947
Group elements 947

Filter elements....948
Collection transformation operations....950
What's next?....951

Nullability in Java and Kotlin....951
Support for nullable types....951
Platform types....953
Support for definitely non-nullable types....953
Checking the result of a function call....954
Default values instead of null....955
Functions returning a value or null....955
Aggregate operations....955
Casting types safely....956
What's next?....957

Standard input....957
Read from the standard input with Java Scanner....958
Read from the standard input with readln()....959

Browser and DOM API....960
Interaction with the DOM....960
What's next?....961

Use JavaScript code from Kotlin....961
Inline JavaScript....961
external modifier....962
Equality....965

Dynamic type....966

Use dependencies from npm....967

Use Kotlin code from JavaScript....968
Isolating declarations in a separate JavaScript object in plain mode....968
Package structure....968
Kotlin types in JavaScript....974

JavaScript modules 976

Browser targets 976

JavaScript libraries and Node.js files 976

@JsModule annotation 977

Kotlin/JS reflection 979

Class references 979

KType and typeOf() 980

KClass and createInstance() 980

Example 980

Typesafe HTML DSL 980

Interoperability with Swift/Objective-C 982

Importing Swift/Objective-C libraries to Kotlin 982

Using Kotlin in Swift/Objective-C 982

Mappings 984

Casting between mapped types 994

Subclassing 994

C features 995

Unsupported 995

Kotlin/Native as an Apple framework – tutorial 995

Create a Kotlin library 996

Generated framework headers 999

Garbage collection and reference counting 1002

Use code from Objective-C 1002

Use code from Swift 1003

Connect the framework to your iOS project 1003

What's next 1003

Interoperability with Swift using Swift export 1004

Enable Swift export 1004

Current limitations 1006

Mappings....1007
Cross-language inheritance....1014
Evolution of Swift export....1014

Interoperability with C....1015

Setting up your project....1015
Bindings....1015
What's next....1023

Mapping primitive data types from C – tutorial....1023

Types in C language....1024
Create a C library....1024
Create a Kotlin/Native project....1025
Inspect generated Kotlin APIs for a C library....1028
Update Kotlin code....1028
Next step....1029

Mapping struct and union types from C – tutorial....1029

Mapping struct and union C types....1029
Inspect generated Kotlin APIs for a C library....1030
Use struct and union types from Kotlin....1032
Update Kotlin code....1034
Next step....1035

Mapping function pointers from C – tutorial....1036

Mapping function pointer types from C....1036
Inspect generated Kotlin APIs for a C library....1036
Pass Kotlin function as a C function pointer....1037
Use the C function pointer from Kotlin....1037
Update Kotlin code....1038
Next step....1038

Mapping strings from C – tutorial....1039

Working with C strings....1039

Inspect generated Kotlin APIs for a C library 1040
Pass Kotlin strings to C 1041
Read C strings in Kotlin 1041
Receive C string bytes from Kotlin 1041
Update Kotlin code 1042
What's next 1043

Kotlin/Native as a dynamic library – tutorial 1043

Create a Kotlin library 1043
Generated header file 1046
Use generated headers from C 1050
Compile and run the project 1050
What's next 1051

Create an app using C interop and libcurl – tutorial 1051

Before you start 1052
Create a definition file 1053
Add interoperability to the build process 1054
Write the application code 1055
Compile and run the application 1055
What's next 1056

Definition file 1057

Create and configure a definition file 1057
Properties 1058
Generate bindings using command line 1062
What's next 1062

C, Objective-C, and Swift library import 1062

BetaStability of C and Objective-C library import 1062
Swift library import 1066

Kotlin AI skills 1068

Supported workflows 1069

Get support 1069

Kotlin for AI-powered app development 1069

Koog 1070

Model Context Protocol (MCP) Kotlin SDK 1071

Explore other AI-powered application scenarios 1071

What's next 1072

Create a Kotlin app that answers questions with Spring AI — tutorial 1072

Before you start 1072

Create the project 1073

Update the project configuration 1076

Create a controller to load and search documents 1077

Implement an AI chat endpoint 1079

What's next 1082

Kotlin for data analysis 1082

Kotlin DataFrame 1082

Kandy 1083

What's next 1084

Retrieve data from files 1084

Before you start 1085

Retrieve data 1085

Display data 1085

Inspect data structure 1086

Refine data 1087

Export data 1088

What's next 1089

Retrieve data from web sources and APIs 1089

Before you start 1089

Fetch data from an API 1090

Clean and refine data 1091

Analyze data in Kotlin Notebook 1091
What's next 1093

Connect and retrieve data from databases 1093
Before you start 1094
Connect to a database 1094
Inspect database schema 1095
Load data 1095
Process data 1096
Analyze data 1096
What's next 1097

Data visualization with Kandy 1097
Before you start 1097
Create a DataFrame 1098
Create a line chart 1099
Create a points chart 1099
Create a bar chart 1100
What's next 1101

Data visualization with Lets-Plot for Kotlin 1102
Before you start 1102
Prepare the data 1103
Create a scatter plot 1104
Create a box plot 1105
Create a 2D density plot 1106
What's next 1108

Kotlin and Java libraries for data analysis 1108
Kotlin libraries 1108
Java libraries 1110

Collections overview 1111
Collection types 1112

Constructing collections 1117
Construct from elements 1117
Create with collection builder functions 1117
Empty collections 1117
Initializer functions for lists 1118
Concrete type constructors 1118
Copy 1118
Invoke functions on other collections 1119
Iterators 1119
List iterators 1120
Mutable iterators 1121
Ordering 1122
Natural order 1123
Custom orders 1124
Check sorted order 1124
Reverse order 1125
Random order 1126
Grouping 1126
Collection transformation operations 1127
Map 1127
Zip 1128
Associate 1129
Flatten 1130
String representation 1130
Filtering collections 1131
Filter by predicate 1131
Partition 1132
Test predicates 1132
Retrieve collection parts 1133

Slice....1133
Take and drop....1133
Chunked....1134
Windowed....1135
Retrieve single elements....1135
Retrieve by position....1136
Retrieve by condition....1136
Retrieve with selector....1137
Random element....1137
Check element existence....1138
Collection operations overview....1138
Extension and member functions....1138
Common operations....1139
Write operations....1140
Aggregate operations....1140
Fold and reduce....1141
Collection write operations....1143
Adding elements....1143
Removing elements....1143
Updating elements....1144
List-specific operations....1145
Retrieve elements by index....1145
Retrieve list parts....1145
Find element positions....1145
List write operations....1147
Set-specific operations....1149
Map-specific operations....1150
Retrieve keys and values....1150
Filter....1151

Plus and minus operators 1152
Map write operations 1152
Plus and minus operators 1155
Sequences 1155
Construct 1155
Sequence operations 1157
Sequence processing example 1157
Ranges and progressions 1159
Ranges 1159
Progressions 1160
Read standard input 1161
Handle standard input safely 1162
Opt-in requirements 1163
Opt in to API 1163
Require opt-in to use API 1168
Require opt-in to extend API 1170
Opt-in requirements for pre-stable APIs 1170
Scope functions 1171
Function selection 1171
Distinctions 1172
Functions 1176
takeIf and takeUnless 1179
Time measurement 1180
Calculate duration 1180
Measure time 1184
Time sources 1186
UUIDs 1187
Generate UUIDs 1187

Parse UUIDs 1188
Convert UUIDs to strings 1189
Compare UUIDs 1190
Work with binary representations 1190
Serialize UUIDs 1192
Use UUIDs with Java APIs 1192

Jumping between threads....1307

Job in the context....1308

Children of a coroutine....1308

Parental responsibilities....1309

Naming coroutines for debugging....1310

Combining context elements....1311

Coroutine scope....1311

Channels **1314**
Channel basics 1314
Closing and iteration over channels 1314
Building channel producers 1315
Pipelines 1315
Prime numbers with pipeline 1316
Fan-out 1318
Fan-in 1319
Buffered channels 1320
Channels are fair 1320
Ticker channels 1321

Coroutine exceptions handling **1322**
Exception propagation 1323
CoroutineExceptionHandler 1323
Cancellation and exceptions 1324
Exceptions aggregation 1326
Supervision 1328

Shared mutable state and concurrency **1331**
The problem 1331
Volatiles are of no help 1332
Thread-safe data structures 1333
Thread confinement fine-grained 1334
Thread confinement coarse-grained 1335
Mutual exclusion 1336

Select expression (experimental) **1337**
Selecting from channels 1337
Selecting on close 1339
Selecting to send 1341
Selecting deferred values 1342

Switch over a channel of deferred values....1343

Debug coroutines....1346

Enable debug mode....1346

Stack trace recovery....1347

ExperimentalThe debug agent....1351

What's next....1359

Debug coroutines using IntelliJ IDEA – tutorial....1359

Create coroutines....1359

Debug coroutines....1360

Debug Kotlin Flow using IntelliJ IDEA – tutorial....1363

Create a Kotlin flow....1363

Debug the coroutine....1365

Add a concurrently running coroutine....1368

Debug a Kotlin flow with two coroutines....1368

Serialization....1369

Kotlin serialization libraries....1369

Supported serialization formats....1370

Supported serialization types....1370

What's next....1370

Get started with Kotlin serialization....1371

Add plugins and dependencies....1371

Serialize objects to JSON....1374

Deserialize objects from JSON....1375

What's next....1376

Serialize built-in types....1376

Basic types....1376

Standard library types....1379

What's next....1382

Serialize classes....1383

The @Serializable annotation....1383
Optional properties....1385
Customize class serialization....1389
What's next....1391
JSON serialization overview....1391
What's next....1392
Customize the Json instance....1392
Customize JSON structure....1393
Customize JSON deserialization....1399
Customize name mapping between JSON and Kotlin....1403
What's next....1405
JSON elements....1405
Parse strings to JSON elements....1406
Access the contents of JSON elements....1406
Create JSON elements....1407
Decode Json elements....1411
What's next....1411
Transform JSON structure....1412
Modify JSON structure....1412
Select the appropriate polymorphic class based on the JSON content....1415
ExperimentalAdd custom behavior to the default serializer....1417
ExperimentalImplement custom serialization logic in JSON....1418
What's next....1421
ExperimentalSerialize JSON with I/O sources....1421
Serialize JSON to JVM output streams....1422
Deserialize JSON from JVM input streams....1422
JSON serialization with kotlinx-io and Okio....1423
What's next....1426
Serialize polymorphic classes....1426

Serialize closed polymorphic classes 1427
Define custom serial names for subclasses 1429
Base class properties with backing fields 1430
Serialize objects in polymorphic class hierarchies 1430
Serialize open polymorphic classes 1431
What's next 1445

Create and use serializers 1445
Obtain serializers 1446
Create custom serializers 1447
Apply serializers 1463
What's next 1469

Kotlin Metadata JVM library 1469
Add the library to your project 1469
Read and parse metadata 1470
Modify metadata 1476
Create metadata from scratch 1477
What's next? 1480

Overview 1480
How Lincheck works 1481
Explore Lincheck 1481
Learn more 1482

Getting started with Lincheck 1482
Create a project 1482
Add dependencies 1482
Write your first test 1483
Write a test for a data structure 1484
What's next 1485

Testing arbitrary code 1486
Example: test ConcurrentHashMap functions 1487

What's next 1488

Kotlin Docs

Get started with Kotlin

Kotlin is a modern language that's concise, multiplatform, and interoperable with Java and other languages.

New to Kotlin? Take our tour to learn the fundamentals directly in your browser.

Start the Kotlin tour

Install Kotlin

Kotlin is included in each IntelliJ IDEA and Android Studio release. Download and install one of these IDEs to start using Kotlin.

Choose your Kotlin use case

Console

Here you'll learn how to develop a console application and create unit tests with Kotlin.

1. Create a basic JVM application with the IntelliJ IDEA project wizard.
2. Write your first unit test.

Backend

Here you'll learn how to develop a backend application with Kotlin server-side.

- **Introduce Kotlin to your Java project:**
  - Configure a Java project to work with Kotlin
  - Add Kotlin tests to your Java Maven project
- **Create a backend app from scratch with Kotlin:**
  - Create a RESTful web service with Spring Boot
  - Create HTTP APIs with Ktor

Cross-platform

Here you'll learn how to develop a cross-platform application using Kotlin Multiplatform.

1. Set up your environment for cross-platform development.
2. **Create your first application for iOS and Android:**
   - Create a cross-platform application from scratch and:
     - Share business logic while keeping the UI native
     - Share business logic and UI
   - Make your existing Android application work on iOS
   - Create a cross-platform application using Ktor and SQLdelight
3. **Explore** sample projects.

Android

To start using Kotlin for Android development, read Google's recommendation for getting started with Kotlin on Android.

Data analysis

From building data pipelines to productionizing machine learning models, Kotlin is a great choice for working with data and getting the most out of it.

1. **Explore and experiment with your data:**
   - DataFrame – a library for data analysis and manipulation.
   - Kandy – a plotting tool for data visualization.
2. **Follow Kotlin for Data Analysis on Twitter:** KotlinForData.

Get support

If you encounter any difficulties or problems, ask for help in Slack: get an invite or report an issue in our issue tracker.

If anything is missing or seems confusing on this page, please share your feedback.

Welcome to our tour of Kotlin!

These tours can be completed entirely within your browser. There is no installation required.

Quickly learn the essentials of the Kotlin programming language through our tours.

Beginner

Grasp the fundamentals.

Start

Intermediate

Take your understanding of Kotlin to the next level.

Start

Hello world

Here is a simple program that prints "Hello, world!":

```
fun main() {
    println("Hello, world!")
    // Hello, world!
}
```

In Kotlin:

- `fun` is used to declare a function
- The `main()` function is where your program starts from
- The body of a function is written within curly braces `{}`
- `println()` and `print()` functions print their arguments to standard output

A function is a set of instructions that performs a specific task. Once you create a function, you can use it whenever you need to perform that task, without having to write the instructions all over again. Functions are discussed in more detail in a couple of chapters. Until then, all examples use the `main()` function.

Variables

All programs need to be able to store data, and variables help you to do just that. In Kotlin, you can declare:

- Read-only variables with `val`
- Mutable variables with `var`

> You can't change a read-only variable once you have given it a value.

To assign a value, use the assignment operator `=`.

For example:

```
fun main() {
    val popcorn = 5    // There are 5 boxes of popcorn
    val hotdog = 7     // There are 7 hotdogs
    var customers = 10 // There are 10 customers in the queue

    // Some customers leave the queue
    customers = 8
    println(customers)
    // 8
}
```

> Variables can be declared outside the `main()` function at the beginning of your program. Variables declared in this way are said to be declared at **top level**.

As `customers` is a mutable variable, its value can be reassigned after declaration.

> We recommend declaring all variables as read-only (`val`) by default. Only use mutable variables (`var`) if you really need to. That way, you're less likely to accidentally change something that wasn't meant to change.

String templates

It's useful to know how to print the contents of variables to standard output. You can do this with **string templates**. You can use template expressions to access data stored in variables and other objects, and convert them into strings. A string value is a sequence of characters in double quotes `"`. Template expressions always start with a dollar sign `$`.

To evaluate a piece of code in a template expression, place the code within curly braces `{}` after the dollar sign `$`.

For example:

```
fun main() {
    val customers = 10
    println("There are $customers customers")
    // There are 10 customers

    println("There are ${customers + 1} customers")
    // There are 11 customers
}
```

For more information, see String templates.

You will notice that there aren't any types declared for variables. Kotlin has inferred the type itself: `Int`. This tour explains the different Kotlin basic types and how to declare them in the next chapter.

Practice

Exercise

Complete the code to make the program print `"Mary is 20 years old"` to standard output:

```
fun main() {
    val name = "Mary"
    val age = 20
    // Write your code here
}
```

```
fun main() {
    val name = "Mary"
    val age = 20
    println("$name is $age years old")
}
```

- Next step

Basic types

Every variable and data structure in Kotlin has a type. Types are important because they tell the compiler what you are allowed to do with that variable or data structure. In other words, what functions and properties it has.

In the last chapter, Kotlin was able to tell in the previous example that `customers` has type `Int`. Kotlin's ability to **infer** the type is called **type inference**. `customers` is assigned an integer value. From this, Kotlin infers that `customers` has a numerical type `Int`. As a result, the compiler knows that you can perform arithmetic operations with `customers`:

```
fun main() {
    var customers = 10

    // Some customers leave the queue
    customers = 8

    customers = customers + 3 // Example of addition: 11
    customers += 7            // Example of addition: 18
    customers -= 3            // Example of subtraction: 15
    customers *= 2            // Example of multiplication: 30
    customers /= 3            // Example of division: 10

    println(customers) // 10
}
```

`+=`, `-=`, `*=`, `/=`, and `%=` are augmented assignment operators. For more information, see Augmented assignments.

In total, Kotlin has the following basic types:

Category	Basic types	Example code
Integers	`Byte`, `Short`, `Int`, `Long`	`val year: Int = 2020` `val amount: Long = 350_000_000`
Unsigned integers	`UByte`, `UShort`, `UInt`, `ULong`	`val score: UInt = 100u`
Floating-point numbers	`Float`, `Double`	`val currentTemp: Float = 24.5f` `val price: Double = 19.99`
Booleans	`Boolean`	`val isEnabled: Boolean = true`
Characters	`Char`	`val separator: Char = ','`
Strings	`String`	`val message: String = "Hello, world!"`

For more information on basic types and their properties, see Types overview.

With this knowledge, you can declare variables and initialize them later. Kotlin can manage this as long as variables are initialized before the first read.

To declare a variable without initializing it, specify its type with `:`. For example:

```
fun main() {
    // Variable declared without initialization
    val d: Int
    // Variable initialized
    d = 3

    // Variable explicitly typed and initialized
    val e: String = "hello"

    // Variables can be read because they have been initialized
    println(d) // 3
    println(e) // hello
}
```

If you don't initialize a variable before it is read, you see an error:

```
fun main() {
    // Variable declared without initialization
    val d: Int

    // Triggers an error
    println(d)
    // Variable 'd' must be initialized
}
```

Now that you know how to declare basic types, it's time to learn about collections.

Practice

Exercise

Explicitly declare the correct type for each variable:

```
fun main() {
    val a: Int = 1000
    val b = "log message"
    val c = 3.14
    val d = 100_000_000_000_000
    val e = false
    val f = '\n'
}
```

```
fun main() {
    val a: Int = 1000
    val b: String = "log message"
    val c: Double = 3.14
    val d: Long = 100_000_000_000_000
    val e: Boolean = false
    val f: Char = '\n'
}
```

Previous step

Next step

Collections

When programming, it is useful to be able to group data into structures for later processing. Kotlin provides collections for exactly this purpose.

Kotlin has the following collections for grouping items:

Collection type	Description
Lists	Ordered collections of items
Sets	Unique unordered collections of items
Maps	Sets of key-value pairs where keys are unique and map to only one value

Each collection type can be mutable or read only.

List

Lists store items in the order that they are added, and allow for duplicate items.

To create a read-only list (`List`), use the `listOf()` function.

To create a mutable list (`MutableList`), use the `mutableListOf()` function.

When creating lists, Kotlin can infer the type of items stored. To declare the type explicitly, add the type within angled brackets `<>` after the list declaration:

```
fun main() {
    // Read only list
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println(readOnlyShapes)
    // [triangle, square, circle]

    // Mutable list with explicit type declaration
    val shapes: MutableList<String> = mutableListOf("triangle", "square", "circle")
    println(shapes)
    // [triangle, square, circle]
}
```

To prevent unwanted modifications, you can create a read-only view of a mutable list by assigning it to a `List` :

```
val shapes: MutableList<String> = mutableListOf("triangle", "square", "circle")
    val shapesLocked: List<String> = shapes
```

This is also called **casting**.

Lists are ordered so to access an item in a list, use the indexed access operator `[]` :

```
fun main() {
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println("The first item in the list is: ${readOnlyShapes[0]}")
    // The first item in the list is: triangle
}
```

To get the first or last item in a list, use `.first()` and `.last()` functions respectively:

```
fun main() {
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println("The first item in the list is: ${readOnlyShapes.first()}")
    // The first item in the list is: triangle
}
```

`.first()` and `.last()` functions are examples of **extension** functions. To call an extension function on an object, write the function name after the object appended with a period `.`

Extension functions are covered in detail in the intermediate tour. For now, you only need to know how to call them.

To get the number of items in a list, use the `.count()` function:

```
fun main() {
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println("This list has ${readOnlyShapes.count()} items")
    // This list has 3 items
}
```

To check that an item is in a list, use the `in` operator:

```
fun main() {
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println("circle" in readOnlyShapes)
    // true
}
```

To add or remove items from a mutable list, use `.add()` and `.remove()` functions respectively:

```
fun main() {
    val shapes: MutableList<String> = mutableListOf("triangle", "square", "circle")
    // Add "pentagon" to the list
    shapes.add("pentagon")
    println(shapes)
    // [triangle, square, circle, pentagon]

    // Remove the first "pentagon" from the list
    shapes.remove("pentagon")
    println(shapes)
    // [triangle, square, circle]
}
```

Set

Whereas lists are ordered and allow duplicate items, sets are **unordered** and only store **unique** items.

To create a read-only set (`Set`), use the `setOf()` function.

To create a mutable set (`MutableSet`), use the `mutableSetOf()` function.

When creating sets, Kotlin can infer the type of items stored. To declare the type explicitly, add the type within angled brackets `<>` after the set declaration:

```
fun main() {
    // Read-only set
    val readOnlyFruit = setOf("apple", "banana", "cherry", "cherry")
    // Mutable set with explicit type declaration
    val fruit: MutableSet<String> = mutableSetOf("apple", "banana", "cherry", "cherry")

    println(readOnlyFruit)
    // [apple, banana, cherry]
}
```

You can see in the previous example that because sets only contain unique elements, the duplicate `"cherry"` item is dropped.

To prevent unwanted modifications, you can create a read-only view of a mutable set by assigning it to a `Set` :

```
val fruit: MutableSet<String> = mutableSetOf("apple", "banana", "cherry", "cherry")
    val fruitLocked: Set<String> = fruit
```

As sets are **unordered**, you can't access an item at a particular index.

To get the number of items in a set, use the `.count()` function:

```
fun main() {
    val readOnlyFruit = setOf("apple", "banana", "cherry", "cherry")
    println("This set has ${readOnlyFruit.count()} items")
    // This set has 3 items
}
```

To check that an item is in a set, use the `in` operator:

```
fun main() {
    val readOnlyFruit = setOf("apple", "banana", "cherry", "cherry")
    println("banana" in readOnlyFruit)
    // true
}
```

To add or remove items from a mutable set, use `.add()` and `.remove()` functions respectively:

```
fun main() {
    val fruit: MutableSet<String> = mutableSetOf("apple", "banana", "cherry", "cherry")
    fruit.add("dragonfruit")    // Add "dragonfruit" to the set
    println(fruit)              // [apple, banana, cherry, dragonfruit]

    fruit.remove("dragonfruit") // Remove "dragonfruit" from the set
    println(fruit)              // [apple, banana, cherry]
}
```

Map

Maps store items as key-value pairs. You access the value by referencing the key. You can imagine a map like a food menu. You can find the price (value), by finding the food (key) you want to eat. Maps are useful if you want to look up a value without using a numbered index, like in a list.

- Every key in a map must be unique so that Kotlin can understand which value you want to get.
- You can have duplicate values in a map.

To create a read-only map (`Map`), use the `mapOf()` function.

To create a mutable map (`MutableMap`), use the `mutableMapOf()` function.

When creating maps, Kotlin can infer the type of items stored. To declare the type explicitly, add the types of the keys and values within angled brackets `<>` after the map declaration. For example: `MutableMap<String, Int>` . The keys have type `String` and the values have type `Int` .

The easiest way to create maps is to use `to` between each key and its related value:

```
fun main() {
    // Read-only map
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println(readOnlyJuiceMenu)
    // {apple=100, kiwi=190, orange=100}

    // Mutable map with explicit type declaration
    val juiceMenu: MutableMap<String, Int> = mutableMapOf("apple" to 100, "kiwi" to 190, "orange" to
100)
    println(juiceMenu)
    // {apple=100, kiwi=190, orange=100}
}
```

To prevent unwanted modifications, you can create a read-only view of a mutable map by assigning it to a `Map` :

```
val juiceMenu: MutableMap<String, Int> = mutableMapOf("apple" to 100, "kiwi" to 190, "orange"
to 100)
    val juiceMenuLocked: Map<String, Int> = juiceMenu
```

To access a value in a map, use the indexed access operator `[]` with its key:

```
fun main() {
    // Read-only map
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println("The value of apple juice is: ${readOnlyJuiceMenu["apple"]}")
    // The value of apple juice is: 100
}
```

If you try to access a key-value pair with a key that doesn't exist in a map, you see a `null` value:

```
fun main() {
    // Read-only map
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println("The value of pineapple juice is: ${readOnlyJuiceMenu["pineapple"]}")
    // The value of pineapple juice is: null
}
```

This tour explains null values later in the Null safety chapter.

You can also use the indexed access operator `[]` to add items to a mutable map:

```
fun main() {
    val juiceMenu: MutableMap<String, Int> = mutableMapOf("apple" to 100, "kiwi" to 190, "orange" to
100)
    juiceMenu["coconut"] = 150 // Add key "coconut" with value 150 to the map
    println(juiceMenu)
    // {apple=100, kiwi=190, orange=100, coconut=150}
}
```

To remove items from a mutable map, use the `.remove()` function:

```
fun main() {
    val juiceMenu: MutableMap<String, Int> = mutableMapOf("apple" to 100, "kiwi" to 190, "orange" to
100)
    juiceMenu.remove("orange")     // Remove key "orange" from the map
    println(juiceMenu)
    // {apple=100, kiwi=190}
}
```

To get the number of items in a map, use the `.count()` function:

```
fun main() {
    // Read-only map
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println("This map has ${readOnlyJuiceMenu.count()} key-value pairs")
    // This map has 3 key-value pairs
}
```

To check if a specific key is already included in a map, use the `.containsKey()` function:

```
fun main() {
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println(readOnlyJuiceMenu.containsKey("kiwi"))
    // true
}
```

To obtain a collection of the keys or values of a map, use the `keys` and `values` properties respectively:

```
fun main() {
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println(readOnlyJuiceMenu.keys)
    // [apple, kiwi, orange]
    println(readOnlyJuiceMenu.values)
    // [100, 190, 100]
}
```

`keys` and `values` are examples of **properties** of an object. To access the property of an object, write the property name after the object appended with a period `.`

Properties are discussed in more detail in the Classes chapter. At this point in the tour, you only need to know how to access them.

To check that a key or value is in a map, use the `in` operator:

```
fun main() {
    val readOnlyJuiceMenu = mapOf("apple" to 100, "kiwi" to 190, "orange" to 100)
    println("orange" in readOnlyJuiceMenu.keys)
    // true

    // Alternatively, you don't need to use the keys property
    println("orange" in readOnlyJuiceMenu)
    // true

    println(200 in readOnlyJuiceMenu.values)
    // false
}
```

For more information on what you can do with collections, see Collections.

Now that you know about basic types and how to manage collections, it's time to explore the control flow that you can use in your programs.

Practice

Exercise 1

You have a list of “green” numbers and a list of “red” numbers. Complete the code to print how many numbers there are in total.

```
fun main() {
    val greenNumbers = listOf(1, 4, 23)
    val redNumbers = listOf(17, 2)
    // Write your code here
}
```

```
fun main() {
    val greenNumbers = listOf(1, 4, 23)
    val redNumbers = listOf(17, 2)
    val totalCount = greenNumbers.count() + redNumbers.count()
    println(totalCount)
}
```

Exercise 2

You have a set of protocols supported by your server. A user requests to use a particular protocol. Complete the program to check whether the requested protocol is supported or not (`isSupported` must be a Boolean value).

```
fun main() {
    val SUPPORTED = setOf("HTTP", "HTTPS", "FTP")
    val requested = "smtp"
    val isSupported = // Write your code here
    println("Support for $requested: $isSupported")
}
```

Hint

Make sure that you check the requested protocol in upper case. You can use the `.uppercase()` function to help you with this.

```
fun main() {
    val SUPPORTED = setOf("HTTP", "HTTPS", "FTP")
    val requested = "smtp"
    val isSupported = requested.uppercase() in SUPPORTED
    println("Support for $requested: $isSupported")
}
```

Exercise 3

Define a map that relates integer numbers from 1 to 3 to their corresponding spelling. Use this map to spell the given number.

```
fun main() {
    val number2word = // Write your code here
    val n = 2
    println("$n is spelled as '${<Write your code here >}'")
}
```

```
fun main() {
    val number2word = mapOf(1 to "one", 2 to "two", 3 to "three")
    val n = 2
    println("$n is spelled as '${number2word[n]}'")
}
```

Previous step

Next step

Control flow

Like other programming languages, Kotlin is capable of making decisions based on whether a piece of code is evaluated to be true. Such pieces of code are called **conditional expressions**. Kotlin is also able to create and iterate through loops.

Conditional expressions

Kotlin provides `if` and `when` for checking conditional expressions.

If you have to choose between `if` and `when`, we recommend using `when` because it:

- Makes your code easier to read.
- Makes it easier to add another branch.
- Leads to fewer mistakes in your code.

If

To use `if`, add the conditional expression within parentheses `()` and the action to take if the result is true within curly braces `{}`:

```
fun main() {
    val d: Int
    val check = true

    if (check) {
        d = 1
    } else {
        d = 2
    }

    println(d)
    // 1
}
```

There is no ternary operator `condition ? then : else` in Kotlin. Instead, `if` can be used as an expression. If there is only one line of code per action, the curly braces `{}` are optional:

```
fun main() {
    val a = 1
    val b = 2

    println(if (a > b) a else b) // Returns a value: 2
}
```

When

Use `when` when you have a conditional expression with multiple branches.

To use `when`:

- Place the value you want to evaluate within parentheses `()`.
- Place the branches within curly braces `{}`.
- Use `->` in each branch to separate each check from the action to take if the check is successful.

`when` can be used either as a statement or as an expression. A **statement** doesn't return anything but performs actions instead.

Here is an example of using `when` as a statement:

```
fun main() {
    val obj = "Hello"

    when (obj) {
        // Checks whether obj equals to "1"
        "1" -> println("One")
        // Checks whether obj equals to "Hello"
        "Hello" -> println("Greeting")
        // Default statement
        else -> println("Unknown")
    }
    // Greeting
}
```

Note that all branch conditions are checked sequentially until one of them is satisfied. So only the first suitable branch is executed.

An **expression** returns a value that can be used later in your code.

Here is an example of using `when` as an expression. The `when` expression is assigned immediately to a variable which is later used with the `println()` function:

```
fun main() {
//sampleStart
    val obj = "Hello"

    val result = when (obj) {
        // If obj equals "1", sets result to "one"
        "1" -> "One"
        // If obj equals "Hello", sets result to "Greeting"
        "Hello" -> "Greeting"
        // Sets result to "Unknown" if no previous condition is satisfied
        else -> "Unknown"
    }
    println(result)
    // Greeting
}
```

The examples of `when` that you've seen so far both had a subject: `obj`. But `when` can also be used without a subject.

This example uses a `when` expression **without** a subject to check a chain of Boolean expressions:

```
fun main() {
    val trafficLightState = "Red" // This can be "Green", "Yellow", or "Red"

    val trafficAction = when {
        trafficLightState == "Green" -> "Go"
        trafficLightState == "Yellow" -> "Slow down"
        trafficLightState == "Red" -> "Stop"
        else -> "Malfunction"
    }

    println(trafficAction)
    // Stop
}
```

However, you can have the same code but with `trafficLightState` as the subject:

```
fun main() {
    val trafficLightState = "Red" // This can be "Green", "Yellow", or "Red"

    val trafficAction = when (trafficLightState) {
        "Green" -> "Go"
        "Yellow" -> "Slow down"
        "Red" -> "Stop"
        else -> "Malfunction"
    }

    println(trafficAction)
    // Stop
}
```

Using `when` with a subject makes your code easier to read and maintain. When you use a subject with a `when` expression, it also helps Kotlin check that all possible cases are covered. Otherwise, if you don't use a subject with a `when` expression, you need to provide an else branch.

Conditional expressions practice

Exercise 1

Create a simple game where you win if throwing two dice results in the same number. Use `if` to print `You win :)` if the dice match or `You lose :(` otherwise.

> In this exercise, you import a package so that you can use the `Random.nextInt()` function to give you a random `Int`. For more information about importing packages, see Packages and imports.

Hint

Use the equality operator (`==`) to compare the dice results.

```
import kotlin.random.Random

fun main() {
    val firstResult = Random.nextInt(6)
    val secondResult = Random.nextInt(6)
    // Write your code here
}
```

```
import kotlin.random.Random

fun main() {
    val firstResult = Random.nextInt(6)
    val secondResult = Random.nextInt(6)
    if (firstResult == secondResult)
        println("You win :)")
    else
        println("You lose :(")
}
```

Exercise 2

Using a `when` expression, update the following program so that it prints the corresponding actions when you input the names of game console buttons.

Button	Action
A	Yes
B	No
X	Menu
Y	Nothing
Other	There is no such button

```
fun main() {
    val button = "A"

    println(
        // Write your code here
    )
}
```

```
fun main() {
    val button = "A"

    println(
        when (button) {
            "A" -> "Yes"
            "B" -> "No"
            "X" -> "Menu"
            "Y" -> "Nothing"
            else -> "There is no such button"
        }
    )
}
```

Ranges

Before talking about loops, it's useful to know how to construct ranges for loops to iterate over.

The most common way to create a range in Kotlin is to use the `..` operator. For example, `1..4` is equivalent to `1, 2, 3, 4`.

To declare a range that doesn't include the end value, use the `..<` operator. For example, `1..<4` is equivalent to `1, 2, 3`.

To declare a range in reverse order, use `downTo`. For example, `4 downTo 1` is equivalent to `4, 3, 2, 1`.

To declare a range that increments in a step that isn't 1, use `step` and your desired increment value. For example, `1..5 step 2` is equivalent to `1, 3, 5`.

You can also do the same with `Char` ranges:

- `'a'..'d'` is equivalent to `'a', 'b', 'c', 'd'`
- `'z' downTo 's' step 2` is equivalent to `'z', 'x', 'v', 't'`

Loops

The two most common loop structures in programming are `for` and `while`. Use `for` to iterate over a range of values and perform an action. Use `while` to continue an action until a particular condition is satisfied.

For

Using your new knowledge of ranges, you can create a `for` loop that iterates over numbers 1 to 5 and prints the number each time.

Place the iterator and range within parentheses `()` with keyword `in`. Add the action you want to complete within curly braces `{}`:

```
fun main() {
    for (number in 1..5) {
        // number is the iterator and 1..5 is the range
        print(number)
    }
    // 12345
}
```

Collections can also be iterated over by loops:

```
fun main() {
    val cakes = listOf("carrot", "cheese", "chocolate")

    for (cake in cakes) {
        println("Yummy, it's a $cake cake!")
    }
    // Yummy, it's a carrot cake!
    // Yummy, it's a cheese cake!
    // Yummy, it's a chocolate cake!
}
```

While

`while` can be used in two ways:

- To execute a code block while a conditional expression is true. (`while`)
- To execute the code block first and then check the conditional expression. (`do-while`)

In the first use case (`while`):

- Declare the conditional expression for your while loop to continue within parentheses `()`.
- Add the action you want to complete within curly braces `{}`.

The following examples use the increment operator `++` to increment the value of the `cakesEaten` variable.

```
fun main() {
    var cakesEaten = 0
    while (cakesEaten < 3) {
        println("Eat a cake")
        cakesEaten++
    }
    // Eat a cake
    // Eat a cake
    // Eat a cake
}
```

In the second use case (`do-while`):

- Declare the conditional expression for your while loop to continue within parentheses `()` .
- Define the action you want to complete within curly braces `{}` with the keyword `do` .

```
fun main() {
    var cakesEaten = 0
    var cakesBaked = 0
    while (cakesEaten < 3) {
        println("Eat a cake")
        cakesEaten++
    }
    do {
        println("Bake a cake")
        cakesBaked++
    } while (cakesBaked < cakesEaten)
    // Eat a cake
    // Eat a cake
    // Eat a cake
    // Bake a cake
    // Bake a cake
    // Bake a cake
}
```

For more information and examples of conditional expressions and loops, see Conditions and loops.

Now that you know the fundamentals of Kotlin control flow, it's time to learn how to write your own functions.

Loops practice

Exercise 1

You have a program that counts pizza slices until there's a whole pizza with 8 slices. Refactor this program in two ways:

- Use a `while` loop.
- Use a `do-while` loop.

```
fun main() {
    var pizzaSlices = 0
    // Start refactoring here
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    println("There's only $pizzaSlices slice/s of pizza :(")
    pizzaSlices++
    // End refactoring here
    println("There are $pizzaSlices slices of pizza. Hooray! We have a whole pizza! :D")
}
```

```
fun main() {
    var pizzaSlices = 0
    while ( pizzaSlices < 7 ) {
        pizzaSlices++
        println("There's only $pizzaSlices slice/s of pizza :(")
    }
    pizzaSlices++
    println("There are $pizzaSlices slices of pizza. Hooray! We have a whole pizza! :D")
}
```

```
fun main() {
    var pizzaSlices = 0
    pizzaSlices++
    do {
        println("There's only $pizzaSlices slice/s of pizza :(")
        pizzaSlices++
    } while ( pizzaSlices < 8 )
    println("There are $pizzaSlices slices of pizza. Hooray! We have a whole pizza! :D")
}
```

Exercise 2

Write a program that simulates the Fizz buzz game. Your task is to print numbers from 1 to 100 incrementally, replacing any number divisible by three with the word "fizz", and any number divisible by five with the word "buzz". Any number divisible by both 3 and 5 must be replaced with the word "fizzbuzz".

Hint 1

Use a `for` loop to count numbers and a `when` expression to decide what to print at each step.

Hint 2

Use the modulo operator (`%`) to return the remainder of a number being divided. Use the equality operator (`==`) to check if the remainder equals zero.

```
fun main() {
    // Write your code here
}
```

```
fun main() {
    for (number in 1..100) {
        println(
            when {
                number % 15 == 0 -> "fizzbuzz"
                number % 3 == 0 -> "fizz"
                number % 5 == 0 -> "buzz"
                else -> "$number"
            }
        )
    }
}
```

Exercise 3

You have a list of words. Use `for` and `if` to print only the words that start with the letter `l`.

Hint

Use the `.startsWith()` function for `String` type.

```
fun main() {
    val words = listOf("dinosaur", "limousine", "magazine", "language")
    // Write your code here
}
```

```
fun main() {
    val words = listOf("dinosaur", "limousine", "magazine", "language")
    for (w in words) {
        if (w.startsWith("l"))
            println(w)
    }
}
```

Previous step

Next step

Functions

You can declare your own functions in Kotlin using the `fun` keyword.

```
fun hello() {
    return println("Hello, world!")
}

fun main() {
    hello()
    // Hello, world!
}
```

In Kotlin:

- Function parameters are written within parentheses `()`.
- Each parameter must have a type, and multiple parameters must be separated by commas `,`.
- The return type is written after the function's parentheses `()`, separated by a colon `:`.
- The body of a function is written within curly braces `{}`.
- The `return` keyword is used to exit or return something from a function.

If a function doesn't return anything useful, the return type and `return` keyword can be omitted. Learn more about this in Functions without return.

In the following example:

- `x` and `y` are function parameters.
- `x` and `y` have type `Int`.
- The function's return type is `Int`.
- The function returns a sum of `x` and `y` when called.

```
fun sum(x: Int, y: Int): Int {
    return x + y
}

fun main() {
    println(sum(1, 2))
    // 3
}
```

We recommend in our coding conventions that you name functions starting with a lowercase letter and use camel case with no underscores.

Named arguments

For concise code, when calling your function, you don't have to include parameter names. However, including parameter names does make your code easier to read. This is called using **named arguments**. If you do include parameter names, then you can write the parameters in any order.

In the following example, string templates (`$`) are used to access the parameter values, convert them to `String` type, and then concatenate them into a string for printing.

```
fun printMessageWithPrefix(message: String, prefix: String) {
    println("[$prefix] $message")
}

fun main() {
    // Uses named arguments with swapped parameter order
    printMessageWithPrefix(prefix = "Log", message = "Hello")
    // [Log] Hello
}
```

Default parameter values

You can define default values for your function parameters. Any parameter with a default value can be omitted when calling your function. To declare a default value, use the assignment operator `=` after the type:

```
fun printMessageWithPrefix(message: String, prefix: String = "Info") {
    println("[$prefix] $message")
}

fun main() {
    // Function called with both parameters
    printMessageWithPrefix("Hello", "Log")
    // [Log] Hello

    // Function called only with message parameter
    printMessageWithPrefix("Hello")
    // [Info] Hello

    printMessageWithPrefix(prefix = "Log", message = "Hello")
    // [Log] Hello
}
```

You can skip specific parameters with default values, rather than omitting them all. However, after the first skipped parameter, you must name all subsequent parameters.

Functions without return

If your function doesn't return a useful value, then its return type is `Unit`. `Unit` is a type with only one value – `Unit`. You don't have to declare that `Unit` is returned explicitly in your function body. This means that you don't have to use the `return` keyword or declare a return type:

```
fun printMessage(message: String) {
    println(message)
    // `return Unit` or `return` is optional
}

fun main() {
    printMessage("Hello")
    // Hello
}
```

Single-expression functions

To make your code more concise, you can use single-expression functions. For example, the `sum()` function can be shortened:

```
fun sum(x: Int, y: Int): Int {
    return x + y
}

fun main() {
    println(sum(1, 2))
    // 3
}
```

You can remove the curly braces `{}` and declare the function body using the assignment operator `=`. When you use the assignment operator `=`, Kotlin uses type inference, so you can also omit the return type. The `sum()` function then becomes one line:

```
fun sum(x: Int, y: Int) = x + y

fun main() {
    println(sum(1, 2))
    // 3
}
```

However, if you want your code to be quickly understood by other developers, it's a good idea to explicitly define the return type even when using the assignment operator `=`.

If you use `{}` curly braces to declare your function body, you must declare the return type unless it is the `Unit` type.

Early returns in functions

To stop the code in your function from being processed further than a certain point, use the `return` keyword. This example uses `if` to return from a function early if the conditional expression is found to be true:

```kotlin
// A list of registered usernames
val registeredUsernames = mutableListOf("john_doe", "jane_smith")

// A list of registered emails
val registeredEmails = mutableListOf("john@example.com", "jane@example.com")

fun registerUser(username: String, email: String): String {
    // Early return if the username is already taken
    if (username in registeredUsernames) {
        return "Username already taken. Please choose a different username."
    }

    // Early return if the email is already registered
    if (email in registeredEmails) {
        return "Email already registered. Please use a different email."
    }

    // Proceed with the registration if the username and email are not taken
    registeredUsernames.add(username)
    registeredEmails.add(email)

    return "User registered successfully: $username"
}

fun main() {
    println(registerUser("john_doe", "newjohn@example.com"))
    // Username already taken. Please choose a different username.
    println(registerUser("new_user", "newuser@example.com"))
    // User registered successfully: new_user
}
```

Functions practice

Exercise 1

Write a function called `circleArea` that takes the radius of a circle in integer format as a parameter and outputs the area of that circle.

> In this exercise, you import a package so that you can access the value of π via `PI`. For more information about importing packages, see Packages and imports.

Hint

The formula for calculating the area of a circle is πr^2, where r is the radius.

```kotlin
import kotlin.math.PI

// Write your code here

fun main() {
    println(circleArea(2))
}
```

```
import kotlin.math.PI

fun circleArea(radius: Int): Double {
    return PI * radius * radius
}

fun main() {
    println(circleArea(2)) // 12.566370614359172
}
```

Exercise 2

Rewrite the `circleArea` function from the previous exercise as a single-expression function.

```
import kotlin.math.PI

// Write your code here

fun main() {
    println(circleArea(2))
}
```

```
import kotlin.math.PI

fun circleArea(radius: Int): Double = PI * radius * radius

fun main() {
    println(circleArea(2)) // 12.566370614359172
}
```

Exercise 3

You have a function that translates a time interval given in hours, minutes, and seconds into seconds. In most cases, you need to pass only one or two function parameters while the rest are equal to 0. Improve the function and the code that calls it by using default parameter values and named arguments so that the code is easier to read.

```
fun intervalInSeconds(hours: Int, minutes: Int, seconds: Int) =
    ((hours * 60) + minutes) * 60 + seconds

fun main() {
    println(intervalInSeconds(1, 20, 15))
    println(intervalInSeconds(0, 1, 25))
    println(intervalInSeconds(2, 0, 0))
    println(intervalInSeconds(0, 10, 0))
    println(intervalInSeconds(1, 0, 1))
}
```

```
fun intervalInSeconds(hours: Int = 0, minutes: Int = 0, seconds: Int = 0) =
    ((hours * 60) + minutes) * 60 + seconds

fun main() {
    println(intervalInSeconds(1, 20, 15))
    println(intervalInSeconds(minutes = 1, seconds = 25))
    println(intervalInSeconds(hours = 2))
    println(intervalInSeconds(minutes = 10))
    println(intervalInSeconds(hours = 1, seconds = 1))
}
```

Lambda expressions

Kotlin allows you to write even more concise code for functions by using lambda expressions.

For example, the following `uppercaseString()` function:

```
fun uppercaseString(text: String): String {
    return text.uppercase()
}
fun main() {
    println(uppercaseString("hello"))
    // HELLO
}
```

Can also be written as a lambda expression:

```
fun main() {
    val upperCaseString = { text: String -> text.uppercase() }
    println(upperCaseString("hello"))
    // HELLO
}
```

Lambda expressions can be hard to understand at first glance, so let's break it down. Lambda expressions are written within curly braces `{}`.

Within the lambda expression, you write:

- The parameters followed by an `->`.
- The function body after the `->`.

In the previous example:

- `text` is a function parameter.
- `text` has type `String`.
- The function returns the result of the `.uppercase()` function called on `text`.
- The entire lambda expression is assigned to the `upperCaseString` variable with the assignment operator `=`.
- The lambda expression is called by using the variable `upperCaseString` like a function and the string `"hello"` as a parameter.
- The `println()` function prints the result.

If you declare a lambda without parameters, then there is no need to use `->`. For example:

```
{ println("Log message") }
```

Lambda expressions can be used in a number of ways. You can:

- Pass a lambda expression as a parameter to another function
- Return a lambda expression from a function
- Invoke a lambda expression on its own

Pass to another function

A great example of when it is useful to pass a lambda expression to a function, is using the `.filter()` function on collections:

```
fun main() {
        val numbers = listOf(1, -2, 3, -4, 5, -6)

    val positives = numbers.filter ({ x -> x > 0 })

    val isNegative = { x: Int -> x < 0 }
    val negatives = numbers.filter(isNegative)

    println(positives)
    // [1, 3, 5]
    println(negatives)
    // [-2, -4, -6]
    //sampleEnd
}
```

The `.filter()` function accepts a lambda expression as a predicate and applies it to each element of the list. The function keeps an element only if the predicate returns `true`:

- `{ x -> x > 0 }` returns `true` if the element is positive.
- `{ x -> x < 0 }` returns `true` if the element is negative.

This example demonstrates two ways of passing a lambda expression to a function:

- For positive numbers, the example adds the lambda expression directly in the `.filter()` function.
- For negative numbers, the example assigns the lambda expression to the `isNegative` variable. Then the `isNegative` variable is used as a function parameter in the `.filter()` function. In this case, you have to specify the type of function parameters (`x`) in the lambda expression.

If a lambda expression is the only function parameter, you can drop the function parentheses `()`:

```
val positives = numbers.filter { x -> x > 0 }
```

This is an example of a trailing lambda, which is discussed in more detail at the end of this chapter.

Another good example is using the `.map()` function to transform items in a collection:

```
fun main() {
        val numbers = listOf(1, -2, 3, -4, 5, -6)
    val doubled = numbers.map { x -> x * 2 }

    val isTripled = { x: Int -> x * 3 }
    val tripled = numbers.map(isTripled)

    println(doubled)
    // [2, -4, 6, -8, 10, -12]
    println(tripled)
    // [3, -6, 9, -12, 15, -18]
    //sampleEnd
}
```

The `.map()` function accepts a lambda expression as a transform function:

- `{ x -> x * 2 }` takes each element of the list and returns that element multiplied by 2.
- `{ x -> x * 3 }` takes each element of the list and returns that element multiplied by 3.

Function types

Before you can return a lambda expression from a function, you first need to understand **function types**.

You have already learned about basic types but functions themselves also have a type. Kotlin's type inference can infer a function's type from the parameter type. But there may be times when you need to explicitly specify the function type. The compiler needs the function type so that it knows what is and isn't allowed for that function.

The syntax for a function type has:

- Each parameter's type written within parentheses `()` and separated by commas `,`.
- The return type written after `->`.

For example: `(String) -> String` or `(Int, Int) -> Int`.

This is what a lambda expression looks like if a function type for `upperCaseString()` is defined:

```
val upperCaseString: (String) -> String = { text -> text.uppercase() }

fun main() {
    println(upperCaseString("hello"))
    // HELLO
}
```

If your lambda expression has no parameters, then the parentheses `()` are left empty. For example: `() -> Unit`

> You must declare parameter and return types either in the lambda expression or as a function type. Otherwise, the compiler won't be able to know what type your lambda expression is.
>
> For example, the following won't work:
>
> `val upperCaseString = { str -> str.uppercase() }`

Return from a function

Lambda expressions can be returned from a function. So that the compiler understands what type the lambda expression returned is, you must declare a function type.

In the following example, the `toSeconds()` function has function type `(Int) -> Int` because it always returns a lambda expression that takes a parameter of type `Int` and returns an `Int` value.

This example uses a `when` expression to determine which lambda expression is returned when `toSeconds()` is called:

```
fun toSeconds(time: String): (Int) -> Int = when (time) {
    "hour" -> { value -> value * 60 * 60 }
    "minute" -> { value -> value * 60 }
    "second" -> { value -> value }
    else -> { value -> value }
}

fun main() {
    val timesInMinutes = listOf(2, 10, 15, 1)
    val min2sec = toSeconds("minute")
    val totalTimeInSeconds = timesInMinutes.map(min2sec).sum()
    println("Total time is $totalTimeInSeconds secs")
    // Total time is 1680 secs
}
```

Invoke separately

Lambda expressions can be invoked on their own by adding parentheses `()` after the curly braces `{}` and including any parameters within the parentheses:

```
fun main() {
        println({ text: String -> text.uppercase() }("hello"))
    // HELLO
    //sampleEnd
}
```

Trailing lambdas

As you have already seen, if a lambda expression is the only function parameter, you can drop the function parentheses `()`. If a lambda expression is passed as the last parameter of a function, then the expression can be written outside the function parentheses `()`. In both cases, this syntax is called a **trailing lambda**.

For example, the `.fold()` function accepts an initial value and an operation:

```
fun main() {
        // The initial value is zero.
    // The operation sums the initial value with every item in the list cumulatively.
    println(listOf(1, 2, 3).fold(0, { x, item -> x + item })) // 6

    // Alternatively, in the form of a trailing lambda
    println(listOf(1, 2, 3).fold(0) { x, item -> x + item })  // 6
    //sampleEnd
}
```

For more information on lambda expressions, see Lambda expressions and anonymous functions.

The next step in our tour is to learn about classes in Kotlin.

Lambda expressions practice

Exercise 1

You have a list of actions supported by a web service, a common prefix for all requests, and an ID of a particular resource. To request an action `title` over the resource with ID: 5, you need to create the following URL: `https://example.com/book-info/5/title`. Use a lambda expression to create a list of URLs from the list of actions.

```
fun main() {
    val actions = listOf("title", "year", "author")
    val prefix = "https://example.com/book-info"
    val id = 5
    val urls = // Write your code here
    println(urls)
}
```

```
fun main() {
    val actions = listOf("title", "year", "author")
    val prefix = "https://example.com/book-info"
    val id = 5
    val urls = actions.map { action -> "$prefix/$id/$action" }
    println(urls)
}
```

Exercise 2

Write a function that takes an `Int` value and an action (a function with type `() -> Unit`) which then repeats the action the given number of times. Then use this function to print “Hello” 5 times.

```
fun repeatN(n: Int, action: () -> Unit) {
    // Write your code here
}

fun main() {
    // Write your code here
}
```

```
fun repeatN(n: Int, action: () -> Unit) {
    for (i in 1..n) {
        action()
    }
}

fun main() {
    repeatN(5) {
        println("Hello")
    }
}
```

Previous step

Next step

Classes

Kotlin supports object-oriented programming with classes and objects. Objects are useful for storing data in your program. Classes allow you to declare a set of characteristics for an object. When you create objects from a class, you can save time and effort because you don't have to declare these characteristics every time.

To declare a class, use the `class` keyword:

```
class Customer
```

Properties

Characteristics of a class's object can be declared in properties. You can declare properties for a class:

- Within parentheses `()` after the class name.

```
class Contact(val id: Int, var email: String)
```

- Within the class body defined by curly braces `{}`.

```
class Contact(val id: Int, var email: String) {
    val category: String = ""
}
```

We recommend that you declare properties as read-only (`val`) unless they need to be changed after an instance of the class is created.

You can declare properties without `val` or `var` within parentheses but these properties are not accessible after an instance has been created.

- The content contained within parentheses `()` is called the **class header**.
- You can use a trailing comma when declaring class properties.

Just like with function parameters, class properties can have default values:

```
class Contact(val id: Int, var email: String = "example@gmail.com") {
    val category: String = "work"
}
```

Create instance

To create an object from a class, you declare a class **instance** using a **constructor**.

By default, Kotlin automatically creates a constructor with the parameters declared in the class header.

For example:

```
class Contact(val id: Int, var email: String)

fun main() {
    val contact = Contact(1, "mary@gmail.com")
}
```

In the example:

- `Contact` is a class.
- `contact` is an instance of the `Contact` class.
- `id` and `email` are properties.
- `id` and `email` are used with the default constructor to create `contact`.

Kotlin classes can have many constructors, including ones that you define yourself. To learn more about how to declare multiple constructors, see Constructors.

Access properties

To access a property of an instance, write the name of the property after the instance name appended with a period `.`:

```
class Contact(val id: Int, var email: String)

fun main() {
    val contact = Contact(1, "mary@gmail.com")

    // Prints the value of the property: email
    println(contact.email)
    // mary@gmail.com

    // Updates the value of the property: email
    contact.email = "jane@gmail.com"

    // Prints the new value of the property: email
    println(contact.email)
    // jane@gmail.com
}
```

To concatenate the value of a property as part of a string, you can use string templates (`$`). For example:

```
println("Their email address is: ${contact.email}")
```

Member functions

In addition to declaring properties as part of an object's characteristics, you can also define an object's behavior with member functions.

In Kotlin, member functions must be declared within the class body. To call a member function on an instance, write the function name after the instance name appended with a period `.`. For example:

```
class Contact(val id: Int, var email: String) {
    fun printId() {
        println(id)
    }
}

fun main() {
    val contact = Contact(1, "mary@gmail.com")
    // Calls member function printId()
    contact.printId()
    // 1
}
```

Data classes

Kotlin has **data classes** which are particularly useful for storing data. Data classes have the same functionality as classes, but they come automatically with additional member functions. These member functions allow you to easily print the instance to readable output, compare instances of a class, copy instances, and more. As these functions are automatically available, you don't have to spend time writing the same boilerplate code for each of your classes.

To declare a data class, use the keyword `data`:

```
data class User(val name: String, val id: Int)
```

The Kotlin compiler only uses the properties defined inside the primary constructor when generating member functions. If you declare properties in the data class body, they aren't included in the output of the generated functions.

The most useful predefined member functions of data classes are:

Function	Description
`toString()`	Prints a readable string of the class instance and its properties.
`equals()` or `==`	Compares instances of a class.
`copy()`	Creates a class instance by copying another, potentially with some different properties.

See the following sections for examples of how to use each function:

- Print as string
- Compare instances
- Copy instance

Print as string

To print a readable string of a class instance, you can explicitly call the `toString()` function, or use print functions (`println()` and `print()`) which automatically call `toString()` for you:

```
data class User(val name: String, val id: Int)

fun main() {
        val user = User("Alex", 1)

    // Automatically uses toString() function so that output is easy to read
    println(user)
    // User(name=Alex, id=1)
    //sampleEnd
}
```

This is particularly useful when debugging or creating logs.

Compare instances

To compare data class instances, use the equality operator `==` :

```
data class User(val name: String, val id: Int)

fun main() {
        val user = User("Alex", 1)
    val secondUser = User("Alex", 1)
    val thirdUser = User("Max", 2)

    // Compares user to second user
    println("user == secondUser: ${user == secondUser}")
    // user == secondUser: true

    // Compares user to third user
    println("user == thirdUser: ${user == thirdUser}")
    // user == thirdUser: false
    //sampleEnd
}
```

Copy instance

To create an exact copy of a data class instance, call the `copy()` function on the instance.

To create a copy of a data class instance **and** change some properties, call the `copy()` function on the instance **and** add replacement values for properties as function parameters.

For example:

```
data class User(val name: String, val id: Int)

fun main() {
        val user = User("Alex", 1)

    // Creates an exact copy of user
    println(user.copy())
    // User(name=Alex, id=1)

    // Creates a copy of user with name: "Max"
    println(user.copy("Max"))
    // User(name=Max, id=1)

    // Creates a copy of user with id: 3
    println(user.copy(id = 3))
    // User(name=Alex, id=3)
    //sampleEnd
}
```

Creating a copy of an instance is safer than modifying the original instance because any code that relies on the original instance isn't affected by the copy and what you do with it.

For more information about data classes, see Data classes.

The last chapter of this tour is about Kotlin's null safety.

Practice

Exercise 1

Define a data class `Employee` with two properties: one for a name, and another for a salary. Make sure that the property for salary is mutable, otherwise you won't get a salary boost at the end of the year! The main function demonstrates how you can use this data class.

```
// Write your code here

fun main() {
    val emp = Employee("Mary", 20)
    println(emp)
    emp.salary += 10
    println(emp)
}
```

```
data class Employee(val name: String, var salary: Int)

fun main() {
    val emp = Employee("Mary", 20)
    println(emp)
    emp.salary += 10
    println(emp)
}
```

Exercise 2

Declare the additional data classes that are needed for this code to compile.

```
data class Person(val name: Name, val address: Address, val ownsAPet: Boolean = true)
// Write your code here
// data class Name(...)

fun main() {
    val person = Person(
        Name("John", "Smith"),
        Address("123 Fake Street", City("Springfield", "US")),
        ownsAPet = false
    )
}
```

```
data class Person(val name: Name, val address: Address, val ownsAPet: Boolean = true)
data class Name(val first: String, val last: String)
data class Address(val street: String, val city: City)
data class City(val name: String, val countryCode: String)

fun main() {
    val person = Person(
        Name("John", "Smith"),
        Address("123 Fake Street", City("Springfield", "US")),
        ownsAPet = false
    )
}
```

Exercise 3

To test your code, you need a generator that can create random employees. Define a `RandomEmployeeGenerator` class with a fixed list of potential names (inside the class body). Configure the class with a minimum and maximum salary (inside the class header). In the class body, define the `generateEmployee()` function. Once again, the main function demonstrates how you can use this class.

> In this exercise, you import a package so that you can use the `Random.nextInt()` function. For more information about importing packages, see Packages and imports.

Hint 1

Lists have an extension function called `.random()` that returns a random item within a list.

Hint 2

`Random.nextInt(from = ..., until = ...)` gives you a random `Int` number within specified limits.

```
import kotlin.random.Random

data class Employee(val name: String, var salary: Int)

// Write your code here

fun main() {
    val empGen = RandomEmployeeGenerator(10, 30)
    println(empGen.generateEmployee())
    println(empGen.generateEmployee())
    println(empGen.generateEmployee())
    empGen.minSalary = 50
    empGen.maxSalary = 100
    println(empGen.generateEmployee())
}
```

```
import kotlin.random.Random

data class Employee(val name: String, var salary: Int)

class RandomEmployeeGenerator(var minSalary: Int, var maxSalary: Int) {
    val names = listOf("John", "Mary", "Ann", "Paul", "Jack", "Elizabeth")
    fun generateEmployee() =
        Employee(names.random(),
            Random.nextInt(from = minSalary, until = maxSalary))
}

fun main() {
    val empGen = RandomEmployeeGenerator(10, 30)
    println(empGen.generateEmployee())
    println(empGen.generateEmployee())
    println(empGen.generateEmployee())
    empGen.minSalary = 50
    empGen.maxSalary = 100
    println(empGen.generateEmployee())
}
```

Previous step

Next step

Null safety

In Kotlin, it's possible to have a `null` value. Kotlin uses `null` values when something is missing or not yet set. You've already seen an example of Kotlin returning a `null` value in the Collections chapter when you tried to access a key-value pair with a key that doesn't exist in the map. Although it's useful to use `null` values in this way, you might run into problems if your code isn't prepared to handle them.

To help prevent issues with `null` values in your programs, Kotlin has null safety in place. Null safety detects potential problems with `null` values at compile time, rather than at run time.

Null safety is a combination of features that allow you to:

- Explicitly declare when `null` values are allowed in your program.
- Check for `null` values.
- Use safe calls to properties or functions that may contain `null` values.

- Declare actions to take if `null` values are detected.

Nullable types

Kotlin supports nullable types which allows the possibility for the declared type to have `null` values. By default, a type is **not** allowed to accept `null` values. Nullable types are declared by explicitly adding `?` after the type declaration.

For example:

```
fun main() {
    // neverNull has String type
    var neverNull: String = "This can't be null"

    // Throws a compiler error
    neverNull = null

    // nullable has nullable String type
    var nullable: String? = "You can keep a null here"

    // This is OK
    nullable = null

    // By default, null values aren't accepted
    var inferredNonNull = "The compiler assumes non-nullable"

    // Throws a compiler error
    inferredNonNull = null

    // notNull doesn't accept null values
    fun strLength(notNull: String): Int {
        return notNull.length
    }

    println(strLength(neverNull)) // 18
    println(strLength(nullable))  // Throws a compiler error
}
```

`length` is a property of the String class that contains the number of characters within a string.

Check for null values

You can check for the presence of `null` values within conditional expressions. In the following example, the `describeString()` function has an `if` statement that checks whether `maybeString` is **not** `null` and if its `length` is greater than zero:

```
fun describeString(maybeString: String?): String {
    if (maybeString != null && maybeString.length > 0) {
        return "String of length ${maybeString.length}"
    } else {
        return "Empty or null string"
    }
}

fun main() {
    val nullString: String? = null
    println(describeString(nullString))
    // Empty or null string
}
```

Use safe calls

To safely access properties of an object that might contain a `null` value, use the safe call operator `?.`. The safe call operator returns `null` if either the object or one of its accessed properties is `null`. This is useful if you want to avoid the presence of `null` values triggering errors in your code.

In the following example, the `lengthString()` function uses a safe call to return either the length of the string or `null`:

```
fun lengthString(maybeString: String?): Int? = maybeString?.length

fun main() {
    val nullString: String? = null
    println(lengthString(nullString))
    // null
}
```

Safe calls can be chained so that if any property of an object contains a `null` value, then `null` is returned without an error being thrown. For example:

```
person.company?.address?.country
```

The safe call operator can also be used to safely call an extension or member function. In this case, a null check is performed before the function is called. If the check detects a `null` value, then the call is skipped and `null` is returned.

In the following example, `nullString` is `null` so the invocation of `.uppercase()` is skipped and `null` is returned:

```
fun main() {
    val nullString: String? = null
    println(nullString?.uppercase())
    // null
}
```

Use Elvis operator

You can provide a default value to return if a `null` value is detected by using the **Elvis operator** `?:`.

Write on the left-hand side of the Elvis operator what should be checked for a `null` value. Write on the right-hand side of the Elvis operator what should be returned if a `null` value is detected.

In the following example, `nullString` is `null` so the safe call to access the `length` property returns a `null` value. As a result, the Elvis operator returns `0`:

```
fun main() {
    val nullString: String? = null
    println(nullString?.length ?: 0)
    // 0
}
```

For more information about null safety in Kotlin, see Null safety.

Practice

Exercise

You have the `employeeById` function that gives you access to a database of employees of a company. Unfortunately, this function returns a value of the `Employee?` type, so the result can be `null`. Your goal is to write a function that returns the salary of an employee when their `id` is provided, or `0` if the employee is missing from the database.

```
data class Employee (val name: String, var salary: Int)

fun employeeById(id: Int) = when(id) {
    1 -> Employee("Mary", 20)
    2 -> null
    3 -> Employee("John", 21)
    4 -> Employee("Ann", 23)
    else -> null
}

fun salaryById(id: Int) = // Write your code here

fun main() {
    println((1..5).sumOf { id -> salaryById(id) })
}
```

```
data class Employee (val name: String, var salary: Int)

fun employeeById(id: Int) = when(id) {
    1 -> Employee("Mary", 20)
    2 -> null
    3 -> Employee("John", 21)
    4 -> Employee("Ann", 23)
    else -> null
}

fun salaryById(id: Int) = employeeById(id)?.salary ?: 0

fun main() {
    println((1..5).sumOf { id -> salaryById(id) })
}
```

What's next?

Congratulations! Now that you have completed the beginner tour, take your understanding of Kotlin to the next level with our intermediate tour:

Previous step

Start intermediate Kotlin tour

Extension functions

In this chapter, you'll explore special Kotlin functions that make your code more concise and readable. Learn how they can help you use efficient design patterns to take your projects to the next level.

Extension functions

In software development, you often need to modify a program's behavior without changing the original source code. For example, you might want to add extra functionality to a class from a third-party library.

You can do this by adding *extension functions* to extend a class. You call extension functions the same way you call member functions of a class, using a period `.`.

Before introducing the complete syntax for extension functions, you need to understand what a **receiver** is. The receiver is what the function is called on. In other words, the receiver is where or with whom the information is shared.

```
fun main() {
    val readOnlyShapes = listOf("triangle", "square", "circle")
    println("The first item in the list is: ${readOnlyShapes.first()}")
    // The first item in the list is: triangle
}
```

Receiver

An example of sender and receiver

In this example, the `main()` function calls the `.first()` function to return the first element in a list. The `.first()` function is called **on** the `readOnlyShapes` variable, so the `readOnlyShapes` variable is the receiver.

To create an extension function, write the name of the class that you want to extend followed by a `.` and the name of your function. Continue with the rest of the function declaration, including its parameters and return type.

For example:

```
fun String.bold(): String = "<b>$this</b>"

fun main() {
    // "hello" is the receiver
    println("hello".bold())
    // <b>hello</b>
}
```

In this example:

- `String` is the extended class.
- `bold` is the name of the extension function.

- The `.bold()` extension function's return type is `String`.
- `"hello"`, an instance of `String`, as the receiver.
- The receiver is accessed inside the body by the keyword: `this`.
- A string template (`$`) is used to access the value of `this`.
- The `.bold()` extension function takes a string and returns it in a `<b>` HTML element for bold text.

Extension-oriented design

You can define extension functions anywhere, which enables you to create extension-oriented designs. These designs separate core functionality from useful but non-essential features, making your code easier to read and maintain.

A good example is the `HttpClient` class from the Ktor library, which helps perform network requests. The core of its functionality is a single function `request()`, which takes all the information needed for an HTTP request:

```
class HttpClient {
    fun request(method: String, url: String, headers: Map<String, String>): HttpResponse {
        // Network code
    }
}
```

In practice, the most popular HTTP requests are GET or POST requests. It makes sense for the library to provide shorter names for these common use cases. However, these don't require writing new network code, only a specific request call. In other words, they are perfect candidates to be defined as separate `.get()` and `.post()` extension functions:

```
fun HttpClient.get(url: String): HttpResponse = request("GET", url, emptyMap())
fun HttpClient.post(url: String): HttpResponse = request("POST", url, emptyMap())
```

These `.get()` and `.post()` functions extend the `HttpClient` class. They can directly use the `request()` function from the `HttpClient` class because they're called on an instance of the `HttpClient` class as the receiver. You can use these extension functions to call the `request()` function with the appropriate HTTP method, which simplifies your code and makes it easier to understand:

```
class HttpClient {
    fun request(method: String, url: String, headers: Map<String, String>): HttpResponse {
        println("Requesting $method to $url with headers: $headers")
        return HttpResponse("Response from $url")
    }
}

fun HttpClient.get(url: String): HttpResponse = request("GET", url, emptyMap())

fun main() {
    val client = HttpClient()

    // Making a GET request using request() directly
    val getResponseWithMember = client.request("GET", "https://example.com", emptyMap())

    // Making a GET request using the get() extension function
    // The client instance is the receiver
    val getResponseWithExtension = client.get("https://example.com")
}
```

This extension-oriented approach is widely used in Kotlin's standard library and other libraries. For example, the `String` class has many extension functions to help you work with strings.

For more information about extension functions, see Extensions.

Practice

Exercise 1

Write an extension function called `isPositive` that takes an integer and checks whether it is positive.

```
fun Int.// Write your code here

fun main() {
    println(1.isPositive())
    // true
}
```

```
fun Int.isPositive(): Boolean = this > 0

fun main() {
    println(1.isPositive())
    // true
}
```

Exercise 2

Write an extension function called `toLowercaseString` that takes a string and returns a lowercase version.

Hint

Use the `.lowercase()` function for the `String` type.

```
fun // Write your code here

fun main() {
    println("Hello World!".toLowercaseString())
    // hello world!
}
```

```
fun String.toLowercaseString(): String = this.lowercase()

fun main() {
    println("Hello World!".toLowercaseString())
    // hello world!
}
```

Previous step

Next step

Scope functions

In this chapter, you'll build on your understanding of extension functions to learn how to use scope functions to write more idiomatic code.

Scope functions

In programming, a scope is the area in which your variable or object is recognized. The most commonly referred to scopes are the global scope and the local scope:

- **Global scope** – a variable or object that is accessible from anywhere in the program.
- **Local scope** – a variable or object that is only accessible within the block or function where it is defined.

In Kotlin, there are also scope functions that allow you to create a temporary scope around an object and execute some code.

Scope functions make your code more concise because you don't have to refer to the name of your object within the temporary scope. Depending on the scope function, you can access the object either by referencing it via the keyword `this` or using it as an argument via the keyword `it`.

Kotlin has five scope functions in total: `let`, `apply`, `run`, `also`, and `with`.

Each scope function takes a lambda expression and returns either the object or the result of the lambda expression. In this tour, we explain each scope function and how to use it.

> You can also watch the Back to the Stdlib: Making the Most of Kotlin's Standard Library talk on scope functions by Sebastian Aigner, Kotlin developer advocate.

Let

Use the `let` scope function when you want to perform null checks in your code and later perform further actions with the returned object.

Consider the example:

```
fun sendNotification(recipientAddress: String): String {
    println("Yo $recipientAddress!")
    return "Notification sent!"
}

fun getNextAddress(): String {
    return "sebastian@jetbrains.com"
}

fun main() {
    val address: String? = getNextAddress()
    sendNotification(address)
}
```

The example has two functions:

- `sendNotification()`, which has a function parameter `recipientAddress` and returns a string.
- `getNextAddress()`, which has no function parameters and returns a string.

The example creates a variable `address` that has a nullable `String` type. But this becomes a problem when you call the `sendNotification()` function because this function doesn't expect that `address` could be a `null` value. The compiler reports an error as a result:

```
Argument type mismatch: actual type is 'String?', but 'String' was expected.
```

From the beginner tour, you already know that you can perform a null check with an if condition or use the Elvis operator `?:`. But what if you want to use the returned object later in your code? You could achieve this with an if condition **and** an else branch:

```
fun sendNotification(recipientAddress: String): String {
    println("Yo $recipientAddress!")
    return "Notification sent!"
}

fun getNextAddress(): String {
    return "sebastian@jetbrains.com"
}

fun main() {
        val address: String? = getNextAddress()
    val confirm = if(address ≠ null) {
        sendNotification(address)
    } else { null }
    //sampleEnd
}
```

However, a more concise approach is to use the `let` scope function:

```
fun sendNotification(recipientAddress: String): String {
    println("Yo $recipientAddress!")
    return "Notification sent!"
}

fun getNextAddress(): String {
    return "sebastian@jetbrains.com"
}

fun main() {
        val address: String? = getNextAddress()
    val confirm = address?.let {
        sendNotification(it)
    }
    //sampleEnd
}
```

The example:

- Creates variables called `address` and `confirm`.
- Uses a safe call for the `let` scope function on the `address` variable.
- Creates a temporary scope within the `let` scope function.
- Passes the `sendNotification()` function as a lambda expression into the `let` scope function.
- Refers to the `address` variable via `it`, using the temporary scope.
- Assigns the result to the `confirm` variable.

With this approach, your code can handle the `address` variable potentially being a `null` value, and you can use the `confirm` variable later in your code.

Apply

Use the `apply` scope function to initialize objects, like a class instance, at the time of creation rather than later on in your code. This approach makes your code easier to read and manage.

Consider the example:

```
class Client() {
    var token: String? = null
    fun connect() = println("connected!")
    fun authenticate() = println("authenticated!")
    fun getData() : String {
        println("getting data!")
        return "Mock data"
    }
}

val client = Client()

fun main() {
    client.token = "asdf"
    client.connect()
    // connected!
    client.authenticate()
    // authenticated!
    client.getData()
    // getting data!
}
```

The example has a `Client` class that contains one property called `token` and three member functions: `connect()`, `authenticate()`, and `getData()`.

The example creates `client` as an instance of the `Client` class before initializing its `token` property and calling its member functions in the `main()` function.

Although this example is compact, in the real world, it can be a while before you can configure and use the class instance (and its member functions) after you've created it. However, if you use the `apply` scope function you can create, configure and use member functions on your class instance all in the same place in your code:

```
class Client() {
    var token: String? = null
    fun connect() = println("connected!")
    fun authenticate() = println("authenticated!")
    fun getData() : String {
        println("getting data!")
        return "Mock data"
    }
}
val client = Client().apply {
    token = "asdf"
    connect()
    // connected!
    authenticate()
    // authenticated!
}

fun main() {
    client.getData()
    // getting data!
}
```

The example:

- Creates `client` as an instance of the `Client` class.
- Uses the `apply` scope function on the `client` instance.
- Creates a temporary scope within the `apply` scope function so that you don't have to explicitly refer to the `client` instance when accessing its properties or functions.
- Passes a lambda expression to the `apply` scope function that updates the `token` property and calls the `connect()` and `authenticate()` functions.
- Calls the `getData()` member function on the `client` instance in the `main()` function.

As you can see, this strategy is convenient when you are working with large pieces of code.

Run

Similar to `apply`, you can use the `run` scope function to initialize an object, but it's better to use `run` to initialize an object at a specific moment in your code **and** immediately compute a result.

Let's continue the previous example for the `apply` function, but this time, you want the `connect()` and `authenticate()` functions to be grouped so that they are called on every request.

For example:

```
class Client() {
    var token: String? = null
    fun connect() = println("connected!")
    fun authenticate() = println("authenticated!")
    fun getData() : String {
        println("getting data!")
        return "Mock data"
    }
}

val client: Client = Client().apply {
    token = "asdf"
}

fun main() {
    val result: String = client.run {
        connect()
        // connected!
        authenticate()
        // authenticated!
        getData()
        // getting data!
    }
}
```

The example:

- Creates `client` as an instance of the `Client` class.
- Uses the `apply` scope function on the `client` instance.
- Creates a temporary scope within the `apply` scope function so that you don't have to explicitly refer to the `client` instance when accessing its properties or functions.
- Passes a lambda expression to the `apply` scope function that updates the `token` property.

The `main()` function:

- Creates a `result` variable with type `String`.
- Uses the `run` scope function on the `client` instance.
- Creates a temporary scope within the `run` scope function so that you don't have to explicitly refer to the `client` instance when accessing its properties or functions.
- Passes a lambda expression to the `run` scope function that calls the `connect()`, `authenticate()`, and `getData()` functions.
- Assigns the result to the `result` variable.

Now you can use the returned result further in your code.

Also

Use the `also` scope function to complete an additional action with an object and then return the object to continue using it in your code, like writing a log.

Consider the example:

```
fun main() {
    val medals: List<String> = listOf("Gold", "Silver", "Bronze")
    val reversedLongUppercaseMedals: List<String> =
        medals
            .map { it.uppercase() }
            .filter { it.length > 4 }
            .reversed()
    println(reversedLongUppercaseMedals)
    // [BRONZE, SILVER]
}
```

The example:

- Creates the `medals` variable that contains a list of strings.
- Creates the `reversedLongUpperCaseMedals` variable that has the `List<String>` type.
- Uses the `.map()` extension function on the `medals` variable.
- Passes a lambda expression to the `.map()` function that refers to `medals` via the `it` keyword and calls the `.uppercase()` extension function on it.
- Uses the `.filter()` extension function on the `medals` variable.
- Passes a lambda expression as a predicate to the `.filter()` function that refers to `medals` via the `it` keyword and checks if the item in the list has more than 4 characters.
- Uses the `.reversed()` extension function on the `medals` variable.
- Assigns the result to the `reversedLongUpperCaseMedals` variable.
- Prints the list contained in the `reversedLongUpperCaseMedals` variable.

It would be useful to add some logging in between the function calls to see what is happening to the `medals` variable. The `also` function helps with that:

```
fun main() {
    val medals: List<String> = listOf("Gold", "Silver", "Bronze")
    val reversedLongUppercaseMedals: List<String> =
        medals
            .map { it.uppercase() }
            .also { println(it) }
            // [GOLD, SILVER, BRONZE]
            .filter { it.length > 4 }
            .also { println(it) }
            // [SILVER, BRONZE]
            .reversed()
    println(reversedLongUppercaseMedals)
    // [BRONZE, SILVER]
}
```

Now the example:

- Uses the `also` scope function on the `medals` variable.
- Creates a temporary scope within the `also` scope function so that you don't have to explicitly refer to the `medals` variable when using it as a function parameter.
- Passes a lambda expression to the `also` scope function that calls the `println()` function using the `medals` variable as a function parameter via the `it` keyword.

Since the `also` function returns the object, it is useful for not only logging but debugging, chaining multiple operations, and performing other side effect operations that don't affect the main flow of your code.

With

Unlike the other scope functions, `with` is not an extension function, so the syntax is different. You pass the receiver object to `with` as an argument.

Use the `with` scope function when you want to call multiple functions on an object.

Consider this example:

```
class Canvas {
    fun rect(x: Int, y: Int, w: Int, h: Int): Unit = println("$x, $y, $w, $h")
    fun circ(x: Int, y: Int, rad: Int): Unit = println("$x, $y, $rad")
    fun text(x: Int, y: Int, str: String): Unit = println("$x, $y, $str")
}

fun main() {
    val mainMonitorPrimaryBufferBackedCanvas = Canvas()

    mainMonitorPrimaryBufferBackedCanvas.text(10, 10, "Foo")
    mainMonitorPrimaryBufferBackedCanvas.rect(20, 30, 100, 50)
    mainMonitorPrimaryBufferBackedCanvas.circ(40, 60, 25)
    mainMonitorPrimaryBufferBackedCanvas.text(15, 45, "Hello")
    mainMonitorPrimaryBufferBackedCanvas.rect(70, 80, 150, 100)
    mainMonitorPrimaryBufferBackedCanvas.circ(90, 110, 40)
    mainMonitorPrimaryBufferBackedCanvas.text(35, 55, "World")
    mainMonitorPrimaryBufferBackedCanvas.rect(120, 140, 200, 75)
    mainMonitorPrimaryBufferBackedCanvas.circ(160, 180, 55)
    mainMonitorPrimaryBufferBackedCanvas.text(50, 70, "Kotlin")
}
```

The example creates a `Canvas` class that has three member functions: `rect()`, `circ()`, and `text()`. Each of these member functions prints a statement constructed from the function parameters that you provide.

The example creates `mainMonitorPrimaryBufferBackedCanvas` as an instance of the `Canvas` class before calling a sequence of member functions on the instance with different function parameters.

You can see that this code is hard to read. If you use the `with` function, the code is streamlined:

```
class Canvas {
    fun rect(x: Int, y: Int, w: Int, h: Int): Unit = println("$x, $y, $w, $h")
    fun circ(x: Int, y: Int, rad: Int): Unit = println("$x, $y, $rad")
    fun text(x: Int, y: Int, str: String): Unit = println("$x, $y, $str")
}

fun main() {
        val mainMonitorSecondaryBufferBackedCanvas = Canvas()
    with(mainMonitorSecondaryBufferBackedCanvas) {
        text(10, 10, "Foo")
        rect(20, 30, 100, 50)
        circ(40, 60, 25)
        text(15, 45, "Hello")
        rect(70, 80, 150, 100)
        circ(90, 110, 40)
        text(35, 55, "World")
        rect(120, 140, 200, 75)
        circ(160, 180, 55)
        text(50, 70, "Kotlin")
    }
    //sampleEnd
}
```

This example:

- Uses the `with` scope function with the `mainMonitorSecondaryBufferBackedCanvas` instance as the receiver.
- Creates a temporary scope within the `with` scope function so that you don't have to explicitly refer to the `mainMonitorSecondaryBufferBackedCanvas` instance when calling its member functions.
- Passes a lambda expression to the `with` scope function that calls a sequence of member functions with different function parameters.

Now that this code is much easier to read, you are less likely to make mistakes.

Use case overview

This section has covered the different scope functions available in Kotlin and their main use cases for making your code more idiomatic. You can use this table as a quick reference. It's important to note that you don't need a complete understanding of how these functions work in order to use them in your code.

Function	Access to `x` via	Return value	Use case
`let`	`it`	Lambda result	Perform null checks in your code and later perform further actions with the returned object.
`apply`	`this`	`x`	Initialize objects at the time of creation.
`run`	`this`	Lambda result	Initialize objects at the time of creation **AND** compute a result.
`also`	`it`	`x`	Complete additional actions before returning the object.

Function	Access to `x` via	Return value	Use case
`with`	`this`	Lambda result	Call multiple functions on an object.

For more information about scope functions, see Scope functions.

Practice

Exercise 1

Rewrite the `.getPriceInEuros()` function as a single-expression function that uses safe call operators `?.` and the `let` scope function.

Hint

Use safe call operators `?.` to safely access the `priceInDollars` property from the `getProductInfo()` function. Then, use the `let` scope function to convert the value of `priceInDollars` into euros.

```
data class ProductInfo(val priceInDollars: Double?)

class Product {
    fun getProductInfo(): ProductInfo? {
        return ProductInfo(100.0)
    }
}

// Rewrite this function
fun Product.getPriceInEuros(): Double? {
    val info = getProductInfo()
    if (info == null) return null
    val price = info.priceInDollars
    if (price == null) return null
    return convertToEuros(price)
}

fun convertToEuros(dollars: Double): Double {
    return dollars * 0.85
}

fun main() {
    val product = Product()
    val priceInEuros = product.getPriceInEuros()

    if (priceInEuros != null) {
        println("Price in Euros: €$priceInEuros")
        // Price in Euros: €85.0
    } else {
        println("Price information is not available.")
    }
}
```

```
data class ProductInfo(val priceInDollars: Double?)

class Product {
    fun getProductInfo(): ProductInfo? {
        return ProductInfo(100.0)
    }
}

fun Product.getPriceInEuros() = getProductInfo()?.priceInDollars?.let { convertToEuros(it) }

fun convertToEuros(dollars: Double): Double {
    return dollars * 0.85
}

fun main() {
    val product = Product()
    val priceInEuros = product.getPriceInEuros()

    if (priceInEuros != null) {
        println("Price in Euros: €$priceInEuros")
        // Price in Euros: €85.0
    } else {
        println("Price information is not available.")
    }
}
```

Exercise 2

You have an `updateEmail()` function that updates the email address of a user. Use the `apply` scope function to update the email address and then the `also` scope function to print a log message: `Updating email for user with ID: ${it.id}`.

```
data class User(val id: Int, var email: String)

fun updateEmail(user: User, newEmail: String): User = // Write your code here

fun main() {
    val user = User(1, "old_email@example.com")
    val updatedUser = updateEmail(user, "new_email@example.com")
    // Updating email for user with ID: 1

    println("Updated User: $updatedUser")
    // Updated User: User(id=1, email=new_email@example.com)
}
```

```
data class User(val id: Int, var email: String)

fun updateEmail(user: User, newEmail: String): User = user.apply {
    this.email = newEmail
}.also { println("Updating email for user with ID: ${it.id}") }

fun main() {
    val user = User(1, "old_email@example.com")
    val updatedUser = updateEmail(user, "new_email@example.com")
    // Updating email for user with ID: 1

    println("Updated User: $updatedUser")
    // Updated User: User(id=1, email=new_email@example.com)
}
```

Lambda expressions with receiver

In this chapter, you'll learn how to use receivers with another type of function, lambda expressions, and how they can help you create a domain-specific language.

Lambda expressions with receiver

In the beginner tour, you learned how to use lambda expressions. Lambda expressions can also have a receiver. In this case, lambda expressions can access any member functions or properties of the receiver without having to explicitly specify the receiver each time. Without these additional references, your code is easier to read and maintain.

> Lambda expressions with receiver are also known as function literals with receiver.

The syntax for a lambda expression with receiver is different when you define the function type. First, write the receiver that you want to extend. Next, put a `.` and then complete the rest of your function type definition. For example:

```
MutableList<Int>.() -> Unit
```

This function type has:

- `MutableList<Int>` as the receiver.
- No function parameters within the parentheses `()`.
- No return value: `Unit`.

Consider this example that draws shapes on a canvas:

```
class Canvas {
    fun drawCircle() = println("🟠 Drawing a circle")
    fun drawSquare() = println("🟥 Drawing a square")
}

// Lambda expression with receiver definition
fun render(block: Canvas.() → Unit): Canvas {
    val canvas = Canvas()
    // Use the lambda expression with receiver
    canvas.block()
    return canvas
}

fun main() {
    render {
        drawCircle()
        // 🟠 Drawing a circle
        drawSquare()
        // 🟥 Drawing a square
    }
}
```

In this example:

- The `Canvas` class has two functions that simulate drawing a circle or a square.
- The `render()` function takes a `block` parameter and returns an instance of the `Canvas` class.
- The `block` parameter is a lambda expression with receiver, where the `Canvas` class is the receiver.
- The `render()` function creates an instance of the `Canvas` class and calls the `block()` lambda expression on the `canvas` instance, using it as the receiver.
- The `main()` function calls the `render()` function with a lambda expression, which is passed to the `block` parameter.
- Inside the lambda passed to the `render()` function, the program calls the `drawCircle()` and `drawSquare()` functions on an instance of the `Canvas` class.

  Because the `drawCircle()` and `drawSquare()` functions are called in the lambda expression with receiver, they can be called directly as if they are inside the `Canvas` class.

Lambda expressions with receiver are helpful when you want to create a domain-specific language (DSL). Since you have access to the receiver's member functions and properties without explicitly referencing the receiver, your code becomes leaner.

To demonstrate this, consider an example that configures items in a menu. Let's begin with a `MenuItem` class and a `Menu` class that contains a function to add items to the menu called `item()`, as well as a list of all menu items `items`:

```
class MenuItem(val name: String)

class Menu(val name: String) {
    val items = mutableListOf<MenuItem>()

    fun item(name: String) {
        items.add(MenuItem(name))
    }
}
```

Let's use a lambda expression with receiver passed as a function parameter (`init`) to the `menu()` function that builds a menu as a starting point:

```
fun menu(name: String, init: Menu.() -> Unit): Menu {
    // Creates an instance of the Menu class
    val menu = Menu(name)
    // Calls the lambda expression with receiver init() on the class instance
    menu.init()
    return menu
}
```

Now you can use the DSL to configure a menu and create a `printMenu()` function to print the menu structure to the console:

```
class MenuItem(val name: String)

class Menu(val name: String) {
    val items = mutableListOf<MenuItem>()

    fun item(name: String) {
        items.add(MenuItem(name))
    }
}

fun menu(name: String, init: Menu.() -> Unit): Menu {
    val menu = Menu(name)
    menu.init()
    return menu
}

fun printMenu(menu: Menu) {
    println("Menu: ${menu.name}")
    menu.items.forEach { println("  Item: ${it.name}") }
}

// Use the DSL
fun main() {
    // Create the menu
    val mainMenu = menu("Main Menu") {
        // Add items to the menu
        item("Home")
        item("Settings")
        item("Exit")
    }

    // Print the menu
    printMenu(mainMenu)
    // Menu: Main Menu
    //   Item: Home
    //   Item: Settings
    //   Item: Exit
}
```

As you can see, using a lambda expression with receiver greatly simplifies the code needed to create your menu. Lambda expressions are not only useful for setup and creation but also for configuration. They are commonly used in building DSLs for APIs, UI frameworks, and configuration builders to produce streamlined code, allowing you to focus more easily on the underlying code structure and logic.

Kotlin's ecosystem has many examples of this design pattern, such as in the `buildList()` and `buildString()` functions from the standard library.

Lambda expressions with receivers can be combined with **type-safe builders** in Kotlin to make DSLs that detect any problems with types at compile time rather than at runtime. To learn more, see Type-safe builders.

Practice

Exercise 1

You have a `fetchData()` function that accepts a lambda expression with receiver. Update the lambda expression to use the `append()` function so that the output of your code is: `Data received - Processed`.

```
fun fetchData(callback: StringBuilder.() -> Unit) {
    val builder = StringBuilder("Data received")
    builder.callback()
}

fun main() {
    fetchData {
        // Write your code here
        // Data received - Processed
    }
}
```

```
fun fetchData(callback: StringBuilder.() -> Unit) {
    val builder = StringBuilder("Data received")
    builder.callback()
}

fun main() {
    fetchData {
        append(" - Processed")
        println(this.toString())
        // Data received - Processed
    }
}
```

Exercise 2

You have a `Button` class and `ButtonEvent` and `Position` data classes. Write some code that triggers the `onEvent()` member function of the `Button` class to trigger a double-click event. Your code should print `"Double click!"`.

```
class Button {
    fun onEvent(action: ButtonEvent.() -> Unit) {
        // Simulate a double-click event (not a right-click)
        val event = ButtonEvent(isRightClick = false, amount = 2, position = Position(100, 200))
        event.action() // Trigger the event callback
    }
}

data class ButtonEvent(
    val isRightClick: Boolean,
    val amount: Int,
    val position: Position
)

data class Position(
    val x: Int,
    val y: Int
)

fun main() {
    val button = Button()

    button.onEvent {
        // Write your code here
        // Double click!
    }
}
```

```
class Button {
    fun onEvent(action: ButtonEvent.() -> Unit) {
        // Simulate a double-click event (not a right-click)
        val event = ButtonEvent(isRightClick = false, amount = 2, position = Position(100, 200))
        event.action() // Trigger the event callback
    }
}

data class ButtonEvent(
    val isRightClick: Boolean,
    val amount: Int,
    val position: Position
)

data class Position(
    val x: Int,
    val y: Int
)

fun main() {
    val button = Button()

    button.onEvent {
        if (!isRightClick && amount == 2) {
            println("Double click!")
            // Double click!
        }
    }
}
```

Exercise 3

Write a function that creates a copy of a list of integers where every element is incremented by 1. Use the provided function skeleton that extends `List<Int>` with an `incremented` function.

```
fun List<Int>.incremented(): List<Int> {
    val originalList = this
    return buildList {
        // Write your code here
    }
}

fun main() {
    val originalList = listOf(1, 2, 3)
    val newList = originalList.incremented()
    println(newList)
    // [2, 3, 4]
}
```

```
fun List<Int>.incremented(): List<Int> {
    val originalList = this
    return buildList {
        for (n in originalList) add(n + 1)
    }
}

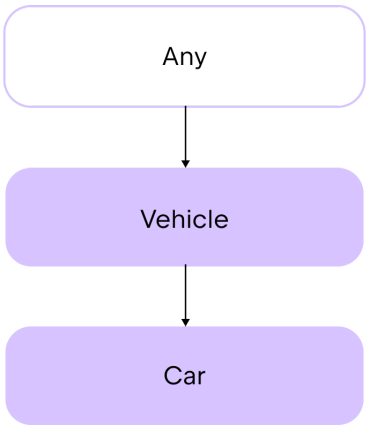
fun main() {
    val originalList = listOf(1, 2, 3)
    val newList = originalList.incremented()
    println(newList)
    // [2, 3, 4]
}
```

Previous step

Next step

Classes and interfaces

In the beginner tour, you learned how to use classes and data classes to store data and maintain a collection of characteristics that can be shared in your code. Eventually, you will want to create a hierarchy to efficiently share code within your projects. This chapter explains the options Kotlin provides for sharing code and how they can make your code safer and easier to maintain.



Class inheritance

In a previous chapter, we covered how you can use extension functions to extend classes without modifying the original source code. But what if you are working on something complex where sharing code **between** classes would be useful? In such cases, you can use class inheritance.

By default, classes in Kotlin can't be inherited. Kotlin is designed this way to prevent unintended inheritance and make your classes easier to maintain.

Kotlin classes only support **single inheritance**, meaning it is only possible to inherit from **one class at a time**. This class is called the **parent**.

The parent of a class inherits from another class (the grandparent), forming a hierarchy. At the top of Kotlin's class hierarchy is the common parent class: `Any`. All classes ultimately inherit from the `Any` class:

An example of the class hierarchy with Any type

The `Any` class provides the `toString()` function as a member function automatically. Therefore, you can use this inherited function in any of your classes. For example:

```
class Car(val make: String, val model: String, val numberOfDoors: Int)

fun main() {
        val car1 = Car("Toyota", "Corolla", 4)

    // Uses the .toString() function via string templates to print class properties
    println("Car1: make=${car1.make}, model=${car1.model}, numberOfDoors=${car1.numberOfDoors}")
    // Car1: make=Toyota, model=Corolla, numberOfDoors=4
    //sampleEnd
}
```

If you want to use inheritance to share some code between classes, first consider using abstract classes.

Abstract classes

Abstract classes can be inherited by default. The purpose of abstract classes is to provide members that other classes inherit or implement. As a result, they have a constructor, but you can't create instances from them. Within the child class, you define the behavior of the parent's properties and functions with the `override` keyword. In this way, you can say that the child class "overrides" the members of the parent class.

When you define the behavior of an inherited function or property, we call that an **implementation**.

Abstract classes can contain both functions and properties **with** implementation as well as functions and properties **without** implementation, known as abstract functions and properties.

To create an abstract class, use the `abstract` keyword:

```
abstract class Animal
```

To declare a function or a property **without** an implementation, you also use the `abstract` keyword:

```
abstract fun makeSound()
abstract val sound: String
```

For example, let's say that you want to create an abstract class called `Product` that you can create child classes from to define different product categories:

```
abstract class Product(val name: String, var price: Double) {
    // Abstract property for the product category
    abstract val category: String

    // A function that can be shared by all products
    fun productInfo(): String {
        return "Product: $name, Category: $category, Price: $price"
    }
}
```

In the abstract class:

- The constructor has two parameters for the product's `name` and `price`.
- There is an abstract property that contains the product category as a string.
- There is a function that prints information about the product.

Let's create a child class for electronics. Before you define an implementation for the `category` property in the child class, you must use the `override` keyword:

```
class Electronic(name: String, price: Double, val warranty: Int) : Product(name, price) {
    override val category = "Electronic"
}
```

The `Electronic` class:

- Inherits from the `Product` abstract class.
- Has an additional parameter in the constructor: `warranty`, which is specific to electronics.
- Overrides the `category` property to contain the string `"Electronic"`.

Now, you can use these classes like this:

```
abstract class Product(val name: String, var price: Double) {
    // Abstract property for the product category
    abstract val category: String

    // A function that can be shared by all products
    fun productInfo(): String {
        return "Product: $name, Category: $category, Price: $price"
    }
}

class Electronic(name: String, price: Double, val warranty: Int) : Product(name, price) {
    override val category = "Electronic"
}

fun main() {
    // Creates an instance of the Electronic class
    val laptop = Electronic(name = "Laptop", price = 1000.0, warranty = 2)

    println(laptop.productInfo())
    // Product: Laptop, Category: Electronic, Price: 1000.0
}
```

Although abstract classes are great for sharing code in this way, they are restricted because classes in Kotlin only support single inheritance. If you need to inherit from multiple sources, consider using interfaces.

Interfaces

Interfaces are similar to classes, but they have some differences:

- You can't create an instance of an interface. They don't have a constructor or header.
- Their functions and properties are implicitly inheritable by default. In Kotlin, we say that they are "open."
- You don't need to mark their functions as `abstract` if you don't give them an implementation.

Similar to abstract classes, you use interfaces to define a set of functions and properties that classes can inherit and implement later. This approach helps you focus on the abstraction described by the interface, rather than the specific implementation details. Using interfaces makes your code:

- More modular, as it isolates different parts, allowing them to evolve independently.
- Easier to understand by grouping related functions into a cohesive set.
- Easier to test, as you can quickly swap an implementation with a mock for testing.

To declare an interface, use the `interface` keyword:

```
interface PaymentMethod
```

Interface implementation

Interfaces support multiple inheritance so a class can implement multiple interfaces at once. First, let's consider the scenario where a class implements **one** interface.

To create a class that implements an interface, add a colon after your class header, followed by the interface name that you want to implement. You don't use parentheses `()` after the interface name because interfaces don't have a constructor:

```
class CreditCardPayment : PaymentMethod
```

For example:

```
interface PaymentMethod {
    // Functions are inheritable by default
    fun initiatePayment(amount: Double): String
}

class CreditCardPayment(val cardNumber: String, val cardHolderName: String, val expiryDate: String) :
PaymentMethod {
    override fun initiatePayment(amount: Double): String {
        // Simulate processing payment with credit card
        return "Payment of $$amount initiated using Credit Card ending in ${cardNumber.takeLast(4)}."
    }
}

fun main() {
    val paymentMethod = CreditCardPayment("1234 5678 9012 3456", "John Doe", "12/25")
    println(paymentMethod.initiatePayment(100.0))
    // Payment of $100.0 initiated using Credit Card ending in 3456.
}
```

In the example:

- `PaymentMethod` is an interface that has an `initiatePayment()` function without an implementation.
- `CreditCardPayment` is a class that implements the `PaymentMethod` interface.
- The `CreditCardPayment` class overrides the inherited `initiatePayment()` function.
- `paymentMethod` is an instance of the `CreditCardPayment` class.
- The overridden `initiatePayment()` function is called on the `paymentMethod` instance with a parameter of `100.0`.

To create a class that implements **multiple** interfaces, add a colon after your class header followed by the name of the interfaces that you want to implement separated by a comma:

```
class CreditCardPayment : PaymentMethod, PaymentType
```

For example:

```
interface PaymentMethod {
    fun initiatePayment(amount: Double): String
}

interface PaymentType {
    val paymentType: String
}

class CreditCardPayment(val cardNumber: String, val cardHolderName: String, val expiryDate: String) :
PaymentMethod,
    PaymentType {
    override fun initiatePayment(amount: Double): String {
        // Simulate processing payment with credit card
        return "Payment of $$amount initiated using Credit Card ending in ${cardNumber.takeLast(4)}."
    }

    override val paymentType: String = "Credit Card"
}

fun main() {
    val paymentMethod = CreditCardPayment("1234 5678 9012 3456", "John Doe", "12/25")
    println(paymentMethod.initiatePayment(100.0))
    // Payment of $100.0 initiated using Credit Card ending in 3456.

    println("Payment is by ${paymentMethod.paymentType}")
    // Payment is by Credit Card
}
```

In the example:

- `PaymentMethod` is an interface that has the `initiatePayment()` function without an implementation.
- `PaymentType` is an interface that has the `paymentType` property that isn't initialized.
- `CreditCardPayment` is a class that implements the `PaymentMethod` and `PaymentType` interfaces.
- The `CreditCardPayment` class overrides the inherited `initiatePayment()` function and the `paymentType` property.
- `paymentMethod` is an instance of the `CreditCardPayment` class.

- The overridden `initiatePayment()` function is called on the `paymentMethod` instance with a parameter of `100.0`.
- The overridden `paymentType` property is accessed on the `paymentMethod` instance.

For more information about interfaces and interface inheritance, see Interfaces.

Delegation

Interfaces are useful, but if your interface contains many functions, its child classes can end up with a lot of boilerplate code. If you only want to override a small part of a class's behavior, you need to repeat yourself a lot.

> Boilerplate code is a chunk of code that is reused with little or no alteration in multiple parts of a software project.

For example, let's say that you have an interface called `DrawingTool` that contains a number of functions and one property called `color`:

```
interface DrawingTool {
    val color: String
    fun draw(shape: String)
    fun erase(area: String)
    fun getToolInfo(): String
}
```

You create a class called `PenTool` which implements the `DrawingTool` interface and provides implementations for all of its members:

```
class PenTool : DrawingTool {
    override val color: String = "black"

    override fun draw(shape: String) {
        println("Drawing $shape using a pen in $color")
    }

    override fun erase(area: String) {
        println("Erasing $area with pen tool")
    }

    override fun getToolInfo(): String {
        return "PenTool(color=$color)"
    }
}
```

You want to create a class like `PenTool` with the same behavior but a different `color` value. One approach is to create a new class that expects an object implementing the `DrawingTool` interface as a parameter, like a `PenTool` class instance. Then, inside the class, you can override the `color` property.

But in this scenario, you need to add implementations for each member of the `DrawingTool` interface:

```
interface DrawingTool {
    val color: String
    fun draw(shape: String)
    fun erase(area: String)
    fun getToolInfo(): String
}

class PenTool : DrawingTool {
    override val color: String = "black"

    override fun draw(shape: String) {
        println("Drawing $shape using a pen in $color")
    }

    override fun erase(area: String) {
        println("Erasing $area with pen tool")
    }

    override fun getToolInfo(): String {
        return "PenTool(color=$color)"
    }
}
class CanvasSession(val tool: DrawingTool) : DrawingTool {
    override val color: String = "blue"

    override fun draw(shape: String) {
        tool.draw(shape)
    }

    override fun erase(area: String) {
        tool.erase(area)
    }

    override fun getToolInfo(): String {
        return tool.getToolInfo()
    }
}
fun main() {
    val pen = PenTool()
    val session = CanvasSession(pen)

    println("Pen color: ${pen.color}")
    // Pen color: black

    println("Session color: ${session.color}")
    // Session color: blue

    session.draw("circle")
    // Drawing circle with pen in black

    session.erase("top-left corner")
    // Erasing top-left corner with pen tool

    println(session.getToolInfo())
    // PenTool(color=black)
}
```

You can see that if you have a large number of member functions in the `DrawingTool` interface, the amount of boilerplate code in the `CanvasSession` class can be large. However, there is an alternative.

In Kotlin, you can delegate the interface implementation to a class instance using the `by` keyword. For example:

```
class CanvasSession(val tool: DrawingTool) : DrawingTool by tool
```

Here, `tool` is the name of the `PenTool` class instance where the implementations of member functions are delegated to.

Now you don't have to add implementations for the member functions in the `CanvasSession` class. The compiler does this for you automatically from the `PenTool` class. This saves you from having to write a lot of boilerplate code. Instead, you add code only for the behavior you want to change for your child class.

For example, if you want to change the value of the `color` property:

```
interface DrawingTool {
    val color: String
    fun draw(shape: String)
    fun erase(area: String)
    fun getToolInfo(): String
}

class PenTool : DrawingTool {
    override val color: String = "black"

    override fun draw(shape: String) {
        println("Drawing $shape using a pen in $color")
    }

    override fun erase(area: String) {
        println("Erasing $area with pen tool")
    }

    override fun getToolInfo(): String {
        return "PenTool(color=$color)"
    }
}

class CanvasSession(val tool: DrawingTool) : DrawingTool by tool {
    // No boilerplate code!
    override val color: String = "blue"
}
fun main() {
    val pen = PenTool()
    val session = CanvasSession(pen)

    println("Pen color: ${pen.color}")
    // Pen color: black

    println("Session color: ${session.color}")
    // Session color: blue

    session.draw("circle")
    // Drawing circle with pen in black

    session.erase("top-left corner")
    // Erasing top-left corner with pen tool

    println(session.getToolInfo())
    // PenTool(color=black)
}
```

If you want to, you can also override the behavior of an inherited member function in the `CanvasSession` class, but now you don't have to add new lines of code for every inherited member function.

For more information, see Delegation.

Practice

Exercise 1

Imagine you're working on a smart home system. A smart home typically has different types of devices that all have some basic features but also unique behaviors. In the code sample below, complete the `abstract` class called `SmartDevice` so that the child class `SmartLight` can compile successfully.

Then, create another child class called `SmartThermostat` that inherits from the `SmartDevice` class and implements `turnOn()` and `turnOff()` functions that return print statements describing which thermostat is heating or turned off. Finally, add another function called `adjustTemperature()` that accepts a temperature measurement as an input and prints: `$name thermostat set to $temperature°C.`

Hint

In the `SmartDevice` class, add the `turnOn()` and `turnOff()` functions so that you can override their behavior later in the `SmartThermostat` class.

```
abstract class // Write your code here

class SmartLight(name: String) : SmartDevice(name) {
    override fun turnOn() {
        println("$name is now ON.")
    }

    override fun turnOff() {
        println("$name is now OFF.")
    }

   fun adjustBrightness(level: Int) {
        println("Adjusting $name brightness to $level%.")
    }
}

class SmartThermostat // Write your code here

fun main() {
    val livingRoomLight = SmartLight("Living Room Light")
    val bedroomThermostat = SmartThermostat("Bedroom Thermostat")

    livingRoomLight.turnOn()
    // Living Room Light is now ON.
    livingRoomLight.adjustBrightness(10)
    // Adjusting Living Room Light brightness to 10%.
    livingRoomLight.turnOff()
    // Living Room Light is now OFF.

    bedroomThermostat.turnOn()
    // Bedroom Thermostat thermostat is now heating.
    bedroomThermostat.adjustTemperature(5)
    // Bedroom Thermostat thermostat set to 5°C.
    bedroomThermostat.turnOff()
    // Bedroom Thermostat thermostat is now off.
}
```

```
abstract class SmartDevice(val name: String) {
    abstract fun turnOn()
    abstract fun turnOff()
}

class SmartLight(name: String) : SmartDevice(name) {
    override fun turnOn() {
        println("$name is now ON.")
    }

    override fun turnOff() {
        println("$name is now OFF.")
    }

   fun adjustBrightness(level: Int) {
        println("Adjusting $name brightness to $level%.")
    }
}

class SmartThermostat(name: String) : SmartDevice(name) {
    override fun turnOn() {
        println("$name thermostat is now heating.")
    }

    override fun turnOff() {
        println("$name thermostat is now off.")
    }

   fun adjustTemperature(temperature: Int) {
        println("$name thermostat set to $temperature°C.")
    }
}

fun main() {
    val livingRoomLight = SmartLight("Living Room Light")
    val bedroomThermostat = SmartThermostat("Bedroom Thermostat")

    livingRoomLight.turnOn()
    // Living Room Light is now ON.
    livingRoomLight.adjustBrightness(10)
    // Adjusting Living Room Light brightness to 10%.
    livingRoomLight.turnOff()
    // Living Room Light is now OFF.

    bedroomThermostat.turnOn()
    // Bedroom Thermostat thermostat is now heating.
    bedroomThermostat.adjustTemperature(5)
    // Bedroom Thermostat thermostat set to 5°C.
    bedroomThermostat.turnOff()
    // Bedroom Thermostat thermostat is now off.
}
```

Exercise 2

Create an interface called `Media` that you can use to implement specific media classes like `Audio`, `Video`, or `Podcast`. Your interface must include:

- A property called `title` to represent the title of the media.
- A function called `play()` to play the media.

Then, create a class called `Audio` that implements the `Media` interface. The `Audio` class must use the `title` property in its constructor as well as have an additional property called `composer` that has `String` type. In the class, implement the `play()` function to print the following: `"Playing audio: $title, composed by $composer"`.

Hint

You can use the `override` keyword in class headers to implement a property from an interface in the constructor.

```
interface // Write your code here

class // Write your code here

fun main() {
    val audio = Audio("Symphony No. 5", "Beethoven")
    audio.play()
   // Playing audio: Symphony No. 5, composed by Beethoven
}
```

```
interface Media {
    val title: String
    fun play()
}

class Audio(override val title: String, val composer: String) : Media {
    override fun play() {
        println("Playing audio: $title, composed by $composer")
    }
}

fun main() {
    val audio = Audio("Symphony No. 5", "Beethoven")
    audio.play()
   // Playing audio: Symphony No. 5, composed by Beethoven
}
```

Exercise 3

You're building a payment processing system for an e-commerce application. Each payment method needs to be able to authorize a payment and process a transaction. Some payments also need to be able to process refunds.

1. In the `Refundable` interface, add a function called `refund()` to process refunds.
2. In the `PaymentMethod` abstract class:
    - Add a function called `authorize()` that takes an amount and prints a message containing the amount.
    - Add an abstract function called `processPayment()` that also takes an amount.
3. Create a class called `CreditCard` that implements the `Refundable` interface and `PaymentMethod` abstract class. In this class, add implementations for the `refund()` and `processPayment()` functions so that they print the following statements:
    - `"Refunding $amount to the credit card."`
    - `"Processing credit card payment of $amount."`

```
interface Refundable {
    // Write your code here
}

abstract class PaymentMethod(val name: String) {
    // Write your code here
}

class CreditCard // Write your code here

fun main() {
    val visa = CreditCard("Visa")

    visa.authorize(100.0)
    // Authorizing payment of $100.0.
    visa.processPayment(100.0)
    // Processing credit card payment of $100.0.
    visa.refund(50.0)
    // Refunding $50.0 to the credit card.
}
```

```
interface Refundable {
    fun refund(amount: Double)
}

abstract class PaymentMethod(val name: String) {
    fun authorize(amount: Double) {
        println("Authorizing payment of $$amount.")
    }

    abstract fun processPayment(amount: Double)
}

class CreditCard(name: String) : PaymentMethod(name), Refundable {
    override fun processPayment(amount: Double) {
        println("Processing credit card payment of $$amount.")
    }

    override fun refund(amount: Double) {
        println("Refunding $$amount to the credit card.")
    }
}

fun main() {
    val visa = CreditCard("Visa")

    visa.authorize(100.0)
    // Authorizing payment of $100.0.
    visa.processPayment(100.0)
    // Processing credit card payment of $100.0.
    visa.refund(50.0)
    // Refunding $50.0 to the credit card.
}
```

Exercise 4

You have a simple messaging app that has some basic functionality, but you want to add some functionality for *smart* messages without significantly duplicating your code.

In the code below, define a class called `SmartMessenger` that inherits from the `Messenger` interface but delegates the implementation to an instance of the `BasicMessenger` class.

In the `SmartMessenger` class, override the `sendMessage()` function to send smart messages. The function must accept a `message` as an input and return a printed statement: `"Sending a smart message: $message"`. In addition, call the `sendMessage()` function from the `BasicMessenger` class and prefix the message with `[smart]`.

> You don't need to rewrite the `receiveMessage()` function in the `SmartMessenger` class.

```
interface Messenger {
    fun sendMessage(message: String)
    fun receiveMessage(): String
}

class BasicMessenger : Messenger {
    override fun sendMessage(message: String) {
        println("Sending message: $message")
    }

    override fun receiveMessage(): String {
        return "You've got a new message!"
    }
}

class SmartMessenger // Write your code here

fun main() {
    val basicMessenger = BasicMessenger()
    val smartMessenger = SmartMessenger(basicMessenger)

    basicMessenger.sendMessage("Hello!")
    // Sending message: Hello!
    println(smartMessenger.receiveMessage())
    // You've got a new message!
    smartMessenger.sendMessage("Hello from SmartMessenger!")
    // Sending a smart message: Hello from SmartMessenger!
    // Sending message: [smart] Hello from SmartMessenger!
}
```

```
interface Messenger {
    fun sendMessage(message: String)
    fun receiveMessage(): String
}

class BasicMessenger : Messenger {
    override fun sendMessage(message: String) {
        println("Sending message: $message")
    }

    override fun receiveMessage(): String {
        return "You've got a new message!"
    }
}

class SmartMessenger(val basicMessenger: BasicMessenger) : Messenger by basicMessenger {
    override fun sendMessage(message: String) {
        println("Sending a smart message: $message")
        basicMessenger.sendMessage("[smart] $message")
    }
}

fun main() {
    val basicMessenger = BasicMessenger()
    val smartMessenger = SmartMessenger(basicMessenger)

    basicMessenger.sendMessage("Hello!")
    // Sending message: Hello!
    println(smartMessenger.receiveMessage())
    // You've got a new message!
    smartMessenger.sendMessage("Hello from SmartMessenger!")
    // Sending a smart message: Hello from SmartMessenger!
    // Sending message: [smart] Hello from SmartMessenger!
}
```

Previous step

Next step

Objects

In this chapter, you'll expand your understanding of classes by exploring object declarations. This knowledge will help you efficiently manage behavior across your projects.

Object declarations

In Kotlin, you can use **object declarations** to declare a class with a single instance. In a sense, you declare the class and create the single instance *at the same time*. Object declarations are useful when you want to create a class to use as a single reference point for your program or to coordinate behavior across a system.

> A class that has only one instance that is easily accessible is called a **singleton**.

Objects in Kotlin are **lazy**, meaning they are created only when accessed. Kotlin also ensures that all objects are created in a thread-safe manner so that you don't have to check this manually.

To create an object declaration, use the `object` keyword:

```
object DoAuth {}
```

Following the name of your `object`, add any properties or member functions within the object body defined by curly braces `{}`.

Objects can't have constructors, so they don't have headers like classes.

For example, let's say that you wanted to create an object called `DoAuth` that is responsible for authentication:

```
object DoAuth {
    fun takeParams(username: String, password: String) {
        println("input Auth parameters = $username:$password")
    }
}

fun main(){
    // The object is created when the takeParams() function is called
    DoAuth.takeParams("coding_ninja", "N1njaC0ding!")
    // input Auth parameters = coding_ninja:N1njaC0ding!
}
```

The object has a member function called `takeParams` that accepts `username` and `password` variables as parameters and prints a string to the console. The `DoAuth` object is only created when the function is called for the first time.

Objects can inherit from classes and interfaces. For example:

```
interface Auth {
    fun takeParams(username: String, password: String)
}

object DoAuth : Auth {
    override fun takeParams(username: String, password: String) {
        println("input Auth parameters = $username:$password")
    }
}
```

Data objects

To make it easier to print the contents of an object declaration, Kotlin has **data** objects. Similar to data classes, which you learned about in the beginner tour, data objects automatically come with additional member functions: `toString()` and `equals()`.

Unlike data classes, data objects do not come automatically with the `copy()` member function because they only have a single instance that can't be copied.

To create a data object, use the same syntax as for object declarations but prefix it with the `data` keyword:

```
data object AppConfig {}
```

For example:

```
data object AppConfig {
    var appName: String = "My Application"
    var version: String = "1.0.0"
}

fun main() {
    println(AppConfig)
    // AppConfig

    println(AppConfig.appName)
    // My Application
}
```

For more information about data objects, see Data objects.

Companion objects

In Kotlin, a class can have an object: a **companion** object. You can only have **one** companion object per class. A companion object is created only when its class is referenced for the first time.

Any properties or functions declared inside a companion object are shared across all class instances.

To create a companion object within a class, use the same syntax for an object declaration but prefix it with the `companion` keyword:

```
companion object Bonger {}
```

A companion object doesn't have to have a name. If you don't define one, the default is `Companion`.

To access any properties or functions of the companion object, reference the class name. For example:

```
class BigBen {
    companion object Bonger {
        fun getBongs(nTimes: Int) {
            repeat(nTimes) { print("BONG ") }
            }
        }
    }

fun main() {
    // Companion object is created when the class is referenced for the
    // first time.
    BigBen.getBongs(12)
    // BONG BONG BONG BONG BONG BONG BONG BONG BONG BONG BONG BONG
}
```

This example creates a class called `BigBen` that contains a companion object called `Bonger`. The companion object has a member function called `getBongs()` that accepts an integer and prints `"BONG"` to the console the same number of times as the integer.

In the `main()` function, the `getBongs()` function is called by referring to the class name. The companion object is created at this point. The `getBongs()` function is called with parameter `12`.

For more information, see Companion objects.

Practice

Exercise 1

You run a coffee shop and have a system for tracking customer orders. Consider the code below and complete the declaration of the second data object so that the following code in the `main()` function runs successfully:

```
interface Order {
    val orderId: String
    val customerName: String
    val orderTotal: Double
}

data object OrderOne: Order {
    override val orderId = "001"
    override val customerName = "Alice"
    override val orderTotal = 15.50
}

data object // Write your code here

fun main() {
    // Print the name of each data object
    println("Order name: $OrderOne")
    // Order name: OrderOne
    println("Order name: $OrderTwo")
    // Order name: OrderTwo

    // Check if the orders are identical
    println("Are the two orders identical? ${OrderOne == OrderTwo}")
    // Are the two orders identical? false

    if (OrderOne == OrderTwo) {
        println("The orders are identical.")
    } else {
        println("The orders are unique.")
        // The orders are unique.
    }

    println("Do the orders have the same customer name? ${OrderOne.customerName ==
OrderTwo.customerName}")
    // Do the orders have the same customer name? false
}
```

```
interface Order {
    val orderId: String
    val customerName: String
    val orderTotal: Double
}

data object OrderOne: Order {
    override val orderId = "001"
    override val customerName = "Alice"
    override val orderTotal = 15.50
}

data object OrderTwo: Order {
    override val orderId = "002"
    override val customerName = "Bob"
    override val orderTotal = 12.75
}

fun main() {
    // Print the name of each data object
    println("Order name: $OrderOne")
    // Order name: OrderOne
    println("Order name: $OrderTwo")
    // Order name: OrderTwo

    // Check if the orders are identical
    println("Are the two orders identical? ${OrderOne == OrderTwo}")
    // Are the two orders identical? false

    if (OrderOne == OrderTwo) {
        println("The orders are identical.")
    } else {
        println("The orders are unique.")
        // The orders are unique.
    }

    println("Do the orders have the same customer name? ${OrderOne.customerName ==
OrderTwo.customerName}")
    // Do the orders have the same customer name? false
}
```

Exercise 2

Create an object declaration that inherits from the `Vehicle` interface to create a unique vehicle type: `FlyingSkateboard`. Implement the `name` property and the `move()` function in your object so that the following code in the `main()` function runs successfully:

```
interface Vehicle {
    val name: String
    fun move(): String
}

object // Write your code here

fun main() {
    println("${FlyingSkateboard.name}: ${FlyingSkateboard.move()}")
    // Flying Skateboard: Glides through the air with a hover engine
    println("${FlyingSkateboard.name}: ${FlyingSkateboard.fly()}")
    // Flying Skateboard: Wooooooooo
}
```

```
interface Vehicle {
    val name: String
    fun move(): String
}

object FlyingSkateboard : Vehicle {
    override val name = "Flying Skateboard"
    override fun move() = "Glides through the air with a hover engine"

   fun fly(): String = "Wooooooooo"
}

fun main() {
    println("${FlyingSkateboard.name}: ${FlyingSkateboard.move()}")
    // Flying Skateboard: Glides through the air with a hover engine
    println("${FlyingSkateboard.name}: ${FlyingSkateboard.fly()}")
    // Flying Skateboard: Wooooooooo
}
```

Exercise 3

You are building a user registration module for an app. You want to keep email validation associated with the `User` class but don't want to create an unnecessary `User` instance if the email address is invalid.

For this exercise, consider an email address valid if it contains both `@` and `.`. Complete the data class so that the following code in the `main()` function runs successfully:

Hint

Add an email validation function in a companion object for the `User` class so that you can call the function directly on `User`.

```
data class User(val name: String, val email: String) {
    // Write your code here
}

fun main() {
    val candidates = listOf(
        Pair("Alice", "alice@example.com"),
        Pair("Bob", "bob2example-com")
    )

    for ((name, email) in candidates) {
        if (User.isValidEmail(email)) {
            val user = User(name, email)
            println("Registered: ${user.name}, ${user.email}")
            // Registered: Alice, alice@example.com
        } else {
            println("Error: '${email}' is not valid. The email should contain '@' and '.'")
            // Error: 'bob2example-com' is not valid. The email should contain '@' and '.'
        }
    }
}
```

```
data class User(val name: String, val email: String) {
    companion object {
        fun isValidEmail(email: String): Boolean =
            email.contains('@') && email.contains('.')
    }
}

fun main() {
    val candidates = listOf(
        Pair("Alice", "alice@example.com"),
        Pair("Bob", "bob2example-com")
    )

    for ((name, email) in candidates) {
        if (User.isValidEmail(email)) {
            val user = User(name, email)
            println("Registered: ${user.name}, ${user.email}")
            // Registered: Alice, alice@example.com
        } else {
            println("Error: '${email}' is not valid. The email should contain '@' and '.'")
            // Error: 'bob2example-com' is not valid. The email should contain '@' and '.'
        }
    }
}
```

As an extension of this exercise, try using functions in companion objects as factory methods to construct instances of a class. For an example and more information about this pattern, see Companion objects.

Previous step

Next step

Open and special classes

In this chapter, you'll learn about open classes, how they work with interfaces, and other special types of classes available in Kotlin.

Open classes

If you can't use interfaces or abstract classes, you can explicitly make a class inheritable by declaring it as **open**. To do this, use the `open` keyword before your class declaration:

```
open class Vehicle(val make: String, val model: String)
```

To create a class that inherits from another, add a colon after your class header followed by a call to the constructor of the parent class that you want to inherit from. In this example, the `Car` class inherits from the `Vehicle` class:

```
open class Vehicle(val make: String, val model: String)

class Car(make: String, model: String, val numberOfDoors: Int) : Vehicle(make, model)

fun main() {
    // Creates an instance of the Car class
    val car = Car("Toyota", "Corolla", 4)

    // Prints the details of the car
    println("Car Info: Make - ${car.make}, Model - ${car.model}, Number of doors -
${car.numberOfDoors}")
    // Car Info: Make - Toyota, Model - Corolla, Number of doors - 4
}
```

Just like when creating a normal class instance, if your class inherits from a parent class, then it must initialize all the parameters declared in the parent class header. So in the example, the `car` instance of the `Car` class initializes the parent class parameters: `make` and `model`.

Overriding inherited behavior

If you want to inherit from a class but change some of the behavior, you can override the inherited behavior.

By default, it's not possible to override a member function or property of a parent class. Just like with abstract classes, you need to add special keywords.

Member functions

To allow a function in the parent class to be overridden, use the `open` keyword before its declaration in the parent class:

```
open fun displayInfo() {}
```

To override an inherited member function, use the `override` keyword before the function declaration in the child class:

```
override fun displayInfo() {}
```

For example:

```
open class Vehicle(val make: String, val model: String) {
    open fun displayInfo() {
        println("Vehicle Info: Make - $make, Model - $model")
    }
}

class Car(make: String, model: String, val numberOfDoors: Int) : Vehicle(make, model) {
    override fun displayInfo() {
        println("Car Info: Make - $make, Model - $model, Number of Doors - $numberOfDoors")
    }
}

fun main() {
    val car1 = Car("Toyota", "Corolla", 4)
    val car2 = Car("Honda", "Civic", 2)

    // Uses the overridden displayInfo() function
    car1.displayInfo()
    // Car Info: Make - Toyota, Model - Corolla, Number of Doors - 4
    car2.displayInfo()
    // Car Info: Make - Honda, Model - Civic, Number of Doors - 2
}
```

This example:

- Creates two instances of the `Car` class that inherit from the `Vehicle` class: `car1` and `car2`.
- Overrides the `displayInfo()` function in the `Car` class to also print the number of doors.
- Calls the overridden `displayInfo()` function on `car1` and `car2` instances.

Properties

In Kotlin, it's not common practice to make a property inheritable by using the `open` keyword and overriding it later. Most of the time, you use an abstract class or an interface where properties are inheritable by default.

Properties inside open classes are accessible by their child class. In general, it's better to access them directly rather than override them with a new property.

For example, let's say that you have a property called `transmissionType` that you want to override later. The syntax for overriding properties is exactly the same as for overriding member functions. You can do this:

```
open class Vehicle(val make: String, val model: String) {
    open val transmissionType: String = "Manual"
}

class Car(make: String, model: String, val numberOfDoors: Int) : Vehicle(make, model) {
    override val transmissionType: String = "Automatic"
}
```

However, this is not good practice. Instead, you can add the property to the constructor of your inheritable class and declare its value when you create the `Car` child class:

```
open class Vehicle(val make: String, val model: String, val transmissionType: String = "Manual")

class Car(make: String, model: String, val numberOfDoors: Int) : Vehicle(make, model, "Automatic")
```

Accessing properties directly, instead of overriding them, leads to simpler and more readable code. By declaring properties once in the parent class and passing their values through the constructor, you eliminate the need for unnecessary overrides in child classes.

For more information about class inheritance and overriding class behavior, see Inheritance.

Open classes and interfaces

You can create a class that inherits a class **and** implements multiple interfaces. In this case, you must declare the parent class first, after the colon, before listing the interfaces:

```
// Define interfaces
interface EcoFriendly {
    val emissionLevel: String
}

interface ElectricVehicle {
    val batteryCapacity: Double
}

// Parent class
open class Vehicle(val make: String, val model: String)

// Child class
open class Car(make: String, model: String, val numberOfDoors: Int) : Vehicle(make, model)

// New class that inherits from Car and implements two interfaces
class ElectricCar(
    make: String,
    model: String,
    numberOfDoors: Int,
    val capacity: Double,
    val emission: String
) : Car(make, model, numberOfDoors), EcoFriendly, ElectricVehicle {
    override val batteryCapacity: Double = capacity
    override val emissionLevel: String = emission
}
```

Special classes

In addition to abstract, open, and data classes, Kotlin has special types of classes designed for various purposes, such as restricting specific behavior or reducing the performance impact of creating small objects.

Sealed classes

There may be times when you want to restrict inheritance. You can do this with sealed classes. Sealed classes are a special type of abstract class. Once you declare that a class is sealed, you can only create child classes from it within the same package. It's not possible to inherit from the sealed class outside of this scope.

> A package is a collection of code with related classes and functions, typically within a directory. To learn more about packages in Kotlin, see Packages and imports.

To create a sealed class, use the `sealed` keyword:

```
sealed class Mammal
```

Sealed classes are particularly useful when combined with a `when` expression. By using a `when` expression, you can define the behavior for all possible child classes. For example:

```
sealed class Mammal(val name: String)

class Cat(val catName: String) : Mammal(catName)
class Human(val humanName: String, val job: String) : Mammal(humanName)

fun greetMammal(mammal: Mammal): String {
    when (mammal) {
        is Human -> return "Hello ${mammal.name}; You're working as a ${mammal.job}"
        is Cat -> return "Hello ${mammal.name}"
    }
}

fun main() {
    println(greetMammal(Cat("Snowy")))
    // Hello Snowy
}
```

In the example:

- There is a sealed class called `Mammal` that has the `name` parameter in the constructor.
- The `Cat` class inherits from the `Mammal` sealed class and uses the `catName` parameter in its own constructor as the `name` parameter from the `Mammal` class.
- The `Human` class inherits from the `Mammal` sealed class and uses the `humanName` parameter in its own constructor as the `name` parameter from the `Mammal` class. It also has the `job` parameter in its constructor.
- The `greetMammal()` function accepts an argument of `Mammal` type and returns a string.
- Within the `greetMammal()` function body, there's a `when` expression that uses the `is` operator to check the type of `mammal` and decide which action to perform.
- The `main()` function calls the `greetMammal()` function with an instance of the `Cat` class and `name` parameter called `Snowy`.

This tour discusses the `is` operator in more detail in the Null safety chapter.

For more information about sealed classes and their recommended use cases, see Sealed classes and interfaces.

Enum classes

Enum classes are useful when you want to represent a finite set of distinct values in a class. An enum class contains enum constants, which are themselves instances of the enum class.

To create an enum class, use the `enum` keyword:

```
enum class State
```

Let's say that you want to create an enum class that contains the different states of a process. Each enum constant must be separated by a comma `,`:

```
enum class State {
    IDLE, RUNNING, FINISHED
}
```

The `State` enum class has enum constants: `IDLE`, `RUNNING`, and `FINISHED`. To access an enum constant, use the class name followed by a `.` and the name of the enum constant:

```
val state = State.RUNNING
```

You can use this enum class with a `when` expression to define the action to take depending on the value of the enum constant:

```
enum class State {
    IDLE, RUNNING, FINISHED
}

fun main() {
    val state = State.RUNNING
    val message = when (state) {
        State.IDLE -> "It's idle"
        State.RUNNING -> "It's running"
        State.FINISHED -> "It's finished"
    }
    println(message)
    // It's running
}
```

Enum classes can have properties and member functions just like normal classes.

For example, let's say you're working with HTML and you want to create an enum class containing some colors. You want each color to have a property, let's call it `rgb`, that contains their RGB value as a hexadecimal. When creating the enum constants, you must initialize it with this property:

```
enum class Color(val rgb: Int) {
    RED(0xFF0000),
    GREEN(0x00FF00),
    BLUE(0x0000FF),
    YELLOW(0xFFFF00)
}
```

Kotlin stores hexadecimals as integers, so the `rgb` property has the `Int` type, not the `String` type.

To add a member function to this class, separate it from the enum constants with a semicolon `;`:

```
enum class Color(val rgb: Int) {
    RED(0xFF0000),
    GREEN(0x00FF00),
    BLUE(0x0000FF),
    YELLOW(0xFFFF00);

    fun containsRed() = (this.rgb and 0xFF0000 != 0)
}

fun main() {
    val red = Color.RED

    // Calls containsRed() function on enum constant
    println(red.containsRed())
    // true

    // Calls containsRed() function on enum constants via class names
    println(Color.BLUE.containsRed())
    // false

    println(Color.YELLOW.containsRed())
    // true
}
```

In this example, the `containsRed()` member function accesses the value of the enum constant's `rgb` property using the `this` keyword and checks if the hexadecimal value contains `FF` as its first bits to return a boolean value.

For more information, see Enum classes.

Inline value classes

Sometimes in your code, you may want to create small objects from classes and use them only briefly. This approach can have a performance impact. Inline value classes are a special type of class that avoids this performance impact. However, they can only contain values.

To create an inline value class, use the `value` keyword and the `@JvmInline` annotation:

```
@JvmInline
value class Email
```

> The `@JvmInline` annotation instructs Kotlin to optimize the code when it is compiled. To learn more, see Annotations.

An inline value class **must** have a single property initialized in the class header.

Let's say that you want to create a class that collects an email address:

```
// The address property is initialized in the class header.
@JvmInline
value class Email(val address: String)

fun sendEmail(email: Email) {
    println("Sending email to ${email.address}")
}

fun main() {
    val myEmail = Email("example@example.com")
    sendEmail(myEmail)
    // Sending email to example@example.com
}
```

In the example:

- `Email` is an inline value class that has one property in the class header: `address`.
- The `sendEmail()` function accepts objects with type `Email` and prints a string to the standard output.
- The `main()` function:
  - Creates an instance of the `Email` class called `myEmail`.
  - Calls the `sendEmail()` function on the `myEmail` object.

By using an inline value class, you make the class inlined and can use it directly in your code without creating an object. This can significantly reduce memory footprint and improve your code's runtime performance.

For more information about inline value classes, see Inline value classes.

Practice

Exercise 1

You manage a delivery service and need a way to track the status of packages. Create a sealed class called `DeliveryStatus`, containing data classes to represent the following statuses: `Pending`, `InTransit`, `Delivered`, `Canceled`. Complete the `DeliveryStatus` class declaration so that the code in the `main()` function runs successfully:

```
sealed class // Write your code here

fun printDeliveryStatus(status: DeliveryStatus) {
    when (status) {
        is DeliveryStatus.Pending -> {
            println("The package is pending pickup from ${status.sender}.")
        }
        is DeliveryStatus.InTransit -> {
            println("The package is in transit and expected to arrive by
${status.estimatedDeliveryDate}.")
        }
        is DeliveryStatus.Delivered -> {
            println("The package was delivered to ${status.recipient} on ${status.deliveryDate}.")
        }
        is DeliveryStatus.Canceled -> {
            println("The delivery was canceled due to: ${status.reason}.")
        }
    }
}

fun main() {
    val status1: DeliveryStatus = DeliveryStatus.Pending("Alice")
    val status2: DeliveryStatus = DeliveryStatus.InTransit("2024-11-20")
    val status3: DeliveryStatus = DeliveryStatus.Delivered("2024-11-18", "Bob")
    val status4: DeliveryStatus = DeliveryStatus.Canceled("Address not found")

    printDeliveryStatus(status1)
    // The package is pending pickup from Alice.
    printDeliveryStatus(status2)
    // The package is in transit and expected to arrive by 2024-11-20.
    printDeliveryStatus(status3)
    // The package was delivered to Bob on 2024-11-18.
    printDeliveryStatus(status4)
    // The delivery was canceled due to: Address not found.
}
```

```
sealed class DeliveryStatus {
    data class Pending(val sender: String) : DeliveryStatus()
    data class InTransit(val estimatedDeliveryDate: String) : DeliveryStatus()
    data class Delivered(val deliveryDate: String, val recipient: String) : DeliveryStatus()
    data class Canceled(val reason: String) : DeliveryStatus()
}

fun printDeliveryStatus(status: DeliveryStatus) {
    when (status) {
        is DeliveryStatus.Pending -> {
            println("The package is pending pickup from ${status.sender}.")
        }
        is DeliveryStatus.InTransit -> {
            println("The package is in transit and expected to arrive by
${status.estimatedDeliveryDate}.")
        }
        is DeliveryStatus.Delivered -> {
            println("The package was delivered to ${status.recipient} on ${status.deliveryDate}.")
        }
        is DeliveryStatus.Canceled -> {
            println("The delivery was canceled due to: ${status.reason}.")
        }
    }
}

fun main() {
    val status1: DeliveryStatus = DeliveryStatus.Pending("Alice")
    val status2: DeliveryStatus = DeliveryStatus.InTransit("2024-11-20")
    val status3: DeliveryStatus = DeliveryStatus.Delivered("2024-11-18", "Bob")
    val status4: DeliveryStatus = DeliveryStatus.Canceled("Address not found")

    printDeliveryStatus(status1)
    // The package is pending pickup from Alice.
    printDeliveryStatus(status2)
    // The package is in transit and expected to arrive by 2024-11-20.
    printDeliveryStatus(status3)
    // The package was delivered to Bob on 2024-11-18.
    printDeliveryStatus(status4)
    // The delivery was canceled due to: Address not found.
}
```

Exercise 2

In your program, you want to be able to handle different statuses and types of errors. You have a sealed class to capture the different statuses which are declared in data classes or objects. Complete the code below by creating an enum class called `Problem` that represents the different problem types: `NETWORK`, `TIMEOUT`, and `UNKNOWN`.

```
sealed class Status {
    data object Loading : Status()
    data class Error(val problem: Problem) : Status() {
        // Write your code here
    }

    data class OK(val data: List<String>) : Status()
}

fun handleStatus(status: Status) {
    when (status) {
        is Status.Loading -> println("Loading...")
        is Status.OK -> println("Data received: ${status.data}")
        is Status.Error -> when (status.problem) {
            Status.Error.Problem.NETWORK -> println("Network issue")
            Status.Error.Problem.TIMEOUT -> println("Request timed out")
            Status.Error.Problem.UNKNOWN -> println("Unknown error occurred")
        }
    }
}

fun main() {
    val status1: Status = Status.Error(Status.Error.Problem.NETWORK)
    val status2: Status = Status.OK(listOf("Data1", "Data2"))

    handleStatus(status1)
    // Network issue
    handleStatus(status2)
    // Data received: [Data1, Data2]
}
```

```
sealed class Status {
    data object Loading : Status()
    data class Error(val problem: Problem) : Status() {
        enum class Problem {
            NETWORK,
            TIMEOUT,
            UNKNOWN
        }
    }

    data class OK(val data: List<String>) : Status()
}

fun handleStatus(status: Status) {
    when (status) {
        is Status.Loading -> println("Loading...")
        is Status.OK -> println("Data received: ${status.data}")
        is Status.Error -> when (status.problem) {
            Status.Error.Problem.NETWORK -> println("Network issue")
            Status.Error.Problem.TIMEOUT -> println("Request timed out")
            Status.Error.Problem.UNKNOWN -> println("Unknown error occurred")
        }
    }
}

fun main() {
    val status1: Status = Status.Error(Status.Error.Problem.NETWORK)
    val status2: Status = Status.OK(listOf("Data1", "Data2"))

    handleStatus(status1)
    // Network issue
    handleStatus(status2)
    // Data received: [Data1, Data2]
}
```

Previous step

Next step

Properties

In the beginner tour, you learned how properties are used to declare characteristics of class instances and how to access them. This chapter digs deeper into how properties work in Kotlin and explores other ways that you can use them in your code.

Backing fields

In Kotlin, properties have default `get()` and `set()` functions, known as property accessors, which handle retrieving and modifying their values. While these default functions are not explicitly visible in the code, the compiler automatically generates them to manage property access behind the scenes. These accessors use a **backing field** to store the actual property value.

Backing fields exist if either of the following is true:

- You use the default `get()` or `set()` functions for the property.
- You try to access the property value in code by using the `field` keyword.

`get()` and `set()` functions are also called getters and setters.

For example, this code has the `category` property that has no custom `get()` or `set()` functions and therefore uses the default implementations:

```
class Contact(val id: Int, var email: String) {
    var category: String = ""
}
```

Under the hood, this is equivalent to this pseudocode:

```
class Contact(val id: Int, var email: String) {
    var category: String = ""
        get() = field
        set(value) {
            field = value
        }
}
```

In this example:

- The `get()` function retrieves the property value from the field: `""`.
- The `set()` function accepts `value` as a parameter and assigns it to the field, where `value` is `""`.

Access to the backing field is useful when you want to add extra logic in your `get()` or `set()` functions without causing an infinite loop. For example, you have a `Person` class with a `name` property:

```
class Person {
    var name: String = ""
}
```

You want to ensure that the first letter of the `name` property is capitalized, so you create a custom `set()` function that uses the `.replaceFirstChar()` and `.uppercase()` extension functions. However, if you refer to the property directly in your `set()` function, you create an infinite loop and see a `StackOverflowError` at runtime:

```
class Person {
    var name: String = ""
        set(value) {
            // This causes a runtime error
            name = value.replaceFirstChar { firstChar -> firstChar.uppercase() }
        }
}

fun main() {
    val person = Person()
    person.name = "kodee"
    println(person.name)
    // Exception in thread "main" java.lang.StackOverflowError
}
```

To fix this, you can use the backing field in your `set()` function instead by referencing it with the `field` keyword:

```
class Person {
    var name: String = ""
        set(value) {
            field = value.replaceFirstChar { firstChar -> firstChar.uppercase() }
        }
}

fun main() {
    val person = Person()
    person.name = "kodee"
    println(person.name)
    // Kodee
}
```

Backing fields are also useful when you want to add logging, send notifications when a property value changes, or use additional logic that compares the old and new property values.

For more information, see Backing fields.

Extension properties

Just like extension functions, there are also extension properties. Extension properties allow you to add new properties to existing classes without modifying their source code. However, extension properties in Kotlin do **not** have backing fields. This means that you need to write the `get()` and `set()` functions yourself. Additionally, the lack of a backing field means that they can't hold any state.

To declare an extension property, write the name of the class that you want to extend followed by a `.` and the name of your property. Just like with normal class properties, you need to declare a type for your property. For example:

```
val String.lastChar: Char
```

Extension properties are most useful when you want a property to contain a computed value without using inheritance. You can think of extension properties working like a function with only one parameter: the receiver.

For example, let's say that you have a data class called `Person` with two properties: `firstName` and `lastName`.

```
data class Person(val firstName: String, val lastName: String)
```

You want to be able to access the person's full name without modifying the `Person` data class or inheriting from it. You can do this by creating an extension property with a custom `get()` function:

```
data class Person(val firstName: String, val lastName: String)

// Extension property to get the full name
val Person.fullName: String
    get() = "$firstName $lastName"

fun main() {
    val person = Person(firstName = "John", lastName = "Doe")

    // Use the extension property
    println(person.fullName)
    // John Doe
}
```

Extension properties can't override existing properties of a class.

Just like with extension functions, the Kotlin standard library uses extension properties widely. For example, see the `lastIndex` property for a `CharSequence`.

Delegated properties

You already learned about delegation in the Classes and interfaces chapter. You can also use delegation with properties to delegate their property accessors to another object. This is useful when you have more complex requirements for storing properties that a simple backing field can't handle, such as storing values in a database table, browser session, or map. Using delegated properties also reduces boilerplate code because the logic for getting and setting your properties is contained only in the object that you delegate to.

The syntax is similar to using delegation with classes but operates on a different level. Declare your property, followed by the `by` keyword and the object you want to delegate to. For example:

```
val displayName: String by Delegate
```

Here, the delegated property `displayName` refers to the `Delegate` object for its property accessors.

Every object you delegate to **must** have a `getValue()` operator function, which Kotlin uses to retrieve the value of the delegated property. If the property is mutable, it must also have a `setValue()` operator function for Kotlin to set its value.

By default, the `getValue()` and `setValue()` functions have the following construction:

```
operator fun getValue(thisRef: Any?, property: KProperty<*>): String {}

operator fun setValue(thisRef: Any?, property: KProperty<*>, value: String) {}
```

In these functions:

- The `operator` keyword marks these functions as operator functions, enabling them to overload the `get()` and `set()` functions.
- The `thisRef` parameter refers to the object **containing** the delegated property. By default, the type is set to `Any?`, but you may need to declare a more specific type.
- The `property` parameter refers to the property whose value is accessed or changed. You can use this parameter to access information like the property's name or type. By default, the type is set to `KProperty<*>` but you can also use `Any?`. You don't need to worry about changing this in your code.

The `getValue()` function has a return type of `String` by default, but you can adjust this if you want.

The `setValue()` function has an additional parameter `value`, which is used to hold the new value that's assigned to the property.

So, how does this look in practice? Suppose you want to have a computed property, like a user's display name, that is calculated only once because the operation is expensive and your application is performance-sensitive. You can use a delegated property to cache the display name so that it is only computed once but can be accessed anytime without performance impact.

First, you need to create the object to delegate to. In this case, the object will be an instance of the `CachedStringDelegate` class:

```
class CachedStringDelegate {
    var cachedValue: String? = null
}
```

The `cachedValue` property contains the cached value. Within the `CachedStringDelegate` class, add the behavior that you want from the `get()` function of the delegated property to the `getValue()` operator function body:

```
class CachedStringDelegate {
    var cachedValue: String? = null

    operator fun getValue(thisRef: Any?, property: Any?): String {
        if (cachedValue == null) {
            cachedValue = "Default Value"
            println("Computed and cached: $cachedValue")
        } else {
            println("Accessed from cache: $cachedValue")
        }
        return cachedValue ?: "Unknown"
    }
}
```

The `getValue()` function checks whether the `cachedValue` property is `null`. If it is, the function assigns the `"Default value"` and prints a string for logging purposes. If the `cachedValue` property has already been computed, the property isn't `null`. In this case, another string is printed for logging purposes. Finally, the function uses the Elvis operator to return the cached value or `"Unknown"` if the value is `null`.

Now you can delegate the property that you want to cache (`val displayName`) to an instance of the `CachedStringDelegate` class:

```
class CachedStringDelegate {
    var cachedValue: String? = null

    operator fun getValue(thisRef: User, property: Any?): String {
        if (cachedValue == null) {
            cachedValue = "${thisRef.firstName} ${thisRef.lastName}"
            println("Computed and cached: $cachedValue")
        } else {
            println("Accessed from cache: $cachedValue")
        }
        return cachedValue ?: "Unknown"
    }
}

class User(val firstName: String, val lastName: String) {
    val displayName: String by CachedStringDelegate()
}

fun main() {
    val user = User("John", "Doe")

    // First access computes and caches the value
    println(user.displayName)
    // Computed and cached: John Doe
    // John Doe

    // Subsequent accesses retrieve the value from cache
    println(user.displayName)
    // Accessed from cache: John Doe
    // John Doe
}
```

This example:

- Creates a `User` class that has two properties in the header, `firstName`, and `lastName`, and one property in the class body, `displayName`.
- Delegates the `displayName` property to an instance of the `CachedStringDelegate` class.
- Creates an instance of the `User` class called `user`.
- Prints the result of accessing the `displayName` property on the `user` instance.

Note that in the `getValue()` function, the type for the `thisRef` parameter is narrowed from `Any?` type to the object type: `User`. This is so that the compiler can access the `firstName` and `lastName` properties of the `User` class.

Standard delegates

The Kotlin standard library provides some useful delegates for you so you don't have to always create yours from scratch. If you use one of these delegates, you don't need to define `getValue()` and `setValue()` functions because the standard library automatically provides them.

Lazy properties

To initialize a property only when it's first accessed, use a lazy property. The standard library provides the `Lazy` interface for delegation.

To create an instance of the `Lazy` interface, use the `lazy()` function by providing it with a lambda expression to execute when the `get()` function is called for the first time. Any further calls of the `get()` function return the same result that was provided on the first call. Lazy properties use the trailing lambda syntax to pass the lambda expression.

For example:

```
class Database {
    fun connect() {
        println("Connecting to the database...")
    }

    fun query(sql: String): List<String> {
        return listOf("Data1", "Data2", "Data3")
    }
}

val databaseConnection: Database by lazy {
    val db = Database()
    db.connect()
    db
}

fun fetchData() {
    val data = databaseConnection.query("SELECT * FROM data")
    println("Data: $data")
}

fun main() {
    // First time accessing databaseConnection
    fetchData()
    // Connecting to the database...
    // Data: [Data1, Data2, Data3]

    // Subsequent access uses the existing connection
    fetchData()
    // Data: [Data1, Data2, Data3]
}
```

In this example:

- There is a `Database` class with `connect()` and `query()` member functions.
- The `connect()` function prints a string to the console, and the `query()` function accepts an SQL query and returns a list.
- There is a `databaseConnection` property that is a lazy property.
- The lambda expression provided to the `lazy()` function:
  - Creates an instance of the `Database` class.
  - Calls the `connect()` member function on this instance (`db`).
  - Returns the instance.
- There is a `fetchData()` function that:
  - Creates an SQL query by calling the `query()` function on the `databaseConnection` property.
  - Assigns the SQL query to the `data` variable.
  - Prints the `data` variable to the console.

- The `main()` function calls the `fetchData()` function. The first time it is called, the lazy property is initialized. The second time, the same result is returned as the first call.

Lazy properties are useful not only when initialization is resource-intensive but also when a property might not be used in your code. Additionally, lazy properties are thread-safe by default, which is particularly beneficial if you are working in a concurrent environment.

For more information, see Lazy properties.

Observable properties

To monitor whether the value of a property changes, use an observable property. An observable property is useful when you want to detect a change in the property value and use this knowledge to trigger a reaction. The standard library provides the `Delegates` object for delegation.

To create an observable property, you must first import `kotlin.properties.Delegates.observable`. Then, use the `observable()` function and provide it with a lambda expression to execute whenever the property changes. Just like with lazy properties, observable properties use the trailing lambda syntax to pass the lambda expression.

For example:

```
import kotlin.properties.Delegates.observable

class Thermostat {
    var temperature: Double by observable(20.0) { _, old, new →
        if (new > 25) {
            println("Warning: Temperature is too high! ($old°C → $new°C)")
        } else {
            println("Temperature updated: $old°C → $new°C")
        }
    }
}

fun main() {
    val thermostat = Thermostat()
    thermostat.temperature = 22.5
    // Temperature updated: 20.0°C → 22.5°C

    thermostat.temperature = 27.0
    // Warning: Temperature is too high! (22.5°C → 27.0°C)
}
```

In this example:

- There is a `Thermostat` class that contains an observable property: `temperature`.
- The `observable()` function accepts `20.0` as a parameter and uses it to initialize the property.
- The lambda expression provided to the `observable()` function:
  - Has three parameters:
    - `_`, which refers to the property itself.
    - `old`, which is the old value of the property.
    - `new`, which is the new value of the property.
  - Checks if the `new` parameter is greater than `25` and, depending on the result, prints a string to console.
- The `main()` function:

- Creates an instance of the `Thermostat` class called `thermostat`.
- Updates the value of the `temperature` property of the instance to `22.5`, which triggers a print statement with a temperature update.
- Updates the value of the `temperature` property of the instance to `27.0`, which triggers a print statement with a warning.

Observable properties are useful not only for logging and debugging purposes. You can also use them for use cases like updating a UI or to perform additional checks, like verifying the validity of data.

For more information, see Observable properties.

Practice

Exercise 1

You manage an inventory system at a bookstore. The inventory is stored in a list where each item represents the quantity of a specific book. For example, `listOf(3, 0, 7, 12)` means the store has 3 copies of the first book, 0 of the second, 7 of the third, and 12 of the fourth.

Write a function called `findOutOfStockBooks()` that returns a list of indices for all the books that are out of stock.

Hint 1

Use the `indices` extension property from the standard library.

Hint 2

You can use the `buildList()` function to create and manage a list instead of manually creating and returning a mutable list. The `buildList()` function uses a lambda with a receiver, which you learned about in earlier chapters.

```
fun findOutOfStockBooks(inventory: List<Int>): List<Int> {
    // Write your code here
}

fun main() {
    val inventory = listOf(3, 0, 7, 0, 5)
    println(findOutOfStockBooks(inventory))
    // [1, 3]
}
```

```
fun findOutOfStockBooks(inventory: List<Int>): List<Int> {
    val outOfStockIndices = mutableListOf<Int>()
    for (index in inventory.indices) {
        if (inventory[index] == 0) {
            outOfStockIndices.add(index)
        }
    }
    return outOfStockIndices
}

fun main() {
    val inventory = listOf(3, 0, 7, 0, 5)
    println(findOutOfStockBooks(inventory))
    // [1, 3]
}
```

```
fun findOutOfStockBooks(inventory: List<Int>): List<Int> = buildList {
    for (index in inventory.indices) {
        if (inventory[index] == 0) {
            add(index)
        }
    }
}

fun main() {
    val inventory = listOf(3, 0, 7, 0, 5)
    println(findOutOfStockBooks(inventory))
    // [1, 3]
}
```

Exercise 2

You have a travel app that needs to display distances in both kilometers and miles. Create an extension property for the `Double` type called `asMiles` to convert a distance in kilometers to miles:

> The formula to convert kilometers to miles is `miles = kilometers * 0.621371`.

Hint

Remember that extension properties need a custom `get()` function.

```
val // Write your code here

fun main() {
    val distanceKm = 5.0
    println("$distanceKm km is ${distanceKm.asMiles} miles")
    // 5.0 km is 3.106855 miles

    val marathonDistance = 42.195
    println("$marathonDistance km is ${marathonDistance.asMiles} miles")
    // 42.195 km is 26.218757 miles
}
```

```
val Double.asMiles: Double
    get() = this * 0.621371

fun main() {
    val distanceKm = 5.0
    println("$distanceKm km is ${distanceKm.asMiles} miles")
    // 5.0 km is 3.106855 miles

    val marathonDistance = 42.195
    println("$marathonDistance km is ${marathonDistance.asMiles} miles")
    // 42.195 km is 26.218757 miles
}
```

Exercise 3

You have a system health checker that can determine the state of a cloud system. However, the two functions it can run to perform a health check are performance intensive. Use lazy properties to initialize the checks so that the expensive functions are only run when needed:

```
fun checkAppServer(): Boolean {
    println("Performing application server health check...")
    return true
}

fun checkDatabase(): Boolean {
    println("Performing database health check...")
    return false
}

fun main() {
    // Write your code here

    when {
        isAppServerHealthy -> println("Application server is online and healthy")
        isDatabaseHealthy -> println("Database is healthy")
        else -> println("System is offline")
    }
    // Performing application server health check...
    // Application server is online and healthy
}
```

```
fun checkAppServer(): Boolean {
    println("Performing application server health check...")
    return true
}

fun checkDatabase(): Boolean {
    println("Performing database health check...")
    return false
}

fun main() {
    val isAppServerHealthy by lazy { checkAppServer() }
    val isDatabaseHealthy by lazy { checkDatabase() }

    when {
        isAppServerHealthy -> println("Application server is online and healthy")
        isDatabaseHealthy -> println("Database is healthy")
        else -> println("System is offline")
    }
   // Performing application server health check...
   // Application server is online and healthy
}
```

Exercise 4

You're building a simple budget tracker app. The app needs to observe changes to the user's remaining budget and notify them whenever it goes below a certain threshold. You have a `Budget` class that is initialized with a `totalBudget` property that contains the initial budget amount. Within the class, create an observable property called `remainingBudget` that prints:

- A warning when the value is lower than 20% of the initial budget.
- An encouraging message when the budget is increased from the previous value.

```
import kotlin.properties.Delegates.observable

class Budget(val totalBudget: Int) {
    var remainingBudget: Int // Write your code here
}

fun main() {
    val myBudget = Budget(totalBudget = 1000)
    myBudget.remainingBudget = 800
    myBudget.remainingBudget = 150
    // Warning: Your remaining budget (150) is below 20% of your total budget.
    myBudget.remainingBudget = 50
    // Warning: Your remaining budget (50) is below 20% of your total budget.
    myBudget.remainingBudget = 300
    // Good news: Your remaining budget increased to 300.
}
```

```
import kotlin.properties.Delegates.observable

class Budget(val totalBudget: Int) {
    var remainingBudget: Int by observable(totalBudget) { _, oldValue, newValue →
        if (newValue < totalBudget * 0.2) {
            println("Warning: Your remaining budget ($newValue) is below 20% of your total budget.")
        } else if (newValue > oldValue) {
            println("Good news: Your remaining budget increased to $newValue.")
        }
    }
}

fun main() {
    val myBudget = Budget(totalBudget = 1000)
    myBudget.remainingBudget = 800
    myBudget.remainingBudget = 150
    // Warning: Your remaining budget (150) is below 20% of your total budget.
    myBudget.remainingBudget = 50
    // Warning: Your remaining budget (50) is below 20% of your total budget.
    myBudget.remainingBudget = 300
    // Good news: Your remaining budget increased to 300.
}
```

Null safety

In the beginner tour, you learned how to handle `null` values in your code. This chapter covers common use cases for null safety features and how to make the most of them.

Smart casts and safe casts

Kotlin can sometimes infer the type without explicit declaration. When you tell Kotlin to treat a variable or object as if it belongs to a specific type, this process is called **casting**. When a type is automatically cast, like when it's inferred, it's called **smart casting**.

is and !is operators

Before we explore how casting works, let's see how you can check if an object has a certain type. For this, you can use the `is` and `!is` operators with `when` or `if` conditional expressions:

- `is` checks if the object has the type and returns a boolean value.
- `!is` checks if the object **doesn't** have the type and returns a boolean value.

For example:

```
fun printObjectType(obj: Any) {
    when (obj) {
        is Int -> println("It's an Integer with value $obj")
        !is Double -> println("It's NOT a Double")
        else -> println("Unknown type")
    }
}

fun main() {
    val myInt = 42
    val myDouble = 3.14
    val myList = listOf(1, 2, 3)

    // The type is Int
    printObjectType(myInt)
    // It's an Integer with value 42

    // The type is List, so it's NOT a Double.
    printObjectType(myList)
    // It's NOT a Double

    // The type is Double, so the else branch is triggered.
    printObjectType(myDouble)
    // Unknown type
}
```

You've already seen an example of how to use a `when` conditional expression with the `is` and `!is` operators in the Open and other special classes chapter.

as and as? operators

To explicitly *cast* an object to any other type, use the `as` operator. This includes casting from a nullable type to its non-nullable counterpart. If the cast isn't possible, the program crashes **at runtime**. This is why it's called the **unsafe** cast operator.

```
fun main() {
    val a: String? = null
    val b = a as String

    // Triggers an error at runtime
    print(b)
}
```

To explicitly cast an object to a non-nullable type, but return `null` instead of throwing an error on failure, use the `as?` operator. Since the `as?` operator doesn't trigger an error on failure, it is called the **safe** operator.

```
fun main() {
    val a: String? = null
    val b = a as? String

    // Returns null value
    print(b)
    // null
}
```

You can combine the `as?` operator with the Elvis operator `?:` to reduce several lines of code down to one. For example, the following `calculateTotalStringLength()` function calculates the total length of all strings provided in a mixed list:

```
fun calculateTotalStringLength(items: List<Any>): Int {
    var totalLength = 0

    for (item in items) {
        totalLength += if (item is String) {
            item.length
        } else {
            0  // Add 0 for non-String items
        }
    }

    return totalLength
}
```

The example:

- Uses the `totalLength` variable as a counter.
- Uses a `for` loop to loop through every item in the list.
- Uses an `if` and the `is` operator to check if the current item is a string:
  - If it is, the string's length is added to the counter.
  - If it is not, the counter isn't incremented.
- Returns the final value of the `totalLength` variable.

This code can be reduced to:

```
fun calculateTotalStringLength(items: List<Any>): Int {
    return items.sumOf { (it as? String)?.length ?: 0 }
}
```

The example uses the `.sumOf()` extension function and provides a lambda expression that:

- For each item in the list, performs a safe cast to `String` using `as?`.
- Uses a safe call `?.` to access the `length` property if the call doesn't return a `null` value.
- Uses the Elvis operator `?:` to return `0` if the safe call returns a `null` value.

Null values and collections

In Kotlin, working with collections often involves handling `null` values and filtering out unnecessary elements. Kotlin has useful functions that you can use to write clean, efficient, and null-safe code when working with lists, sets, maps, and other types of collections.

To filter `null` values from a list, use the `filterNotNull()` function:

```
fun main() {
    val emails: List<String?> = listOf("alice@example.com", null, "bob@example.com", null,
"carol@example.com")

    val validEmails = emails.filterNotNull()

    println(validEmails)
    // [alice@example.com, bob@example.com, carol@example.com]
}
```

If you want to perform filtering of `null` values directly when creating a list, use the `listOfNotNull()` function:

```
fun main() {
    val serverConfig = mapOf(
        "appConfig.json" to "App Configuration",
        "dbConfig.json" to "Database Configuration"
    )

    val requestedFile = "appConfig.json"
    val configFiles = listOfNotNull(serverConfig[requestedFile])

    println(configFiles)
    // [App Configuration]
}
```

In both of these examples, if all items are `null` values, an empty list is returned.

Kotlin also provides functions that you can use to find values in collections. If a value isn't found, they return `null` values instead of triggering an error:

- `maxOrNull()` finds the highest value. If one doesn't exist, returns a `null` value.
- `minOrNull()` finds the lowest value. If one doesn't exist, returns a `null` value.

For example:

```
fun main() {
    // Temperatures recorded over a week
    val temperatures = listOf(15, 18, 21, 21, 19, 17, 16)

    // Find the highest temperature of the week
    val maxTemperature = temperatures.maxOrNull()
    println("Highest temperature recorded: ${maxTemperature ?: "No data"}")
    // Highest temperature recorded: 21

    // Find the lowest temperature of the week
    val minTemperature = temperatures.minOrNull()
    println("Lowest temperature recorded: ${minTemperature ?: "No data"}")
    // Lowest temperature recorded: 15
}
```

This example uses the Elvis operator `?:` to return a printed statement if the functions return a `null` value.

The `maxOrNull()`, and `minOrNull()` functions are designed to be used with collections that **don't** contain `null` values. Otherwise, you can't tell whether the function couldn't find the desired value or whether it found a `null` value.

You can use the `singleOrNull()` function with a lambda expression to find a single item that matches a condition. If one doesn't exist or there are multiple items that match, the function returns a `null` value:

```
fun main() {
    // Temperatures recorded over a week
    val temperatures = listOf(15, 18, 21, 21, 19, 17, 16)

    // Check if there was exactly one day with 30 degrees
    val singleHotDay = temperatures.singleOrNull{ it == 30 }
    println("Single hot day with 30 degrees: ${singleHotDay ?: "None"}")
    // Single hot day with 30 degrees: None
}
```

The `singleOrNull()` function is designed to be used with collections that **don't** contain `null` values.

Some functions use a lambda expression to transform a collection and return `null` values if they can't fulfill their purpose.

To transform a collection with a lambda expression and return the first value that isn't `null`, use the `firstNotNullOfOrNull()` function. If no such value exists, the function returns a `null` value:

```
fun main() {
    data class User(val name: String?, val age: Int?)

    val users = listOf(
        User(null, 25),
        User("Alice", null),
        User("Bob", 30)
    )

    val firstNonNullName = users.firstNotNullOfOrNull { it.name }
    println(firstNonNullName)
    // Alice
}
```

To use a lambda expression to process each collection item sequentially and create an accumulated value (or return a `null` value if the collection is empty) use the `reduceOrNull()` function:

```
fun main() {
    // Prices of items in a shopping cart
    val itemPrices = listOf(20, 35, 15, 40, 10)

    // Calculate the total price using the reduceOrNull() function
    val totalPrice = itemPrices.reduceOrNull { runningTotal, price -> runningTotal + price }
    println("Total price of items in the cart: ${totalPrice ?: "No items"}")
    // Total price of items in the cart: 120

    val emptyCart = listOf<Int>()
    val emptyTotalPrice = emptyCart.reduceOrNull { runningTotal, price -> runningTotal + price }
    println("Total price of items in the empty cart: ${emptyTotalPrice ?: "No items"}")
    // Total price of items in the empty cart: No items
}
```

This example also uses the Elvis operator `?:` to return a printed statement if the function returns a `null` value.

The `reduceOrNull()` function is designed to be used with collections that **don't** contain `null` values.

Explore Kotlin's standard library to find more functions that you can use to make your code safer.

Early returns and the Elvis operator

In the beginner tour, you learned how to use early returns to stop your function from being processed further than a certain point. You can use the Elvis operator `?:` with an early return to check preconditions in a function. This approach is a great way to keep your code concise because you don't need to use nested checks. The reduced complexity of your code also makes it easier to maintain. For example:

```
data class User(
    val id: Int,
    val name: String,
    // List of friend user IDs
    val friends: List<Int>
)

// Function to get the number of friends for a user
fun getNumberOfFriends(users: Map<Int, User>, userId: Int): Int {
    // Retrieves the user or return -1 if not found
    val user = users[userId] ?: return -1
    // Returns the number of friends
    return user.friends.size
}

fun main() {
    // Creates some sample users
    val user1 = User(1, "Alice", listOf(2, 3))
    val user2 = User(2, "Bob", listOf(1))
    val user3 = User(3, "Charlie", listOf(1))

    // Creates a map of users
    val users = mapOf(1 to user1, 2 to user2, 3 to user3)

    println(getNumberOfFriends(users, 1))
    // 2
    println(getNumberOfFriends(users, 2))
    // 1
    println(getNumberOfFriends(users, 4))
    // -1
}
```

In this example:

- There is a `User` data class that has properties for the user's `id`, `name` and list of friends.
- The `getNumberOfFriends()` function:
  - Accepts a map of `User` instances and a user ID as an integer.
  - Accesses the value of the map of `User` instances with the provided user ID.
  - Uses an Elvis operator to return the function early with the value of `-1` if the map value is a `null` value.
  - Assigns the value found from the map to the `user` variable.
  - Returns the number of friends in the user's friends list by using the `size` property.
- The `main()` function:
  - Creates three `User` instances.

- Creates a map of these `User` instances and assigns them to the `users` variable.
- Calls the `getNumberOfFriends()` function on the `users` variable with values `1` and `2` that returns two friends for `"Alice"` and one friend for `"Bob"`.
- Calls the `getNumberOfFriends()` function on the `users` variable with value `4`, which triggers an early return with a value of `-1`.

You may notice that the code could be more concise without an early return. However, this approach needs multiple safe calls because the `users[userId]` might return a `null` value, making the code slightly harder to read:

```
fun getNumberOfFriends(users: Map<Int, User>, userId: Int): Int {
    // Retrieve the user or return -1 if not found
    return users[userId]?.friends?.size ?: -1
}
```

Although this example checks only one condition with the Elvis operator, you can add multiple checks to cover any critical error paths. Early returns with the Elvis operator prevent your program from doing unnecessary work and make your code safer by stopping as soon as a `null` value or invalid case is detected.

For more information about how you can use `return` in your code, see Returns and jumps.

Practice

Exercise 1

You are developing a notification system for an app where users can enable or disable different types of notifications. Complete the `getNotificationPreferences()` function so that:

1. The `validUser` variable uses the `as?` operator to check if `user` is an instance of the `User` class. If it isn't, return an empty list.
2. The `userName` variable uses the Elvis `?:` operator to ensure that the user's name defaults to `"Guest"` if it is `null`.
3. The final return statement uses the `.takeIf()` function to include email and SMS notification preferences only if they are enabled.
4. The `main()` function runs successfully and prints the expected output.

The `takeIf()` function returns the original value if the given condition is true, otherwise it returns `null`. For example:

```
fun main() {
    // The user is logged in
    val userIsLoggedIn = true
    // The user has an active session
    val hasSession = true

    // Gives access to the dashboard if the user is logged in
    // and has an active session
    val canAccessDashboard = userIsLoggedIn.takeIf { hasSession }

    println(canAccessDashboard ?: "Access denied")
    // true
}
```

```
data class User(val name: String?)

fun getNotificationPreferences(user: Any, emailEnabled: Boolean, smsEnabled: Boolean): List<String> {
    val validUser = // Write your code here
    val userName = // Write your code here

    return listOfNotNull( /* Write your code here */)
}

fun main() {
    val user1 = User("Alice")
    val user2 = User(null)
    val invalidUser = "NotAUser"

    println(getNotificationPreferences(user1, emailEnabled = true, smsEnabled = false))
    // [Email Notifications enabled for Alice]
    println(getNotificationPreferences(user2, emailEnabled = false, smsEnabled = true))
    // [SMS Notifications enabled for Guest]
    println(getNotificationPreferences(invalidUser, emailEnabled = true, smsEnabled = true))
    // []
}
```

```
data class User(val name: String?)

fun getNotificationPreferences(user: Any, emailEnabled: Boolean, smsEnabled: Boolean): List<String> {
    val validUser = user as? User ?: return emptyList()
    val userName = validUser.name ?: "Guest"

    return listOfNotNull(
        "Email Notifications enabled for $userName".takeIf { emailEnabled },
        "SMS Notifications enabled for $userName".takeIf { smsEnabled }
    )
}

fun main() {
    val user1 = User("Alice")
    val user2 = User(null)
    val invalidUser = "NotAUser"

    println(getNotificationPreferences(user1, emailEnabled = true, smsEnabled = false))
    // [Email Notifications enabled for Alice]
    println(getNotificationPreferences(user2, emailEnabled = false, smsEnabled = true))
    // [SMS Notifications enabled for Guest]
    println(getNotificationPreferences(invalidUser, emailEnabled = true, smsEnabled = true))
    // []
}
```

Exercise 2

You are working on a subscription-based streaming service where users can have multiple subscriptions, but **only one can be active at a time**. Complete the `getActiveSubscription()` function so that it uses the `singleOrNull()` function with a predicate to return a `null` value if there is more than one active subscription:

```
data class Subscription(val name: String, val isActive: Boolean)

fun getActiveSubscription(subscriptions: List<Subscription>): Subscription? // Write your code here

fun main() {
    val userWithPremiumPlan = listOf(
        Subscription("Basic Plan", false),
        Subscription("Premium Plan", true)
    )

    val userWithConflictingPlans = listOf(
        Subscription("Basic Plan", true),
        Subscription("Premium Plan", true)
    )

    println(getActiveSubscription(userWithPremiumPlan))
    // Subscription(name=Premium Plan, isActive=true)

    println(getActiveSubscription(userWithConflictingPlans))
    // null
}
```

```
data class Subscription(val name: String, val isActive: Boolean)

fun getActiveSubscription(subscriptions: List<Subscription>): Subscription? {
    return subscriptions.singleOrNull { subscription -> subscription.isActive }
}

fun main() {
    val userWithPremiumPlan = listOf(
        Subscription("Basic Plan", false),
        Subscription("Premium Plan", true)
    )

    val userWithConflictingPlans = listOf(
        Subscription("Basic Plan", true),
        Subscription("Premium Plan", true)
    )

    println(getActiveSubscription(userWithPremiumPlan))
    // Subscription(name=Premium Plan, isActive=true)

    println(getActiveSubscription(userWithConflictingPlans))
    // null
}
```

```
data class Subscription(val name: String, val isActive: Boolean)

fun getActiveSubscription(subscriptions: List<Subscription>): Subscription? =
    subscriptions.singleOrNull { it.isActive }

fun main() {
    val userWithPremiumPlan = listOf(
        Subscription("Basic Plan", false),
        Subscription("Premium Plan", true)
    )

    val userWithConflictingPlans = listOf(
        Subscription("Basic Plan", true),
        Subscription("Premium Plan", true)
    )

    println(getActiveSubscription(userWithPremiumPlan))
    // Subscription(name=Premium Plan, isActive=true)

    println(getActiveSubscription(userWithConflictingPlans))
    // null
}
```

Exercise 3

You are working on a social media platform where users have usernames and account statuses. You want to see the list of currently active usernames. Complete the `getActiveUsernames()` function so that the `mapNotNull()` function has a predicate that returns the username if it is active or a `null` value if it isn't:

```
data class User(val username: String, val isActive: Boolean)

fun getActiveUsernames(users: List<User>): List<String> {
    return users.mapNotNull { /* Write your code here */ }
}

fun main() {
    val allUsers = listOf(
        User("alice123", true),
        User("bob_the_builder", false),
        User("charlie99", true)
    )

    println(getActiveUsernames(allUsers))
    // [alice123, charlie99]
}
```

Just like in Exercise 1, you can use the `takeIf()` function when you check if the user is active.

```
data class User(val username: String, val isActive: Boolean)

fun getActiveUsernames(users: List<User>): List<String> {
    return users.mapNotNull { user ->
        if (user.isActive) user.username else null
    }
}

fun main() {
    val allUsers = listOf(
        User("alice123", true),
        User("bob_the_builder", false),
        User("charlie99", true)
    )

    println(getActiveUsernames(allUsers))
    // [alice123, charlie99]
}
```

```
data class User(val username: String, val isActive: Boolean)

fun getActiveUsernames(users: List<User>): List<String> =
    users.mapNotNull { user -> user.username.takeIf { user.isActive } }

fun main() {
    val allUsers = listOf(
        User("alice123", true),
        User("bob_the_builder", false),
        User("charlie99", true)
    )

    println(getActiveUsernames(allUsers))
    // [alice123, charlie99]
}
```

Exercise 4

You are working on an inventory management system for an e-commerce platform. Before processing a sale, you need to check if the requested quantity of a product is valid based on the available stock.

Complete the `validateStock()` function so that it uses early returns and the Elvis operator (where applicable) to check if:

- The `requested` variable is `null`.
- The `available` variable is `null`.
- The `requested` variable is a negative value.
- The amount in the `requested` variable is higher than in the `available` variable.

In all of the above cases, the function must return early with the value of `-1`.

```
fun validateStock(requested: Int?, available: Int?): Int {
    // Write your code here
}

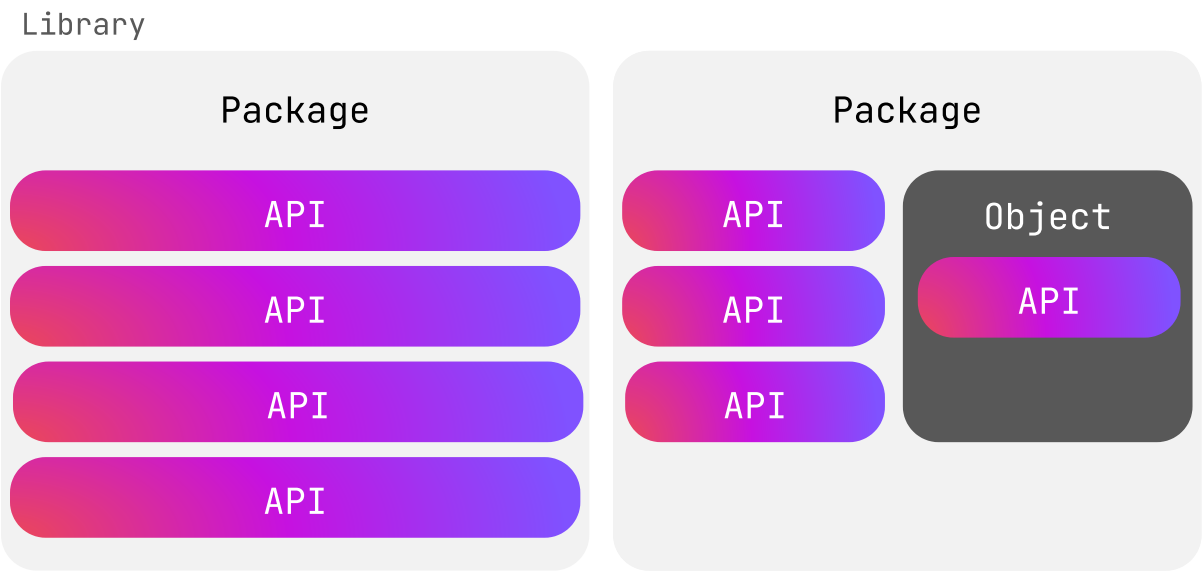
fun main() {
    println(validateStock(5,10))
    // 5
    println(validateStock(null,10))
    // -1
    println(validateStock(-2,10))
    // -1
}
```

```
fun validateStock(requested: Int?, available: Int?): Int {
    val validRequested = requested ?: return -1
    val validAvailable = available ?: return -1

    if (validRequested < 0) return -1
    if (validRequested > validAvailable) return -1

    return validRequested
}

fun main() {
    println(validateStock(5,10))
    // 5
    println(validateStock(null,10))
    // -1
    println(validateStock(-2,10))
    // -1
}
```



Previous step

Next step

Libraries and APIs

To get the most out of Kotlin, use existing libraries and APIs so you can spend more time coding and less time reinventing the wheel.

Libraries distribute reusable code that simplifies common tasks. Within libraries, there are packages and objects that group related classes, functions, and utilities. Libraries expose APIs (Application Programming Interfaces) as a set of functions, classes, or properties that developers can use in their code.

Kotlin libraries and APIs

Let's explore what's possible with Kotlin.

The standard library

Kotlin has a standard library that provides essential types, functions, collections, and utilities to make your code concise and expressive. A large portion of the standard library (everything in the `kotlin` package) is readily available in any Kotlin file without the need to import it explicitly:

```
fun main() {
    val text = "emosewa si niltoK"

   // Use the reversed() function from the standard library
    val reversedText = text.reversed()

    // Use the print() function from the standard library
    print(reversedText)
    // Kotlin is awesome
}
```

However, some parts of the standard library require an import before you can use them in your code. For example, if you want to use the standard library's time measurement features, you need to import the `kotlin.time` package.

At the top of your file, add the `import` keyword followed by the package that you need:

```
import kotlin.time.*
```

The asterisk `*` is a wildcard import that tells Kotlin to import everything within the package. You can't use the asterisk `*` with companion objects. Instead, you need to explicitly declare the members of a companion object that you want to use.

For example:

```
import kotlin.time.Duration
import kotlin.time.Duration.Companion.hours
import kotlin.time.Duration.Companion.minutes

fun main() {
    val thirtyMinutes: Duration = 30.minutes
    val halfHour: Duration = 0.5.hours
    println(thirtyMinutes == halfHour)
    // true
}
```

This example:

- Imports the `Duration` class and the `hours` and `minutes` extension properties from its companion object.
- Uses the `minutes` property to convert `30` into a `Duration` of 30 minutes.
- Uses the `hours` property to convert `0.5` into a `Duration` of 30 minutes.
- Checks if both durations are equal and prints the result.

Search before you build

Before you decide to write your own code, check the standard library to see if what you're looking for already exists. Here's a list of areas where the standard library already provides a number of classes, functions, and properties for you:

- Collections
- Sequences
- String manipulation
- Time management

To learn more about what else is in the standard library, explore its API reference.

Kotlin libraries

The standard library covers many common use cases, but there are some that it doesn't address. Fortunately, the Kotlin team and the rest of the community have developed a wide range of libraries to complement the standard library. For example, `kotlinx-datetime` helps you manage time across different platforms.

You can find useful libraries on our search platform. To use them, you need to take extra steps, like adding a dependency or plugin. Each library has a GitHub repository with instructions on how to include it in your Kotlin projects.

Once you add the library, you can import any package within it. Here's an example of how to import the `kotlinx-datetime` package to find the current time in New York:

```
import kotlinx.datetime.*

fun main() {
    val now = Clock.System.now() // Get current instant
    println("Current instant: $now")

    val zone = TimeZone.of("America/New_York")
    val localDateTime = now.toLocalDateTime(zone)
    println("Local date-time in NY: $localDateTime")
}
```

This example:

- Imports the `kotlinx.datetime` package.
- Uses the `Clock.System.now()` function to create an instance of the `Instant` class that contains the current time and assigns the result to the `now` variable.
- Prints the current time.
- Uses the `TimeZone.of()` function to find the time zone for New York and assigns the result to the `zone` variable.
- Calls the `.toLocalDateTime()` function on the instance containing the current time, with the New York time zone as an argument.
- Assigns the result to the `localDateTime` variable.
- Prints the time adjusted for the time zone in New York.

To explore the functions and classes that this example uses in more detail, see the API reference.

Opt in to APIs

Library authors may mark certain APIs as requiring opt-in before you can use them in your code. They usually do this when an API is still in development and may change in the future. If you don't opt in, you see warnings or errors like this:

```
This declaration needs opt-in. Its usage should be marked with '@...' or '@OptIn(...)'
```

To opt in, write `@OptIn` followed by parentheses containing the class name that categorizes the API, appended by two colons `::` and `class`.

For example, the `uintArrayOf()` function from the standard library falls under `@ExperimentalUnsignedTypes`, as shown in the API reference:

```
@ExperimentalUnsignedTypes
inline fun uintArrayOf(vararg elements: UInt): UIntArray
```

In your code, the opt-in looks like:

```
@OptIn(ExperimentalUnsignedTypes::class)
```

Here's an example that opts in to use the `uintArrayOf()` function to create an array of unsigned integers and modifies one of its elements:

```
@OptIn(ExperimentalUnsignedTypes::class)
fun main() {
    // Create an unsigned integer array
    val unsignedArray: UIntArray = uintArrayOf(1u, 2u, 3u, 4u, 5u)

    // Modify an element
    unsignedArray[2] = 42u
    println("Updated array: ${unsignedArray.joinToString()}")
    // Updated array: 1, 2, 42, 4, 5
}
```

This is the easiest way to opt in, but there are other ways. To learn more, see Opt-in requirements.

Practice

Exercise 1

You are developing a financial application that helps users calculate the future value of their investments. The formula to calculate compound interest is:

$$A = P \times (1 + \frac{r}{n})^{nt}$$

Where:

- `A` is the amount of money accumulated after interest (principal + interest).
- `P` is the principal amount (the initial investment).
- `r` is the annual interest rate (decimal).
- `n` is the number of times interest is compounded per year.
- `t` is the time the money is invested for (in years).

Update the code to:

1. Import the necessary functions from the `kotlin.math` package.
2. Add a body to the `calculateCompoundInterest()` function that calculates the final amount after applying compound interest.

```
// Write your code here

fun calculateCompoundInterest(P: Double, r: Double, n: Int, t: Int): Double {
    // Write your code here
}

fun main() {
    val principal = 1000.0
    val rate = 0.05
    val timesCompounded = 4
    val years = 5
    val amount = calculateCompoundInterest(principal, rate, timesCompounded, years)
    println("The accumulated amount is: $amount")
    // The accumulated amount is: 1282.0372317085844
}
```

```kotlin
import kotlin.math.*

fun calculateCompoundInterest(P: Double, r: Double, n: Int, t: Int): Double {
    return P * (1 + r / n).pow(n * t)
}

fun main() {
    val principal = 1000.0
    val rate = 0.05
    val timesCompounded = 4
    val years = 5
    val amount = calculateCompoundInterest(principal, rate, timesCompounded, years)
    println("The accumulated amount is: $amount")
    // The accumulated amount is: 1282.0372317085844
}
```

Exercise 2

You want to measure the time it takes to perform multiple data processing tasks in your program. Update the code to add the correct import statements and functions from the `kotlin.time` package:

```kotlin
// Write your code here

fun main() {
    val timeTaken = /* Write your code here */ {
        // Simulate some data processing
        val data = List(1000) { it * 2 }
        val filteredData = data.filter { it % 3 == 0 }

        // Simulate processing the filtered data
        val processedData = filteredData.map { it / 2 }
        println("Processed data")
    }

    println("Time taken: $timeTaken") // e.g. 16 ms
}
```

```kotlin
import kotlin.time.measureTime

fun main() {
    val timeTaken = measureTime {
        // Simulate some data processing
        val data = List(1000) { it * 2 }
        val filteredData = data.filter { it % 3 == 0 }

        // Simulate processing the filtered data
        val processedData = filteredData.map { it / 2 }
        println("Processed data")
    }

    println("Time taken: $timeTaken") // e.g. 16 ms
}
```

Exercise 3

There's a new feature in the standard library available in the latest Kotlin release. You want to try it out, but it requires opt-in. The feature falls under `@ExperimentalStdlibApi`. What should the opt-in look like in your code?

```
@OptIn(ExperimentalStdlibApi::class)
```

What's next?

Congratulations! You've completed the intermediate tour! Would you like to share your feedback about your experience?

As a next step, check out our tutorials for popular Kotlin applications:

What's new in Kotlin 2.4.20

Released: September 7, 2026

Kotlin 2.4.20 is out! Here are the release highlights:

- **Standard library:** Support for coroutine stack trace recovery, new functions for checking the equality and uniqueness of collection elements, and new overloads for `kotlin.test` assertion functions
- **Kotlin/Native:** New Swift export features, improved incremental compilation, and automatically generated `Package.swift` files for SwiftPM dependencies
- **Kotlin/Wasm:** Changes to top-level `require()` calls in `@JsFun` declarations, improved initialization order of companion objects, support for Wasmtime in the Kotlin Gradle plugin, new compilation modes, and reduced binary size for functional interfaces
- **Kotlin/JS:** A new DSL for browser testing, support for exporting suspending lambdas as async functions, improved exportability of data classes
- **Gradle:** Support for Gradle 9.7.0 and improved reporting in the Problems API
- **Build tools API:** Support for new targets: Kotlin/JS, Kotlin/Wasm, and Kotlin metadata
- **Kotlin compiler:** `kotlinr` runner command and a separate native image

For information about the Kotlin release cycle, see Kotlin release process.

Update to Kotlin 2.4.20

The latest version of Kotlin is included in the latest versions of IntelliJ IDEA and Android Studio.

To update to the new Kotlin version, make sure your IDE is updated to the latest version and change the Kotlin version to 2.4.20 in your build scripts.

Stable

New features

Kotlin 2.2.20 introduced experimental support for compiling `when` expressions with `invokedynamic` on JVM 21 and later.

In Kotlin 2.4.20, the feature has now graduated to Stable and is enabled by default.

For more information, see the documentation.

New features

The following pre-stable features are available in this release, including those with Beta, Alpha, and Experimental status:

- Standard library: Support for coroutine stack trace recovery
- Standard library: New functions to check collection elements for equality and uniqueness
- Standard library: New overloads for `kotlin.test` assertion functions
- Kotlin/Native: New Swift export features
- Kotlin/Native: Improved incremental compilation of `klib` artifacts
- Kotlin/JS: A new DSL for browser testing
- Kotlin/JS: Support for exporting suspending lambdas as async functions
- Build tools API: Support for Kotlin/JS, Kotlin/Wasm, and Kotlin metadata
- Kotlin compiler: Separate native image

Standard library

Kotlin 2.4.20 adds support for coroutine stack trace recovery and introduces new functions to check collection elements for equality and uniqueness, as well as new overloads for `kotlin.test` assertion functions.

Experimental

Support for coroutine stack trace recovery

Kotlin 2.4.20 adds the `StackTraceRecoverable` interface to the standard library. This improves integration with the `kotlinx.coroutines` library because it lets you define how to create new exception instances for stack trace recovery without adding a dependency on `kotlinx.coroutines`.

Stack trace recovery helps with debugging when one coroutine throws an exception and another rethrows it. It lets you see where the exception originates and where another coroutine rethrows it.

The `kotlinx.coroutines` library performs stack trace recovery by creating a new exception instance with additional coroutine stack trace information. This happens automatically for exceptions with constructors that take only an exception message, a cause, both, or no arguments.

If an exception constructor has additional required arguments, such as a line number or an error code, implement the `StackTraceRecoverable` interface to define how the `kotlinx.coroutines` library creates a new instance of that exception.

To implement the interface, override the `copyForStackTraceRecovery()` function. In the override, return a new exception instance for stack trace recovery, or `null` if you don't want the `kotlinx.coroutines` library to copy the exception.

> The `StackTraceRecoverable` interface is available on all targets, but the `kotlinx.coroutines` library uses it for stack trace recovery only on the JVM.

These APIs are Experimental and require opt-in with the `@OptIn(ExperimentalStdlibCoroutineSupportApi::class)` annotation.

Here's an example of a custom exception that preserves a `line` property when it creates a new instance for stack trace recovery:

```
import kotlin.coroutines.ExperimentalStdlibCoroutineSupportApi
import kotlin.coroutines.debug.StackTraceRecoverable

@OptIn(ExperimentalStdlibCoroutineSupportApi::class)
class FileEditException
// The implementation requires a private constructor
// to pass the cause to the IllegalStateException constructor
private constructor(
    val line: Int,
    private val detail: String,
    cause: Throwable?,
) : IllegalStateException("When editing line $line: $detail", cause),
    // Implements StackTraceRecoverable for stack trace recovery
    StackTraceRecoverable<FileEditException> {

    constructor(line: Int, detail: String) : this(line, detail, null)

    // Copies the line number and message details
    override fun copyForStackTraceRecovery(): FileEditException =
        FileEditException(line, detail, this)
    }

fun main() {
    val original = FileEditException(15, "Unexpected token")

    // Normally, you don't need to call this function directly unless you're testing its behavior
    // The kotlinx.coroutines library invokes it automatically during stack trace recovery
    val copy = original.copyForStackTraceRecovery()

    println(copy.message)
    // When editing line 15: Unexpected token

    println(copy.cause == original)
    // true
}
```

For more information, see the feature's KEEP.

We would appreciate your feedback in YouTrack.

Experimental

New functions to check collection elements for equality and uniqueness

Before Kotlin 2.4.20, if you wanted to check whether collection elements were all distinct or all equal, you had to use inefficient code patterns.

Kotlin 2.4.20 introduces experimental functions to fill this gap:

Function	Checks
`allDistinct()`	Every value in the collection is unique.
`allDistinctBy()`	Every object has a unique value for the selected property.
`allEqual()`	Every value in the collection is the same.
`allEqualBy()`	Every object has the same value for the selected property.

You can use these functions on collections, sequences, and arrays. They compare elements using structural equality just like other collection operations.

These functions are Experimental and require opt-in with the `@OptIn(ExperimentalStdlibApi::class)` annotation or the `-opt-in=kotlin.ExperimentalStdlibApi` compiler option:

```
@OptIn(ExperimentalStdlibApi::class)
fun main() {
    data class Response(
        val participantId: String,
        val answer: String,
        val responseDate: String
    )

    val responses = listOf(
        Response("P001", "Yes", "2026-07-21"),
        Response("P002", "Maybe", "2026-07-21"),
        Response("P003", "No", "2026-07-21")
    )

    // Checks if all participants gave the same answer
    println(responses.allEqualBy { it.answer })
    // false

    // Checks for duplicate participants
    println(responses.allDistinctBy { it.participantId })
    // true

    // Checks if all responses were submitted on the same date
    println(responses.allEqualBy { it.responseDate })
    // true

    val answers = responses.map { it.answer }

    // Checks if answers are identical
    println(answers.allEqual())
    // false

    // Checks if answers are distinct
    println(answers.allDistinct())
    // true
}
```

We would appreciate your feedback in the KEEP.

Experimental

New overloads for `kotlin.test` assertion functions

Kotlin 2.4.20 adds new overloads for `kotlin.test` assertion functions. They accept a lambda that generates error messages lazily, only when the assertion fails.

Previously, `kotlin.test` assertion functions like `assertTrue()` or `assertEquals()` accepted only pre-formatted error messages built on every assertion, even when the assertion succeeded, and the message was never actually used.

The new overloads align the `kotlin.test` API with JUnit 5 and accept a message supplier through a lambda, instead of a plain string. This improves performance, especially for the Power-assert compiler plugin, which generates detailed error messages for assertions.

The new overloads are available for the following assertion functions:

Function	Description
`assertTrue()` / `assertFalse()`	Checks whether the value is `true` or `false`.
`assertEquals()` / `assertNotEquals()`	Checks whether the values are equal or not.
`assertSame()` / `assertNotSame()`	Checks whether the values refer to the same instance.
`assertIs()` / `assertIsNot()`	Checks whether the value is of the specified type. For `assertIs()`, the function smart-casts it to that type.
`assertNull()`	Checks whether the value is `null`.
`assertContains()`	Checks whether the element (key, character, substring, or regex) is present in the collection, array, sequence, range, or map.
`assertContentEquals()`	Checks whether the collections, sequences, or arrays contain equal elements in the same order.

To use the new API, explicitly opt in with the `@OptIn(ExperimentalKotlinTestApi::class)` annotation:

```
import kotlin.test.ExperimentalKotlinTestApi
import kotlin.test.assertEquals
import kotlin.test.assertTrue

@OptIn(ExperimentalKotlinTestApi::class)
fun testValues(actual: Int, expected: Int, items: List<String>) {
    // The message is built only if the assertion fails
    assertTrue(actual > 0) { "Expected a positive value but got $actual" }

    // Avoids formatting the list unless the assertion fails
    assertEquals(expected, actual) { "Unexpected value for items: ${items.joinToString()}" }
}
```

For more information, see the feature's KEEP.

Kotlin/Native

Kotlin 2.4.20 brings automatic generation of `Package.swift` files for SwiftPM dependencies in Kotlin Multiplatform projects, new Swift export features, including support for sealed classes and cross-language inheritance, and improved incremental compilation.

Generated `Package.swift` for SwiftPM dependencies

When exporting an XCFramework that depends on SwiftPM packages, you must publish the resulting SwiftPM package for it to resolve correctly. To help with this, the `assembleSharedXCFramework` Gradle task now generates a `Package.swift` file to be distributed along with the XCFramework.

For details, see the SwiftPM export page.

New Swift export features

Sealed classes

Kotlin 2.4.20 adds support for sealed classes and interfaces to Swift export.

Previously, you had to write a `default` case for every `switch` statement over a sealed type. Now, sealed hierarchies defined in Kotlin are mapped to Swift enums, enabling exhaustive `switch` statements with full autocompletion in Xcode.

Swift export generates a `sealedType()` method on each sealed type. This method returns a Swift enum whose cases match the direct subclasses of the sealed hierarchy. You can nest these calls to match deeper levels of the hierarchy.

For example, declare a sealed interface with a class hierarchy in Kotlin:

```
// Kotlin
sealed interface Shape

class Circle : Shape {
    override fun toString(): String = "Circle"
}

class Rectangle : Shape {
    override fun toString(): String = "Rectangle"
}

fun createCircle(): Shape = Circle()
```

On the Swift side, you can use an exhaustive `switch` without a `default` case:

```
// Swift
let shape = createCircle()

let name = switch shape.sealedType() {
    case let .circle(type): "It's a \(type.value)"
    case let .rectangle(type): "It's a \(type.value)"
}
// name == "It's a Circle"
```

Because the `switch` is exhaustive, the compiler warns you if a new subclass is added to the sealed hierarchy, so you can handle it immediately instead of relying on a `default` case.

Cross-language inheritance in Swift export

Kotlin 2.4.20 introduces cross-language inheritance support in Swift export.

A common use case for this feature is the reverse import pattern, where you define a contract in Kotlin and provide platform-specific implementations on the Swift side. This is especially useful when you need to use pure Swift libraries that can't be directly imported into Kotlin.

To implement the pattern, declare a Kotlin superclass for the Swift implementation to inherit from and a Kotlin interface. Then implement this interface in Swift and pass the Swift object to Kotlin functions that accept that interface. For example, for the CryptoKit library:

1. On the Kotlin side, declare an interface, a function that accepts it, and an `open` base class:

```
// Kotlin
interface CryptoProvider {
    fun hashMD5(input: String): String
}

fun processHash(provider: CryptoProvider, input: String): String = provider.hashMD5(input)

open class SwiftBase
```

2. On the Swift side, inherit from the exported `SwiftBase` class, implement the interface using a pure Swift library, and pass the object back to Kotlin:

```
// Swift
import CryptoKit

final class IosCryptoProvider: SwiftBase, CryptoProvider {
    func hashMD5(input: String) -> String {
        guard let data = input.data(using: .utf8) else { return "failed" }
        return Insecure.MD5.hash(data: data).description
    }
}

let provider = IosCryptoProvider()

// Calls the Kotlin function, which calls hashMD5() back in Swift
print(processHash(provider: provider, input: "Hello, world!"))
```

When Kotlin receives a Swift object, it treats it like an implementation of a regular interface, calling the Swift code directly.

For more details on Swift export, see our documentation.

Beta

Improved incremental compilation of `klib` artifacts

Kotlin 2.4.20 brings stabilization improvements to incremental compilation of `klib` artifacts, which is now in Beta.

This optimization was first introduced in Kotlin 1.9.20 and proved to drastically reduce compilation time for debug builds. Since then, we've fixed a number of bugs and improved performance.

To try out incremental compilation, add the following option to your `gradle.properties` file:

```
kotlin.incremental.native=true
```

We're actively collecting feedback and planning to enable incremental compilation by default for all projects in the next Kotlin releases. If you encounter any issues, please report them to our issue tracker.

Kotlin/Wasm

Kotlin 2.4.20 changes how Kotlin/Wasm handles top-level `require()` calls in `@JsFun` declarations, aligns companion object initialization order with JVM behavior, reduces binary size for functional interfaces, introduces new compilation modes, and adds support for Wasmtime as a runtime for the `wasmWasi` target in the Kotlin Gradle plugin.

Changes to top-level `require()` calls in `@JsFun` declarations

Kotlin/Wasm now reports an error when a `@JsFun` declaration uses the top-level `require()` function.

Previously, the compiler generated a `require` variable in the `import-object.mjs` file, allowing `@JsFun` declarations to call `require()`.

This behavior unintentionally exposed a compiler implementation detail. To support migration away from it, Kotlin/Wasm removes this generated `require` declaration, and the compiler now reports errors for such calls. For example:

```
// Reports an error
@JsFun("(mod) => require(mod)")
external fun loadModule(mod: String): JsAny
```

To prepare for this change, replace top-level `require()` calls in `@JsFun` declarations with the `@JsModule` annotation:

```
@JsModule("module")
external val module: Module

external interface Module {
    // Defines the expected module members
}
```

For dynamic module loading, use the `import()` expression instead. Add the `/* webpackIgnore: true */` magic comment to prevent webpack from parsing the dynamic import:

```
@JsFun("""
    ((module) => () => module)(
        await import(/* webpackIgnore: true */ "module")
    )
""")
private external fun loadModuleDynamically(): JsAny?
```

You can also use the `import()` expression conditionally. For example, you can load a module only when running in Node.js:

```
@JsFun("""
    ((module) => () => module)(
        ((typeof process !== "undefined") && (process.release.name === "node"))
            ? await import(/* webpackIgnore: true */ "module")
            : null
    )
""")
private external fun loadNodeModule(): JsAny?
```

If your project relies on dependencies that require a top-level `require()` function, add it as a property of `globalThis` as a workaround:

```
@JsFun("""
    ((module) => {
        globalThis.require = module.default.createRequire(import.meta.url)
        return () => {}
    })(await import("node:module"))
""")
external fun defineRequire()
```

If you run into any issues, share your feedback in our issue tracker.

Improved companion object initialization order

Kotlin/Wasm now initializes superclass companion objects before subclass companion objects, matching the JVM behavior. Previously, the initialization could be reversed, leading to inconsistent behavior across platforms.

The update improves cross-platform consistency and reduces platform-specific differences in class initialization behavior. It also enables correct handling of companion object initialization in deeper inheritance hierarchies, including cases where intermediate classes don't declare companion objects.

Support for Wasmtime in the Kotlin Gradle plugin

Kotlin 2.4.20 introduces support for Wasmtime as a runtime for the `wasmWasi` target in the Kotlin Gradle plugin.

Previously, the `wasmWasi` target supported only the Node.js runtime, which required a JavaScript bootstrap to run WASI applications. With Wasmtime support, you can now run Kotlin/Wasm applications on a standalone WebAssembly runtime.

To use Wasmtime as the runtime for the `wasmWasi` target, add `wasmtime()` to your Gradle build file:

```
kotlin {
    wasmWasi {
        wasmtime()
    }
}
```

We would appreciate your feedback in YouTrack.

New compilation modes

Kotlin 2.4.20 adds support for selecting a Kotlin/Wasm compilation mode, including new multi-module modes. Previously, the compiler used the monolith compilation mode, which compiles the project and its dependencies together and generates a single binary. This lets the compiler perform dead code elimination and produce the smallest output.

You can now select one of the following compilation modes:

Compilation mode	Compilation	Output	Optimization behavior
`monolith` (default)	Compiles the project and its dependencies together.	A single binary	Removes unreachable declarations and applies optimizations for the entire program, including dependencies.

Compilation mode	Compilation	Output	Optimization behavior
`multimodule-open-world`	Compiles each module independently and recompiles only modules that change.	A separate, independent binary for each module	Doesn't apply cross-module optimizations, which results in larger binaries.
`multimodule-closed-world`	Processes all modules in one invocation and recompiles only modules that change.	Separate binaries that depend on each other	Removes unreachable declarations but optimizes each Wasm binary independently.

To select a compilation mode, add the `kotlin.wasm.compilationMode` property to your `gradle.properties` file:

```
kotlin.wasm.compilationMode=multimodule-open-world
```

You can also configure Kotlin/Wasm to use closed-world multi-module compilation for development builds and monolith compilation for production builds. This reduces recompilation time during development and produces the smallest output for production builds.

To use this configuration, add the following property to your `gradle.properties` file:

```
kotlin.wasm.compilationMode=multimodule-closed-world-only-in-dev
```

We would appreciate your feedback in YouTrack.

Reduced binary size for lambdas and functional interfaces

Kotlin 2.4.20 changes how Kotlin/Wasm compiles lambdas and functional interfaces. Instead of generating separate anonymous classes, the compiler now generates functions and uses shared base classes.

Tests with the KotlinConf application show that this change reduces Wasm binary size by approximately 5–10%.

Because the change introduces more dynamic calls, it may affect runtime performance. If you experience any issues, report them in our issue tracker.

Kotlin/JS

Kotlin 2.4.20 improves exportability of data classes, introduces a new experimental DSL for browser testing, and adds support for exporting suspending lambdas as JavaScript async functions.

Consistent exportability of synthetic functions on exported data classes

Kotlin 2.4.20 fixes an issue which prevented the `@JsExport.Ignore` annotation from being properly applied to data class properties.

Previously, when you marked a data class with the `@JsExport` annotation, the compiler still reported warnings about the data class exportability because of the automatically generated `copy()` and `componentN()` functions. This happened even if the constructor and the properties were explicitly marked as ignored with `@JsExport.Ignore`.

For example, consider a `Session` data class exported to JavaScript that also has a reference to an internal `DatabaseConnection` type that isn't meant to be exported:

```
// Kotlin
// An internal type that isn't exported to JavaScript
class DatabaseConnection

@JsExport
data class Session @JsExport.Ignore constructor(
    val userId: String,
    @JsExport.Ignore val connection: DatabaseConnection,
)
```

Now that the issue is fixed, the compiler accounts for `@JsExport.Ignore` annotations, so `Session`'s synthetic `copy()` and `componentN()` functions no longer trigger warnings about the non-exported type `DatabaseConnection`. This aligns with the visibility rules introduced by the `@ConsistentCopyVisibility` and `@ExposedCopyVisibility` annotations.

Experimental

A new DSL for browser testing

Kotlin 2.4.20 introduces a new experimental DSL for running Kotlin/JS tests in a browser environment.

Currently, the Kotlin Gradle plugin uses Karma as a browser launcher to run JavaScript tests across different browsers. The Karma project has been deprecated for two years now, which has led us to explore alternative ways to support browser testing.

The new DSL is intended to replace Karma as a manager of different tools under the hood and includes:

- Playwright as a browser driver and a distribution manager that supports the Chromium, Firefox, and WebKit (Safari) browser engines.
- Mocha as a test runner.
- webpack as a bundler (will be replaced with Vite in future releases).

To try out the new DSL for browser testing, add the opt-in `test {}` block inside `browser {}` for your Kotlin/JS target:

```
import org.jetbrains.kotlin.gradle.ExperimentalJsTestDsl
import kotlin.time.Duration.Companion.seconds

kotlin {
    js {
        browser {
            // Add and configure the new test {} block
            @OptIn(ExperimentalJsTestDsl::class)
            test {
                // Configure default timeout for all runners
                timeout = 2.seconds
                // Configure headless mode using Gradle providers
                headless = providers
                    .environmentVariable("IS_IN_CI")
                    .map { it.toBoolean() }
                    .orElse(false)
                // Enable and configure Chromium test runner
                chromium {
                    // Override the common timeout option
                    timeout = 5.seconds
                    // Add extra launch arguments
                    launchArgs.add("--no-sandbox")
                }
                // Enable Firefox test runner
                firefox()
                // Enable WebKit test runner
                webkit()
                // Enable and configure an additional WebKit test runner
                webkit("noheadless") {
                    // Set up custom options
                    headless = false
                }
            }
        }
    }
}
```

The new DSL for browser testing is in active development. We would appreciate your feedback in YouTrack.

For more information, see Run tests in Kotlin/JS.

Experimental

Support for exporting suspending lambdas as async functions

With Kotlin 2.4.20, you can now export suspending lambda expressions as JavaScript `async` functions.

Previously, there was no way to export declarations containing suspending lambdas from Kotlin/JS libraries. Now the Kotlin compiler automatically handles the bridging between Kotlin's `suspend` functions and JavaScript's native `async` / `await` model, which is useful for mixed Kotlin/TypeScript codebases.

To enable this feature, add the following compiler option to your `build.gradle.kts` file:

```
kotlin {
    js {
        compilations.all {
            compileTaskProvider.configure {
                compilerOptions {
                    freeCompilerArgs.add("-Xsuspend-lambda-exporting")
                }
            }
        }
    }
}
```

Then, mark the relevant declarations with `@JsExport`:

```
// Kotlin
@JsExport
class TaskRunner {
    suspend fun runTask(task: suspend () -> String): String {
        return task()
    }
}
```

From the TypeScript side, the suspending lambda appears as a regular `async` function:

```
// TypeScript
import { TaskRunner } from "..."

const runner = new TaskRunner();
const result = await runner.runTask(async () => "done");
console.log(result); // "done"
```

For more information on the `@JsExport` annotation, see our documentation.

Gradle

Kotlin 2.4.20 is fully compatible with Gradle 7.6.3 through 9.7.0. You can also use Gradle versions up to the latest Gradle release. However, be aware that doing so may result in deprecation warnings, and some new Gradle features might not work.

Kotlin 2.4.20 also comes with an improved integration with the Problems API.

Improved reporting in Problems API

Kotlin 2.2.0 was the first release in which the Kotlin Gradle Plugin (KGP) integrated with Gradle's Problems API. Kotlin 2.4.0 added support for writing compiler messages to the Problems API for Kotlin/JVM.

Kotlin 2.4.20 adds compiler diagnostic IDs to the information that the compiler passes to the Problems API. It also groups diagnostics by these IDs, making it easier to identify the source of compilation problems.

Starting with Gradle 8.6, the KGP enables this integration by default. As the API is still evolving, use the most recent Gradle version to benefit from the latest improvements.

Build tools API

Kotlin 2.4.20 adds experimental support for Kotlin/JS, Kotlin/Wasm, and Kotlin metadata to the build tools API.

Experimental

Support for Kotlin/JS, Kotlin/Wasm, and Kotlin metadata

In Kotlin 2.2.0, the build tools API (BTA) became available for Kotlin/JVM. Kotlin 2.4.20 takes the next step toward BTA stabilization by adding support for new targets: Kotlin/JS, Kotlin/Wasm, and Kotlin metadata.

This makes the Kotlin Gradle plugin interact with the compiler more consistently. In some cases, you can also benefit from faster, more stable compilation.

The BTA is a universal API that acts as an abstraction layer between build systems and the Kotlin compiler ecosystem. It helps support Kotlin features and compatibility with the Kotlin compiler in available build tools.

In Kotlin 2.4.20, BTA is available as an opt-in for the new targets. To try it out, add the corresponding properties to your `gradle.properties` file:

```
kotlin.wasm.runViaBuildToolsApi=true
kotlin.js.runViaBuildToolsApi=true
kotlin.metadata.runViaBuildToolsApi=true
```

Starting with Kotlin 2.5.0, we plan to enable BTA in Kotlin/JS, Kotlin/Wasm, and Kotlin metadata by default.

If you're curious about the BTA proposal or want to share your feedback, see this KEEP.

Kotlin compiler

Kotlin 2.4.20 includes an update about the changed Kotlin runner command, `kotlinr`, and introduces an experimental Kotlin compiler native image.

Changed the Kotlin runner command from `kotlin` to `kotlinr`

The `kotlinr` command replaces `kotlin` as the Kotlin runner command to avoid a naming conflict with the `kotlin` command in the Kotlin Toolchain. The Kotlin runner also warns you when you use the `kotlin` command and recommends `kotlinr` instead.

Experimental

Native image

Kotlin 2.4.20 features the first Experimental release of the Kotlin compiler native image. The native image provides a drop-in replacement for the standard `kotlinc` command-line tool, while offering faster startup time and higher performance.

To try out the native image, download the build from GitHub Releases.

The native image also bundles the following compiler plugins you can use with the `-Xplugin` or `-Xcompiler-plugin` CLI options:

- Serialization
- Compose compiler
- All-open
- `no-arg`
- SAM with receiver
- Assignment

- Lombok
- Power-assert

For more information on the Kotlin compiler native image, see its README.

Breaking changes and deprecations

This section highlights important breaking changes and deprecations. For a complete overview, see our Compatibility guide.

- Since Apple is dropping support for its 32-bit watchOS targets, the `watchosArm32` Kotlin/Native target is now deprecated. It's planned for removal in Kotlin 2.5.0 to ensure compatibility with Xcode 27.
- Starting with Kotlin 2.4.20, the Kotlin/Native compiler prohibits AtomicFU atomic operations inside a `public` inline function or inside an `internal` inline function called from another file.
- Kotlin 2.4.20 updates the npm dependency for webpack to 5.108.1. This can affect your project in two ways:
  - webpack has moved its built-in minimizer dependency from `terser-webpack-plugin` to the broader `minimizer-webpack-plugin`. Terser remains the default JavaScript minimizer, but if your project configures or depends on `terser-webpack-plugin` directly, you may need to update its configuration.
  - webpack no longer ignores `import.meta` when determining a JavaScript file's module type. If `import.meta` is present, webpack treats the file as an ES module, which can break files that also use CommonJS constructs. For Kotlin/JS, you can configure the target to use ES modules with the `useEsModules()` Gradle DSL. Kotlin/Wasm should work in most cases without additional configuration. If you encounter an `import.meta` error with Kotlin/Wasm, check whether your project's sources or a direct or transitive dependency uses `import.meta`. Update your own code as needed. If a dependency causes the issue, update it to a compatible version if one is available, or report the issue to the library maintainers.
- Starting with Kotlin 2.4.20, Kotlin/Wasm deprecates the generated JavaScript `wasmExports` API. The compiler prohibits access to all exports except `wasmExports.memory`, which remains temporarily available with a warning. Use the `kotlin.wasm.unsafe.wasmMemory` property to access the module's `WebAssembly.Memory` object.

Documentation updates

Since the last release, we've created new pages and tutorials for the Kotlin ecosystem documentation and revamped existing ones:

- Configure an iOS delivery pipeline – Set up continuous delivery for a Kotlin Multiplatform iOS app with TeamCity.
- Compose Multiplatform updates:
  - Popups – Learn how to create and configure popups in Compose Multiplatform.
  - Window and dialog API v2 – Explore the new API for managing desktop windows and dialogs in Compose Multiplatform.
  - Tray and notifications – Learn how to add an application icon to the system tray and send system notifications in Compose Multiplatform for desktop.
  - Menu bar – Learn how to create a menu bar for a specific window in Compose Multiplatform for desktop.

    - Drag and drop – Handle platform-specific data when implementing drag and drop in Compose Multiplatform.
    - UIKit alternative for Liquid Glass – Explore an alternative approach to Liquid Glass that uses UIKit navigation instead of SwiftUI.
    - MCP server for AI agents – Learn how to use the MCP server in Compose Hot Reload to connect AI agents to your development workflow.
- Caching with Spring – Learn how to add caching to a Spring application with new Kotlin examples.
- Exposed IntelliJ IDEA plugin – Learn how to work with Exposed in IntelliJ IDEA using code completion, database-aware inspections, and live templates.
- Kotlin serialization – Learn how to serialize Kotlin data, customize JSON structure and type representation, and work with more advanced serialization scenarios.
- Flow and Flow operators – Learn how to create and collect cold and hot flows, handle exceptions, and use a wide range of flow operators.
- Debug coroutines – Learn how to debug coroutines on the JVM using debug mode, stack trace recovery, and the debug agent.
- Lincheck – Learn how model checking works in Lincheck, how to use operation execution options, and how to verify the test results.
- kapt compiler plugin – Learn how to configure the kapt compiler plugin in Gradle, Maven, and the command-line compiler.
- Code quality tools in Kotlin projects – Explore tools for analyzing JVM bytecode and Kotlin code.
- Power-assert plugin with Maven – Learn how to use the Power-assert plugin to get more detailed test failure messages.
- Multiple-round processing with KSP – Explore how KSP works across multiple processing rounds, including generated files, deferred symbols, and validation.
- Non-denotable types – Learn about platform types, captured types, and intersection types in Kotlin.
- Type aliases – Learn about type alias scope and visibility.
- This expressions – Learn how implicit `this` is resolved and when to use `this` explicitly to refer to a receiver.
- Strings – Learn about string templates, common string operations, building strings, and type conversion.
- Packages and imports – Learn how to organize Kotlin code using packages and imports.

What's new in Kotlin 2.4.0

Released: July 14, 2026

The Kotlin 2.4.0 release is out! Here are the main highlights:

- **Language:** Stable context parameters, explicit backing fields, and multiple features for annotation use-site targets
- **Standard library:** Stabilized support for the UUID API and support for checking sorted order
- **Kotlin/JVM:** Support for Java 26 and annotations in metadata enabled by default

- **Kotlin/Native:** Support for Swift packages as dependencies, updates on Swift export, and the CMS GC enabled by default
- **Kotlin/Wasm:** Incremental compilation enabled by default and support for WebAssembly Component Model
- **Kotlin/JS**: Support for value class export and ES2015 features in JS code inlining
- **Gradle:** Compatibility with Gradle 9.5.0
- **Maven:** Automatic alignment between Java and JVM target versions
- **Kotlin compiler:** More consistent inline function behavior during `.klib` compilation

You can also find an overview of the updates in this video:

Watch video online.

For information about the Kotlin release cycle, see the Kotlin release process.

Update to Kotlin 2.4.0

The latest version of Kotlin is included in the latest versions of IntelliJ IDEA and Android Studio.

To update to the new Kotlin version, make sure your IDE is updated to the latest version and change the Kotlin version to 2.4.0 in your build scripts.

Stable

New features

In previous Kotlin releases, several new features were introduced as Experimental. The following features have now graduated to Stable in Kotlin 2.4.0, so you no longer need to opt in to use them:

- Context parameters, except for context arguments and callable references
- `@all` meta-target for properties
- New defaulting rules for use-site annotation targets
- Explicit backing fields
- Stable UUID API in the common Kotlin standard library
- New API for converting unsigned integers to `BigInteger` on the JVM
- Support for checking sorted order
- Support for value class export to JavaScript/TypeScript
- Support for ES2015 features when inlining JS code
- Maven: Automatic alignment between Java and JVM target versions
- Support for Maven Toolchains

New features

- Explicit context arguments for context parameters

- Support for collection literals
- Improved compile-time constants
- Improved unused result checks for higher-order functions
- New `@IntroducedAt` annotation to generate version-based overloads for optional parameters
- New map fallback functions to distinguish `null` values and missing keys
- Swift package import
- Swift export goes Alpha with improved concurrency support
- Support for the WebAssembly Component Model

Language

Kotlin 2.4.0 promotes context parameters, explicit backing fields, and annotation use-site targets features to Stable. This release also introduces explicit context arguments for context parameters.

Stable features

Kotlin 2.2.0 and 2.3.0 introduced a few language features as Experimental. We're happy to announce that the following language features are now Stable in this release:

- Context parameters, except for context arguments and callable references
- `@all` meta-target for properties
- New defaulting rules for use-site annotation targets
- Explicit backing fields

See the full list of Kotlin language design features and proposals.

No more deprecation warnings on the last segments of imports

In previous Kotlin versions, when a deprecated class was imported, the deprecation error was reported at the call site as well as at the import directive itself. As there's no way to suppress deprecation errors on imports, you may have worked around this by suppressing deprecation reports for the entire file or by using star imports.

Since reporting the deprecation on the import of a called symbol isn't useful in most cases, Kotlin 2.4.0 doesn't issue a warning when the deprecated symbol is referenced in the last segment of the import directive.

For more information, see KT-30155.

Experimental

Explicit context arguments for context parameters

Kotlin 2.4.0 introduces explicit context arguments for context parameters.

Kotlin 2.3.20 changed the overload resolution for context parameters. As a result, calls to overloads that differ only by context parameters can become ambiguous.

You can now resolve this ambiguity by passing an explicit context argument at the call site.

Here's an example:

```
class EmailSender
class SmsSender

context(emailSender: EmailSender)
fun sendNotification() {
    println("Sent email notification")
}

context(smsSender: SmsSender)
fun sendNotification() {
    println("Sent SMS notification")
}

context(defaultEmailSender: EmailSender, defaultSmsSender: SmsSender)
fun notifyUser() {

    // Selects the overload with the EmailSender context parameter
    sendNotification(emailSender = defaultEmailSender)

    // Selects the overload with the SmsSender context parameter
    sendNotification(smsSender = defaultSmsSender)
}
```

You can also use explicit context arguments instead of the `context()` function to reduce nesting and make some calls easier to read. If you need to use the same context arguments in multiple calls, use the `context()` function instead.

This feature is Experimental. To opt in, add the following compiler option to your build file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xexplicit-context-arguments")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xexplicit-context-arguments</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

For more information, see the feature's KEEP.

Experimental

Support for collection literals

Kotlin 2.4.0 introduces experimental support for collection literals. You can now create collections in a simpler and more concise way using brackets `[]`.

For example:

```
fun main() {
    // Mutable list with explicit type declaration
    // val shapes: MutableList<String> = mutableListOf("triangle", "square", "circle")

    // Mutable list with brackets syntax
    val shapes: MutableList<String> = ["triangle", "square", "circle"]
    println(shapes)
    // [triangle, square, circle]
}
```

Currently, collection literals can't be used to construct collections defined in Java. For more information, see KT-80494.

If the compiler doesn't have enough information to infer the collection type, it defaults to the `List` type:

```
fun main() {
    val fruit = ["apple", "banana", "cherry"]

    println(fruit)
    // [apple, banana, cherry]
}
```

You can also declare custom `operator fun of` functions to use bracket syntax with your own types. For example, if you have the following `DoubleMatrix` class:

```
class DoubleMatrix(vararg val rows: Row) {
    companion object {
        operator fun of(vararg rows: Row) = DoubleMatrix(*rows)
    }
    class Row(vararg val elements: Double) {
        companion object {
            operator fun of(vararg elements: Double) = Row(*elements)
        }
    }
}
```

You can create an `identityMatrix` class instance like this:

```
fun main() {
    val identityMatrix: DoubleMatrix = [
        [1.0, 0.0, 0.0],
        [0.0, 1.0, 0.0],
        [0.0, 0.0, 1.0],
    ]
}
```

In this example, the compiler translates the nested collection literals into calls to the corresponding `operator fun of` functions. The compiler resolves these calls recursively and uses the expected types to choose the correct overloads.

This feature is Experimental. To opt in, add the following compiler option to your build file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xcollection-literals")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xcollection-literals</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

For more information, see the feature's KEEP.

Experimental

Improved compile-time constants

Kotlin 2.4.0 brings experimental improvements to compile-time constants, making support for numeric and string types more consistent and easier to use. These improvements include support for:

- Unsigned type operations.
- Standard library functions for strings, like `.lowercase()`, `.uppercase()`, and `.trim()` functions.
- Evaluation of the `.name` property of enum constants and the `KCallable` interface.

To make it clear which functions are evaluated at compile time, Kotlin 2.4.0 introduces the `IntrinsicConstEvaluation` annotation. Some functions are evaluated at compile-time but don't have the annotation yet. Later releases will add the annotation to the remaining functions. For a list of supported functions, see the KEEP appendix.

This feature is Experimental. To opt in, add the following compiler option to your build file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xintrinsic-const-evaluation")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xintrinsic-const-evaluation</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

For more information, see the feature's KEEP.

Experimental

Improved unused result checks for higher-order functions

Kotlin 2.4.0 introduces a new Experimental `returnsResultOf()` contract to improve the unused return value checker.

This contract enables the checker to distinguish between unused results that can be ignored and meaningful unused results from higher-order functions that return the result of a lambda, such as the `let` scope function.

Kotlin contracts are Experimental. To opt in, add the `@OptIn(ExperimentalContracts::class)` annotation when declaring a function with a contract.

To use this feature, add `returnsResultOf()` to the function's contract:

```
import kotlin.contracts.ExperimentalContracts
import kotlin.contracts.contract

@OptIn(ExperimentalContracts::class)
inline fun <T, R> T.customLet(block: (T) -> R): R {
    contract {
        returnsResultOf(block)
    }
    return block(this)
}
```

Here's an example that uses a custom `.customLet()` function with a nullable value:

```
fun handleNullablePackageName(packageName: String?, builder: StringBuilder) {
    // The checker doesn't report a warning
    // because the return value of the append() function can be ignored
    packageName?.customLet { builder.append(it) }

    // The checker reports a warning because the returned string is unused
    packageName?.customLet { "kotlin.$it" }
}
```

The unused return value checker is Experimental and must be enabled to report unused return values. For more information about enabling and configuring the checker, see Unused return value checker.

How to enable

The `returnsResultOf()` contract is Experimental. Be aware that using it produces pre-release binaries that earlier Kotlin compiler versions can't read. To opt in, add the following compiler option to your build file:

Gradle

```
// build.gradle(.kts)
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xallow-returns-result-of")
    }
}
```

Maven

```
<!-- pom.xml -->
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xallow-returns-result-of</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

Experimental

New `@IntroducedAt` annotation to generate version-based overloads for optional parameters

Kotlin 2.4.0 introduces the `@IntroducedAt` annotation for preserving binary compatibility when adding new optional parameters to published APIs.

Previously, adding optional parameters to a function often required using `@JvmOverloads`, which can generate more overloads than needed. Alternatively, preserving binary compatibility required you to keep older signatures as hidden deprecated overloads.

With the `@IntroducedAt` annotation, you can annotate newly added optional parameters with the version in which they were introduced. The compiler uses this information to automatically generate the corresponding hidden overloads.

This annotation is Experimental. To opt in, use the `@OptIn(ExperimentalVersionOverloading::class)` annotation.

Here's an example:

```
@OptIn(ExperimentalVersionOverloading::class)
fun Button(
    label: String = "",
    color: Color = DefaultColor,
    @IntroducedAt("1.1") borderColor: Color = DefaultBorderColor,
    @IntroducedAt("1.2") borderStyle: Style = DefaultBorderStyle,
    @IntroducedAt("1.2") borderWidth: Int = 1,
    onClick: () -> Unit
) {
    // Function body
}
```

In this example, the compiler generates hidden overloads for the older versions of the `Button()` function.

Since both `@IntroducedAt` and `@JvmOverloads` generate overloads, using them together can cause conflicting overloads. If you use both annotations, the compiler reports a warning. If you suppress the warning, the compiler prioritizes overloads generated from the `@IntroducedAt` annotation.

Standard library

Kotlin 2.4.0 stabilizes support for UUIDs in the common Kotlin standard library. It also adds new extension functions for converting unsigned integers to `BigInteger` on the JVM and support for checking sorted order.

Stable UUID API in the common Kotlin standard library

Kotlin 2.0.20 introduced a class for generating UUIDs (universally unique identifiers) and added support for converting between Kotlin and Java UUIDs. Later releases gradually improved this experimental feature by adding support for:

- Comparing UUIDs with `<` and `>` operators
- Parsing UUIDs from hex-and-dash and plain text formats
- Returning `null` when parsing invalid UUIDs.

In Kotlin 2.4.0, the `kotlin.uuid.Uuid` API becomes Stable. The only exceptions are the functions for generating V4 and V7 UUIDs, which remain Experimental and still require opt-in.

For more information about how to work with UUIDs, see UUIDs.

Support for checking sorted order

Kotlin 2.4.0 adds new extension functions for checking sorted order in iterables, arrays, and sequences.

This includes the following extension functions:

- `.isSorted()`
- `.isSortedDescending()`
- `.isSortedWith(comparator)`
- `.isSortedBy(selector)`
- `.isSortedByDescending(selector)`

You can use these extension functions to check whether elements are already sorted, without sorting them again or creating your own helper functions. They return `true` if the elements are in the specified order, or if there are

fewer than two elements, and `false` otherwise. These functions stop as soon as they encounter an out-of-order pair, which makes them efficient for large inputs.

Here's an example of checking sorted order with `.isSorted()` and `.isSortedBy()` functions:

```
data class User(val name: String, val age: Int)

fun main() {
    val numbers = listOf(1, 2, 3, 4)
    println(numbers.isSorted())
    // true

    val users = listOf(
        User("Alice", 24),
        User("Bob", 31),
        User("Charlie", 29),
    )
    println(users.isSortedBy(User::age))
    // false
}
```

New API for converting unsigned integers to `BigInteger` on the JVM

Kotlin 2.4.0 introduces the `UInt.toBigInteger()` and `ULong.toBigInteger()` extension functions on the JVM.

Previously, converting `UInt` and `ULong` values to `BigInteger` required string-based workarounds or custom conversion logic. Starting with Kotlin 2.4.0, you can now use `.toBigInteger()` to convert unsigned integer values directly to `BigInteger`.

Here's an example:

```
fun main() {
        val unsignedLong = Long.MAX_VALUE.toULong() + 1uL
    val unsignedInt = UInt.MAX_VALUE

    println(unsignedLong.toBigInteger())
    // 9223372036854775808

    println(unsignedInt.toBigInteger())
    // 4294967295
   //sampleEnd
}
```

Experimental

New map fallback functions to distinguish `null` values and missing keys

Kotlin 2.4.0 adds new variants of the existing `.getOrElse()` and `.getOrPut()` map extension functions for maps with nullable values. These functions retrieve a value for a key or use a default value as a fallback. For maps with nullable values, the new variants let you choose whether a stored `null` value behaves like a missing key or an existing value, and they make that choice clear in their function names.

The new extension functions include the following:

- `.getOrElseIfNull(key, defaultValue)` and `.getOrPutIfNull(key, defaultValue)`, which return the default value if the key is missing or has a `null` value, similar to the existing `.getOrElse()` and `.getOrPut()` functions.

- `.getOrElseIfMissing(key, defaultValue)` and `.getOrPutIfMissing(key, defaultValue)`, which return the default value only when the map doesn't contain the specified key.

These APIs are Experimental and require opt-in with the `@OptIn(ExperimentalStdlibApi::class)` annotation.

Here's an example that demonstrates the difference between `.getOrPutIfNull()` and `.getOrPutIfMissing()` when the key exists with a `null` value:

```
@OptIn(ExperimentalStdlibApi::class)
fun main() {
    val mapForNull = mutableMapOf<String, String?>("user" to null)
    val mapForMissing = mutableMapOf<String, String?>("user" to null)

    // Replaces the value if "user" has a null value
    mapForNull.getOrPutIfNull("user") { "default_user" }

    println(mapForNull)
    // {user=default_user}

    // Keeps the null value because "user" exists in the map
    mapForMissing.getOrPutIfMissing("user") { "default_user" }

    println(mapForMissing)
    // {user=null}
}
```

You can also use the `.getOrElseIfMissing()` and `.getOrPutIfMissing()` functions for caches that store nullable values. If `defaultValue` returns `null`, the map stores it and doesn't call `defaultValue` again for the same key.

Here's an example:

```
data class Response(val body: String)

class Service {
    var queryCount = 0

    fun query(key: String): Response? {
        queryCount += 1
        return null
    }
}

@OptIn(ExperimentalStdlibApi::class)
fun main() {
    val service = Service()
    val cache = mutableMapOf<String, Response?>()

    fun getCachedResponseOrQuery(key: String): Response? =
        cache.getOrPutIfMissing(key) { service.query(key) }

    // Stores null because the cache doesn't contain "user"
    getCachedResponseOrQuery("user")

    println(cache)
    // {user=null}

    // Uses the cached null and doesn't query the service again
    getCachedResponseOrQuery("user")

    println(service.queryCount)
    // 1
}
```

We would appreciate your feedback in YouTrack.

Kotlin/JVM

Kotlin 2.4.0 supports a new Java version and enables annotations in metadata by default.

Support for Java 26

Starting with Kotlin 2.4.0, the compiler can generate classes containing Java 26 bytecode.

Annotations in metadata enabled by default

The Kotlin Metadata JVM library in Kotlin 2.2.0 introduced support for reading annotations stored in Kotlin metadata. With this support, the Kotlin compiler writes annotations into metadata alongside the JVM bytecode, making them accessible to the Kotlin Metadata JVM library. As a result, annotation processors and other tools can understand and manipulate these annotations at the metadata level without using reflection or modifying source code.

In Kotlin 2.4.0, this support is enabled by default.

Kotlin/Native

Starting with Kotlin 2.4.0, Swift export is promoted to Alpha. This release also brings support for Swift package import, Xcode 26.4, improvements for memory consumption, and garbage collection.

Default concurrent marking in garbage collector

In Kotlin 2.0.20, the Kotlin team introduced experimental support for the concurrent mark and sweep garbage collector (CMS GC). After processing user feedback and fixing regressions, we are now ready to enable CMS by default, starting with Kotlin 2.4.0.

The previous default parallel mark concurrent sweep (PMCS) setup in the garbage collector had to pause application threads while the GC marked objects in the heap. In contrast, CMS allows the marking phase to run concurrently with application threads.

This significantly improves GC pause duration and app responsiveness, which is important for the performance of latency-critical applications. CMS has already demonstrated its effectiveness in benchmarks for UI applications built with Compose Multiplatform.

If you face problems, you can switch back to PMCS. To do that, set the following binary option in your `gradle.properties` file:

```
kotlin.native.binary.gc=pmcs
```

For more information on the Kotlin/Native garbage collector, see our documentation.

Reduced memory consumption during devirtualization analysis

Previously, devirtualization analysis was one of the most memory-consuming phases in the Kotlin/Native compiler. Namely, the link release task consumed too much memory, especially in large projects.

Kotlin 2.4.0 introduces improvements that help reduce peak memory consumption during link release tasks.

According to benchmarks from one of our EAP users, the improved devirtualization analysis reduced memory consumption by link release tasks by half, saving at least 13 GB.

Support for Xcode 26.4

Starting with Kotlin 2.4.0, the Kotlin/Native compiler supports Xcode 26.4 – one of the latest stable versions of Xcode.

You can now update your Xcode and get access to the latest APIs to continue working on your Kotlin projects for Apple operating systems.

LLVM update to version 21

In Kotlin 2.4.0, we updated LLVM from version 19 to 21. The new version includes performance improvements and helps keep the Kotlin/Native compiler up to date.

This update shouldn't affect your code, but if you encounter any issues, please report them to our issue tracker.

Changes to Apple target support

Kotlin 2.4.0 raises the default minimum supported versions of Apple targets:

- For iOS and tvOS, from 14.0 to 15.0.
- For macOS, from 11.0 to 12.0.
- For watchOS, from 7.0 to 8.0.

If you need to support a lower version in your project than the default one, use the `freeCompilerArgs` option in your build file:

```
kotlin {
    targets.withType<org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget>().configureEach {
        binaries.configureEach {
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.ios=14.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.macos=11.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.tvos=14.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.watchos=7.0"
        }
    }
}
```

Swift export goes Alpha with improved concurrency support

Starting with Kotlin 2.4.0, Kotlin's interoperability with Swift through Swift export is officially in Alpha! This release brings major improvements to concurrency support, adding native and direct structured concurrency to Swift export and the ability to export `kotlinx.coroutines` flows to Swift.

Support for structured concurrency

You can now seamlessly call suspending Kotlin code from Swift. Kotlin `suspend` functions and suspend functional types are exported as Swift's idiomatic `async` counterparts:

```
// Kotlin
suspend fun hello(): String {
    delay(1000)
    return "Hello Swift! This is Kotlin."
}
```

```
// Swift
let msg = try await hello()
```

Export of flow types to Swift

This update also adds support for exporting `kotlinx.coroutines` flows to Swift. Flows in `kotlinx.coroutines` represent an asynchronous stream of data that can be emitted and consumed concurrently. They are commonly used for reactive programming patterns, such as listening for database updates, network requests, or UI events.

Previously, the only way to expose the `Flow` interface from `kotlinx.coroutines.flow` to Swift was through third-party solutions. Now you can export flows out of the box into Swift's idiomatic counterpart: `AsyncSequence`.

The feature is enabled by default. You can export any public API with the `Flow` type to Swift while preserving type information. For example:

```
// Kotlin
// Type String is preserved when exporting Flow
fun flowOfStrings(): Flow<String> = flowOf("hello", "any", "world")
```

```
// Swift
var actual: [String] = []

// Type String is correctly inferred from Kotlin
for try await element in flowOfStrings().asAsyncSequence() {
    actual.append(element)
}
```

For more information about Swift export, see our documentation.

Experimental

Swift package import

Kotlin Multiplatform projects now can declare Swift packages as dependencies for an iOS app in their Gradle configuration:

```
// build.gradle.kts
kotlin {
    swiftPMDependencies {
        swiftPackage(
            url = url("https://github.com/firebase/firebase-ios-sdk.git"),
            version = from("12.11.0"),
            products = listOf(
                product("FirebaseAI"),
                product("FirebaseAnalytics"),
                ...
}
```

For working samples and more detailed information, see SwiftPM import.

If your project relies on CocoaPods dependencies, you can migrate the current setup to use Swift packages. The KMP tooling accounts for this use case and helps you reconfigure the project automatically. For details, see our CocoaPods migration guide.

Kotlin/Wasm

Kotlin 2.4.0 enables incremental compilation for Kotlin/Wasm by default and introduces support for the WebAssembly Component Model.

Incremental compilation enabled by default

Kotlin/Wasm introduced incremental compilation in Kotlin 2.1.0. Starting with Kotlin 2.4.0, it is Stable and enabled by default. With this feature, the compiler rebuilds only the files affected by recent changes, which significantly reduces build time.

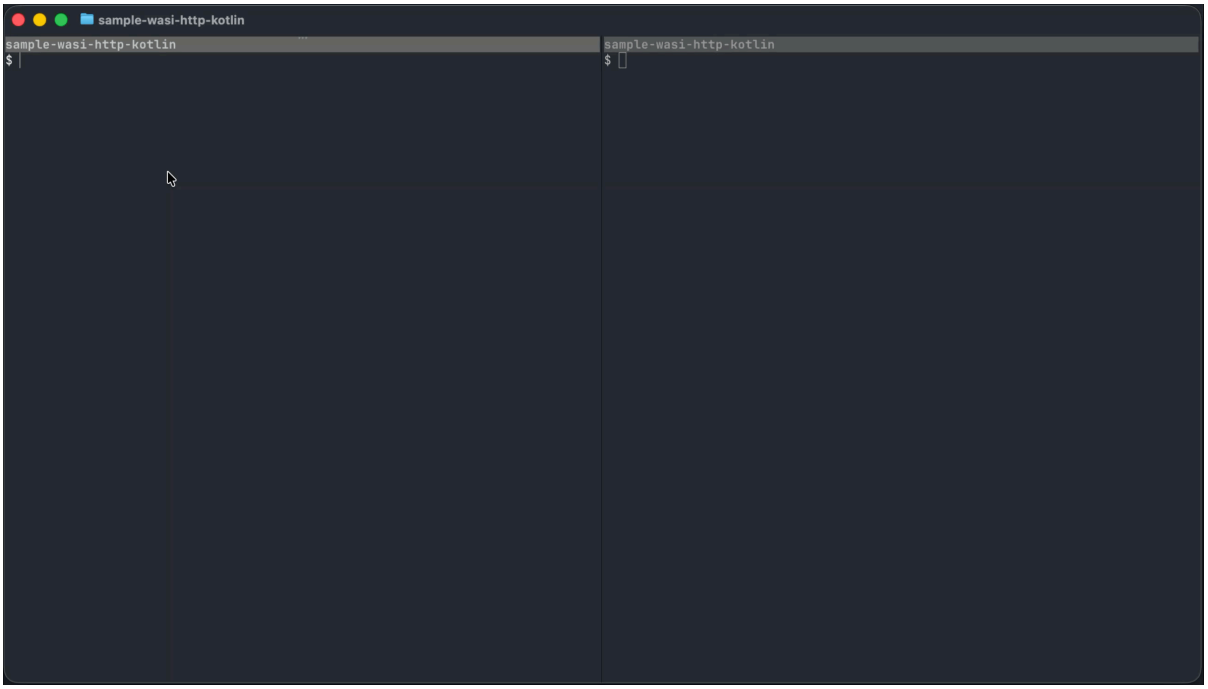
To disable incremental compilation, add the following line to your project's `local.properties` or `gradle.properties` file:

```
# gradle.properties
kotlin.incremental.wasm=false
```

If you run into any issues, report them in YouTrack

Improved display of internal variables in Chrome DevTools

Kotlin 2.4.0 improves the debugging experience for Kotlin/Wasm in Chrome DevTools by making temporary, synthetic, and internal variables easier to distinguish from user-defined variables.



The Kotlin compiler and compiler plugins, such as Compose, can generate these variables. They now use the `~` prefix by default, so they are grouped together and moved to the end of the variable list, which Chrome DevTools sorts by name.

Experimental

Support for the WebAssembly Component Model

Kotlin/Wasm goes a step further in Kotlin 2.4.0 by introducing experimental support for the WebAssembly Component Model. The proposal defines a way to build components from Wasm modules through standardized interfaces and types. This approach helps Wasm evolve from a low-level binary instruction format into a system for composing reusable, language-agnostic components. It enables Kotlin/Wasm to go beyond the browser. For example, Kotlin and WebAssembly are well suited for Function-as-a-Service, also known as FaaS or serverless, applications.

To try this feature, check out a simple server built with `wasi:http` .

Share your feedback in YouTrack.

Kotlin/JS

Kotlin 2.4.0 further improves export to JavaScript/TypeScript, including support for exporting value classes, interfaces, and type variance, as well as ES2015 features when inlining JS code.

Support for value class export to JavaScript/TypeScript

Previously, only regular Kotlin classes could be exported to JavaScript/TypeScript. Kotlin 2.4.0 lifts that limitation. You can now export Kotlin's inline value classes as regular TypeScript classes.

To export a value class, mark it with the `@JsExport` annotation on the Kotlin side:

```
// Kotlin
@JsExport
@JvmInline
value class Email(val address: String) {
    init { require(address.contains("@")) { "Invalid email" } }
}

@JsExport
class AuthService {
    suspend fun login(email: Email): String = ...
}
```

From the TypeScript side, it looks like a regular class:

```
// TypeScript
import { AuthService, Email } from "..."
const auth = new AuthService();

console.log(await auth.login(new Email("jane@example.com")));
// "Welcome, jane@example.com!"
console.log(await auth.login(new Email("not-an-email")));
// "Invalid email"
```

For more information, see `@JsExport` annotation.

Support for ES2015 features when inlining JS code

Starting with Kotlin 2.4.0, JavaScript code inlining has full support for ES2015 features.

It's useful for interoperability with third-party libraries, as well as for direct control over automatic application code generation.

Now you can use modern JS features inside `js()` calls, including:

- `const` and `let` variable declarations
- ES classes
- Generators
- Lambdas (arrow functions)
- Spread and rest operators
- Template strings

Remember that the parameter of the `js()` function should be a string constant because it's parsed at compile time and translated to JavaScript code "as-is". For example, to inline the spread operator, use:

```
fun spreadExample(): dynamic = js("""
    const add = (a, b, c) => a + b + c;

    const nums = [1, 2, 3];
    const sum = add(...nums);

    const a = [1, 2, 3];
    const b = [...a, 4, 5, 6];

    return { sum, b: b };
""")
```

For more information on inlining JavaScript code, see our documentation.

Preserve type variance when exporting to TypeScript

Previously, Kotlin variance information in generic positions was lost when exporting types to TypeScript.

With Kotlin 2.4.0, variance annotation is now saved during export and mapped to TypeScript's variance annotations.

In your Kotlin code, define the variance of your generic type parameters:

```
// Kotlin
// 'out' signals covariance (the interface only produces T)
interface Producer<out T> {
    fun produce(): T
}

// 'in' signals contravariance (the interface only consumes T)
interface Consumer<in T> {
    fun consume(item: T)
}
```

With Kotlin 2.4.0, the `in` and `out` keywords are preserved in the generated TypeScript output:

```
// Generated .d.ts
export interface Producer<out T> {
    produce(): T;
}

export interface Consumer<in T> {
    consume(item: T): void;
}
```

Improved interface export to JavaScript/TypeScript

Kotlin 2.4.0 makes it more convenient to export Kotlin interfaces to JavaScript/TypeScript.

The new `@JsNoRuntime` annotation removes the previously required metadata for implementing Kotlin interfaces, allowing the direct mapping to regular TypeScript interfaces, similar to how external interfaces already behave by default.

To export a Kotlin interface, for example in your Kotlin Multiplatform project, annotate it with `@JsNoRuntime` in the common code:

```
// commonMain
import kotlin.js.JsNoRuntime

@JsNoRuntime
expect interface DataProcessor {
    fun process(data: String): Int
}
```

Then provide the actual implementation in your JS-specific source code:

```
// jsMain
@JsNoRuntime
actual interface DataProcessor {
    actual fun process(data: String)
}
```

Because the required metadata for implementing Kotlin interfaces is removed, the interface is mapped to a regular TypeScript interface:

```
// Generated .d.ts
export interface DataProcessor {
    process(data: string): void;
}
```

The `@JsNoRuntime` annotation is only allowed on standard interfaces, so that TypeScript can treat Kotlin interfaces as regular TypeScript interfaces. Therefore, the following operations are prohibited:

- `is` and `as` type checks.
- Class references with the `::class` syntax.
- Passing an interface as a reified type argument.

Avoid annotating external interfaces with `@JsNoRuntime`, as this results in a compiler warning.

Experimental

Lifting restrictions on exporting interfaces

Kotlin 2.4.0 makes another step toward the stabilization of `@JsExport`, improving how Kotlin interfaces are exported.

Now you can export Kotlin interfaces with nested classes and named companion objects:

```
@JsExport
interface Identity {
    class Metadata(val tag: String)

    companion object Registry {
        val defaultTag = "GUEST"
    }
}
```

For more information, see `@JsExport` annotation.

Gradle

Kotlin 2.4.0 is fully compatible with Gradle 7.6.3 through 9.5.0. You can also use Gradle versions up to the latest Gradle release. However, be aware that doing so may result in deprecation warnings, and some new Gradle features might not work. Kotlin 2.4.0 also brings improvements like consistent default module names across platforms and compiler messages written to the Problems API for the Kotlin/JVM.

Minimum supported AGP version bumped to 8.5.2

Starting with Kotlin 2.4.0, the minimum supported Android Gradle plugin version is 8.5.2.

Consistent module names across platforms

Prior to Kotlin 2.4.0, default module names differed across platforms. This inconsistency could cause naming conflicts and resolution issues. Kotlin 2.4.0 standardizes the default names to `{group}:{project_name}` across all platforms.

If you need to revert the JVM module name to its previous version, add the following to your `build.gradle.kts` file for a Kotlin/JVM project:

```
kotlin {
    compilerOptions.moduleName(project.name)
}
```

For a multiplatform project:

```
kotlin {
    jvm {
        compilerOptions.moduleName(project.name)
    }
}
```

Compiler messages written to Problems API for Kotlin/JVM

In Kotlin 2.2.0, the Kotlin Gradle plugin (KGP) started reporting diagnostics to Gradle's Problems API to provide a consistent experience both in Gradle's CLI and in IntelliJ IDEA.

In Kotlin 2.4.0, the plugin also writes compiler messages to the Problems API for Kotlin/JVM, bringing the API closer to becoming a single source for all logs and messages.

Maven

Kotlin 2.4.0 makes project configuration even easier with support for Maven Toolchains and automatic alignment between Java and JVM target versions.

Automatic alignment between Java and JVM target versions

To simplify project configuration and prevent compatibility issues, the Kotlin Maven plugin now automatically aligns the JVM target version with the Java compiler version configured in the project.

This ensures that the Kotlin and Maven compilers target the same bytecode version, avoiding issues where Kotlin-generated bytecode is incompatible with the rest of the project or the intended deployment environment.

With the `<extensions>` option enabled, you don't need to set the `kotlin.compiler.jvmTarget` or `kotlin.compiler.jdkRelease` options. If neither of them is defined, the Kotlin Maven plugin automatically resolves the JVM target version in the following order:

1. As the `maven.compiler.release` version defined either as a project property or within the `maven-compiler-plugin` configuration.

   In this case, both `jvmTarget` and `jdkRelease` compiler options are set for the Kotlin compiler, limiting the API to a specific JDK version.

2. As the `maven.compiler.target` version in case the Maven release version is not set. The compiler target can be defined either as a project property or within the `maven-compiler-plugin` configuration.

   In this case, only Kotlin's `jvmTarget` is set, and the API is not limited to a specific JDK version.

This greatly simplifies your Kotlin project configuration, so your `pom.xml` file can look like this:

```
<properties>
    <maven.compiler.release>17</maven.compiler.release>
    <kotlin.version>2.4.20</kotlin.version>
</properties>

<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <version>${kotlin.version}</version>
            <extensions>true</extensions>
        </plugin>
    </plugins>
</build>
```

During the build, the plugin outputs a similar message:

```
[INFO] Using jvmTarget=17 (derived from maven.compiler.release=17)
```

The `<extensions>` option only checks project-level properties and the global `maven-compiler-plugin` configuration. It doesn't check the configurations defined in the plugin's `<executions>` section.

For more information about automatic project configuration, see our documentation.

Support for Maven Toolchains

Kotlin 2.4.0 introduces support for Maven Toolchains to the Kotlin Maven plugin.

The feature helps manage the JDK version in your build. With Maven Toolchains, you can specify the JDK version used for Kotlin compilation, independent of the JVM version running Maven (set in `JAVA_HOME`). When the `maven-toolchains-plugin` is configured in the build, the Kotlin Maven plugin automatically picks up the selected JDK toolchain, in the same way the Maven compiler plugin and other Maven plugins do. This allows you to configure a single toolchain to control the JDK used across all plugins in the build, including Kotlin compilation:

```
<plugin>
    <groupId>org.apache.maven.plugins</groupId>
    <artifactId>maven-toolchains-plugin</artifactId>
    <version>3.2.0</version>
    <executions>
        <execution>
            <goals>
                <goal>toolchain</goal>
            </goals>
        </execution>
    </executions>
    <configuration>
        <toolchains>
            <jdk>
                <version>21</version>
            </jdk>
        </toolchains>
    </configuration>
</plugin>
```

Keep in mind the priority of different ways to set up the JDK version:

1. `jdkHome` in the `kotlin-maven-plugin` configuration. An explicitly set `jdkHome` option always takes precedence over the toolchain version.
2. JDK version in `maven-toolchains-plugin`. The JDK version set through Maven Toolchains overrides the JDK version set in the `JAVA_HOME` path.
3. The `JAVA_HOME` path.

You can also use a plugin-specific `<jdkToolchain>` option to directly set the JDK version in the toolchain of `kotlin-maven-plugin`. Compared to using `maven-toolchains-plugin`, this parameter only affects Kotlin compilation and has no impact on other plugins in the build.

Currently, setting `maven-toolchains-plugin` to use a specific JDK version does not affect the `kapt` and `test-kapt` goals of `kotlin-maven-plugin`. To work around this, set the necessary version in the `JAVA_HOME` path. For more details, see KT-79897.

For more information on configuring Kotlin Maven projects, see our documentation.

Build tools API

Kotlin 2.4.0 brings a number of improvements to the build tools API (BTA). The BTA:

- Introduces new type-safe abstractions for most JVM and common compiler options. The BTA now handles their format instead of the client, reducing the risk of errors and providing an additional layer of assistance. This change is backwards-compatible at runtime, but it may break source compatibility.
- Can now track non-source changes in incremental compilation, such as configuring a different Kotlin version or changing compiler options. Build systems can control this behavior through the `BaseIncrementalCompilationConfiguration.TRACK_CONFIGURATION_INPUTS` option.
- Supports binary compatibility validation through the `AbiValidationToolchain`, making it easier for other build systems to add this functionality.
- Introduces a new feature so that build systems can customize how compiler messages are displayed through the `CompilerMessageRenderer` interface and the `JvmCompilationOperation` builder.

- Introduces new options for configuring Kotlin daemon logging:
  - `LOGS_PATH` — the directory for daemon log files.
  - `LOGS_FILE_SIZE_LIMIT` — the maximum log file size in bytes.
  - `LOGS_FILE_COUNT_LIMIT` — the maximum number of retained log files.

  By default, limits are set to a value specific to the Kotlin compiler version. To have no limit, build tools must set the option to `null`.

  Build systems can set the option when configuring the execution policy:

```
val executionPolicy = kotlinToolchains.daemonExecutionPolicy {
    set(ExecutionPolicy.WithDaemon.LOGS_PATH, Paths("/var/log/kotlin-daemon"))
    set(ExecutionPolicy.WithDaemon.LOGS_FILE_SIZE_LIMIT, 10_485_760L)
    set(ExecutionPolicy.WithDaemon.LOGS_FILE_COUNT_LIMIT, 10)
}
```

Kotlin compiler

Kotlin 2.4.0 includes more consistent behavior for inline functions declared in the same module during `.klib` compilation.

Consistent intra-module function inlining during klib compilation

Previously, function inlining behaved inconsistently on different Kotlin platforms. The JetBrains team is working to unify it across all supported platforms to ensure the same compatibility guarantees.

On the Kotlin/JVM, function inlining happens at compile time. So, when Kotlin sources are compiled with the Kotlin/JVM compiler, the resulting class files have no inline function calls in the bytecode because the bodies of inline functions are inlined into their call sites, so their behavior is fixed during compilation.

On the contrary, on Kotlin/Native, Kotlin/JS, and Kotlin/Wasm, function inlining did not happen during source-to-klib compilation, only during binary generation. As a result, the behavior of inline functions wasn't fixed during `.klib` compilation, and `.klib` libraries didn't provide the same compatibility guarantees for inline functions as Kotlin/JVM does.

Kotlin 2.4.0 takes the first step in unifying the behavior of inline functions by enabling intra-module inlining when generating `.klib` artifacts:

```
// Existing logging.klib library
inline fun logDebug(message: String) {
    println("[DEBUG] $message")
}
```

```
// Currently compiled App module
inline fun greetUser(name: String) {
    println("Hello, $name!")
}

fun main() {
    logDebug("App started") // Not inlined: declared in another module
    greetUser("Alice")      // Inlined: declared in the same module
}
```

When compiled to a `.klib`, the code looks something like:

```
// Pseudocode
fun main() {
    logDebug("App started")  // Not inlined, declared in another module
    val tmp0 = "Alice"
    println("Hello, $tmp0!") // Inlined from greetUser()
}
```

This means only inline functions declared in the same module are inlined during `.klib` compilation. Other functions, in this case, are inlined during the generation of platform-specific binaries.

How to enable

Starting with 2.4.0, the intra-module inlining is enabled by default for Kotlin/Native, Kotlin/JS, and Kotlin/Wasm.

If you face unexpected problems with this feature, you can disable it using the following compiler option in the command line:

```
-Xklib-ir-inliner=disabled
```

The next step is to enable cross-module inlining to ensure all inline functions in the project are consistently inlined. This change is planned for future Kotlin releases, but you can already try it out using the following compiler option in the command line:

```
-Xklib-ir-inliner=full
```

Please share your feedback and report any problems in YouTrack.

Consistent partial library linkage across Kotlin compilers

In Kotlin 1.9.0, partial library linkage was enabled by default for both the Kotlin/Native and Kotlin/JS compilers, with Kotlin/Wasm following in Kotlin 2.0.0. This feature effectively makes compilers treat linkage issues in Kotlin libraries consistently with Kotlin/JVM.

Since then, we haven't received negative feedback and haven't noticed users disabling the partial linkage in their projects. That's why starting with Kotlin 2.4.0, the partial linkage is always enabled, and the `-Xpartial-linkage` compiler option is now deprecated.

The default log level for all Kotlin compilers is `SILENT`. Linkage issues are not reported during compilation. To change this behavior in your projects, set the `-Xpartial-linkage-loglevel` compiler option in your build file:

```
// build.gradle.kts
kotlin {
    macosX64("native") {
        binaries.executable()

        compilations.configureEach {
            compilerOptions.configure {
                // To report linkage issues with the “info” log level:
                freeCompilerArgs.add("-Xpartial-linkage-loglevel=INFO")

                // To report issues as errors:
                freeCompilerArgs.add("-Xpartial-linkage-loglevel=ERROR")
            }
        }
    }
}
```

- `INFO` reports linkage issues with the "info" log level.
- `WARNING` reports warnings at compile time and records them in compilation logs.
- `ERROR` allows compilation to fail in case of linkage issues and reports errors in compilation logs. Use this option to examine the linkage issues more closely.

If you encounter issues with this feature, please report them in our issue tracker.

Kotlin compiler plugins

In Kotlin 2.4.0, Kotlin's compiler plugins received notable updates, too. The kapt plugin can now exclude unnecessary annotation processors from the compile classpath, and the Power-assert plugin offers simplified configuration through the new runtime library.

kapt: Exclude annotation processors from compile classpath

Kotlin 2.4.0 adds support for the `includeCompileClasspath` configuration option for annotation processor discovery, similar to the Kotlin Gradle plugin. The new option allows you to exclude unnecessary annotation processors from the compile classpath.

To configure this in your build file, set the `includeCompileClasspath` option to `false` in the `<execution>` section of the kapt plugin:

```
<execution>
    <id>kapt</id>
        <goals><goal>kapt</goal></goals>
        <configuration>
            <!-- Add new option -->
            <includeCompileClasspath>false</includeCompileClasspath>
            <sourceDirs>...</sourceDirs>
            <annotationProcessorPaths>...</annotationProcessorPaths>
        </configuration>
</execution>
```

Alternatively, you can do the same with the `kapt.include.compile.classpath` in the `<properties>` section:

```
<properties>
    <kapt.include.compile.classpath>false</kapt.include.compile.classpath>
</properties>
```

With the option set to `false`, annotation processors not included in the `<annotationProcessorPaths>` section of the kapt configuration are excluded from the kapt processing.

If `includeCompileClasspath` is not set and kapt detects an annotation processor on the compile classpath that is not explicitly defined in the `<annotationProcessorPaths>` section, you'll see the following deprecation warning:

```
[WARNING] Annotation processors discovery from compile classpath is deprecated. Set
'kapt.include.compile.classpath=false' to disable discovery.
```

For more information on kapt configuration, see our documentation.

Power-assert: New runtime library

Kotlin 2.4.0 makes Power-assert capable functions more discoverable and easier to configure with the new runtime library.

Previously, adopting Power-assert required complex build configurations and function parameter conventions. Starting with this release, Power-assert capable functions can use the new runtime library to integrate directly with the compiler plugin transformations.

This brings major improvements for both plugin users and library authors:

- The new `CallExplanation` data structure provides detailed information about the call site. This enables more dynamic diagram rendering for assertion failures and better integration with external tools.
- The new `@PowerAssert` annotation makes assertion functions instantly discoverable by the compiler plugin. That way, you can now add out-of-the-box support for Power-assert into your libraries.

> Use our example collection as a playground for experimenting with the new features.

For more information, see our documentation.

Compose compiler

With Kotlin 2.4.0, the Compose compiler offers more consistent incremental compilation and advances the deprecation cycle of several feature flags.

Consistent incremental compilation for internal declarations

Starting from Kotlin 2.4.0, the Compose compiler offers more consistent incremental compilation. Stability of internal types across different files is now inferred during runtime. This allows Compose to update inferred stability values even when class usages are not recompiled.

As a side effect, the size of your artifacts may increase whenever a `@Composable` function uses an `internal` class from a different file as a parameter. This is caused by the compiler encoding the execution paths for both stable and unstable cases, since stability has to be decided during runtime. This overhead of runtime stability is removed by minifiers that perform full-app optimizations (such as R8) as they are able to infer the unnecessary execution path and eliminate it.

This update does not change the final stability value, so the behavior of `@Composable` functions remains unchanged.

Feature flag deprecations

Kotlin 2.4.0 advances the deprecation cycle of experimental feature flags that graduated to stable and are now enabled by default:

- `StrongSkipping`, `IntrinsicRemember`, and associated DSL properties are advanced to `DeprecationLevel.ERROR`. They will be removed in Kotlin 2.5.0.
- `OptimizeNonSkippingGroups` and `PausableComposition` are now deprecated. They are scheduled to be removed in Kotlin 2.6.0.

Breaking changes and deprecations

This section highlights important breaking changes and deprecations. For a complete overview, see our Compatibility guide.

- Starting with Kotlin 2.4.0, the compiler no longer supports `-language-version=1.9`. As a result, the K1 compiler is no longer supported.
- Kotlin 2.4.0 streamlines the DSL for binary compatibility validation in the Kotlin Gradle plugin and deprecates some parts. For the latest DSL, see Binary compatibility validation in the Kotlin Gradle plugin.
- Support for Kotlin script execution through the `KotlinScriptMojo` Maven plugin has been removed.

Documentation updates

We made the following documentation changes in the Kotlin ecosystem:

- Liquid Glass in a Compose Multiplatform app – Migrate an iOS app from fully Compose-driven navigation to native SwiftUI navigation with iOS 26 Liquid Glass styling.
- Adding Swift packages as dependencies to KMP modules – Learn how to set up a SwiftPM dependency in your KMP project.
- Switch Kotlin Multiplatform project from CocoaPods to SwiftPM dependencies manually or with Junie – Learn how you can use Junie and Kotlin AI skills to make migration easier.
- Configure TeamCity for a KMP app – Use TeamCity to build, test, and deploy your KMP applications.
- Recommended serialization approaches for Navigation 3 – Find the best way to use serialization with Navigation 3 in your CMP application.
- Multiplatform ViewModel – Learn how to set up and work with ViewModels in a multiplatform project.
- Backend development with Kotlin – Explore the different frameworks you can use for backend development.
- Create a task manager app with Spring Boot and Claude – Learn how Claude can help you create an app with Spring Boot from scratch.
- Configure a Maven project – Set up Kotlin compilation in your existing Java Maven project or in a new Kotlin Maven project.
- Test Kotlin projects with Maven – Learn how to create tests with JUnit and use Maven plugins to run unit and integration tests.
- Use annotation processors in Kotlin projects – Choose between kapt and KSP to process annotations in your backend project.
- Kotlin AI skills – Use agent skills to help you perform Kotlin-specific tasks.
- Kotlin Language Server – Read about JetBrains' official implementation of the Language Server Protocol (LSP) for Kotlin.
- Numbers – Explore Kotlin's number types and how to work with them.
- Getting started with KSP – Learn how to add a KSP-based processor to your project or create your own.
- Migrate from kapt to KSP – Migrate your annotation processors to get the best out of Kotlin's features.
- Lincheck overview – Understand how Lincheck works behind the scenes to test concurrent code on the JVM.
- Getting started with Lincheck – Create a project and run tests with Lincheck.

- Testing arbitrary code with Lincheck – Learn how to test concurrent code with Lincheck.
- How to test data structures with Lincheck – Dive into Lincheck's data structure testing process.
- Testing strategies with Lincheck – Learn about Lincheck's testing strategies: model checking and stress testing.
- Configuring a testing strategy with Lincheck – Explore the different options for Lincheck's testing strategies.
- Deploy a Ktor application with Dokku – Learn about the deployment workflow with Dokku.

Compatibility guide for Kotlin 2.4.x

Keeping the Language Modern and *Comfortable Updates* are among the fundamental principles in Kotlin Language Design. The former says that constructs which obstruct language evolution should be removed, and the latter says that this removal should be well-communicated beforehand to make code migration as smooth as possible.

While most of the language changes were already announced through other channels, like update changelogs or compiler warnings, this document summarizes them all, providing a complete reference for migration from Kotlin 2.3 to Kotlin 2.4. This document also includes information about tool-related changes.

Basic terms

In this document, we introduce several kinds of compatibility:

- *source*: source-incompatible change stops code that used to compile fine (without errors or warnings) from compiling anymore
- *binary*: two binary artifacts are said to be binary-compatible if interchanging them doesn't lead to loading or linkage errors
- *behavioral*: a change is said to be behavioral-incompatible if the same program demonstrates different behavior before and after applying the change

Remember that those definitions are given only for pure Kotlin. Compatibility of Kotlin code from the other languages perspective (for example, from Java) is out of the scope of this document.

Language

Drop support for `-language-version=1.9` and the K1 compiler

Issue: KT-80590

Component: Compiler

Incompatible change type: source

Short summary: Starting with Kotlin 2.4, the compiler no longer supports `-language-version=1.9`. As a result, the K1 compiler is no longer supported.

Deprecation cycle:

- 2.2.0: report a warning when using `-language-version` with version 1.9
- 2.4.0: raise the warning to an error

Prohibit flexible explicit nullable type arguments for Java types

Issue: KTLC-284

Component: Core language

Incompatible change type: source

Short summary: Previously, when calling Java APIs from Kotlin, the compiler could treat explicitly specified nullable type arguments as flexible type arguments. Kotlin 2.4.0 no longer applies this behavior for nullable type arguments, so the compiler now reports errors for code that could break type safety or fail at runtime.

Deprecation cycle:

- 2.2.0: report a warning for explicitly specified nullable type arguments that are treated as flexible types
- 2.4.0: raise the warning to an error

Prohibit always-false `is` checks for definitely incompatible types

Issue: KTLC-365

Component: Core language

Incompatible change type: source

Short summary: The compiler now prevents meaningless `is` checks that are always false because the checked types are definitely incompatible. This keeps the behavior consistent with other operations involving incompatible types.

Deprecation cycle:

- 2.0.0: report a warning for `is` checks with definitely incompatible types
- 2.4.0: raise the warning to an error

Prohibit exposing types and declarations with lower visibility in inline functions

Issue: KTLC-283

Component: Core language

Incompatible change type: source

Short summary: The compiler now prevents inline functions from exposing types and declarations that have lower visibility than the inline function itself.

Deprecation cycle:

- 2.3.0: report a warning for exposing types and declarations with lower visibility in inline functions
- 2.4.0: raise the warning to an error

Change default use-site target selection for annotations

Issue: KTLC-391

Component: Core language

Incompatible change type: binary

Short summary: Kotlin 2.4.0 updates the defaulting rules for propagating annotations to parameters, properties, and fields. This can affect annotation processing, reflection, and binary metadata after recompilation. When you don't specify a use-site target, the compiler now uses `param` and `property` if they apply, and uses `field` only if `property` doesn't apply.

You can specify a use-site target explicitly, such as `@param:Annotation` instead of `@Annotation`. To use the previous defaulting rule for your whole project, add `-Xannotation-default-target=first-only` to your build file.

Deprecation cycle:

- 2.2.0: report a warning when the new defaulting rule changes the chosen use-site targets
- 2.4.0: enable the new defaulting rule

Forbid implicit references to inaccessible types

Issue: KTLC-384

Component: Core language

Incompatible change type: source

Short summary: Using declarations that implicitly reference inaccessible types from indirect dependencies now results in an error.

To migrate, add an explicit dependency on the module that declares the inaccessible type, or update the intermediate API so it doesn't expose that type.

Deprecation cycle:

- 2.3.0: report a warning for implicit references to inaccessible types
- 2.4.0: raise the warning to an error

Enforce Jakarta nullability annotations

Issue: KTLC-285

Component: Core language

Incompatible change type: source

Short summary: The compiler now enforces declared nullability in Kotlin for Java declarations that use `jakarta.annotation.Nullable` or `jakarta.annotation.Nonnull`. If you assign a Java declaration marked as nullable by these annotations to a non-null Kotlin type, the compiler reports an error.

Deprecation cycle:

- 2.2.0: report a warning for nullability mismatches in Java declarations annotated with Jakarta nullability annotations
- 2.4.0: raise the warning to an error

Report misplaced type arguments in callable reference qualifiers

Issue: KTLC-388

Component: Core language

Incompatible change type: source

Short summary: The compiler now checks the left-hand side of callable references and reports a warning if an inner class contains type arguments in the wrong part of the qualifier.

To migrate, update the reference so that each type argument belongs to the class that declares it. For example, write the full type `Outer<Int>.Inner<String>::toString` instead of `Inner<String, Int>::toString`.

Deprecation cycle:

- 2.4.0: report a warning when type arguments in the left-hand side of a callable reference belong to another part of the qualifier

Report errors for class literals from reified type parameters with nullable upper bounds

Issue: KTLC-370

Component: Core language

Incompatible change type: source

Short summary: The compiler now reports an error when you use `::class` on an expression whose type comes from a reified type parameter with a nullable upper bound. If you use `::class` on such an expression, make the value non-null first with an explicit null check or the `!!` operator.

Deprecation cycle:

- 2.3.0: report a warning when `::class` is used on an expression whose type comes from a reified type parameter with a nullable upper bound
- 2.4.0: raise the warning to an error

Prohibit initialization before declarations in anonymous objects

Issue: KTLC-290

Component: Core language

Incompatible change type: source

Short summary: Kotlin now reports an error when you initialize a property in an `init` block of an anonymous object before declaring that property.

Deprecation cycle:

- 2.2.20: report a warning when an `init` block in an anonymous object initializes a property before the property declaration
- 2.4.0: raise the warning to an error

Enforce exhaustiveness for `when` expressions with non-abstract Java sealed classes

Issue: KTLC-366

Component: Core language

Incompatible change type: source

Short summary: Kotlin now checks exhaustiveness more strictly and requires an `else` branch or a branch that matches the sealed class itself when you use a `when` expression with a non-abstract Java sealed class. Previously, Kotlin could treat such `when` expressions as exhaustive even though the Java sealed class itself could be instantiated directly.

Deprecation cycle:

- 2.3.0: report a warning for non-exhaustive `when` expressions with non-abstract Java sealed classes
- 2.4.0: raise the warning to an error

Prohibit `operator` modifier on `getValue()` and `setValue()` functions with too many parameters

Issue: KTLC-289

Component: Core language

Incompatible change type: source

Short summary: When you mark the `getValue()` or `setValue()` functions with the `operator` modifier, the compiler now checks that they have the required number of value parameters. The `getValue()` function must have exactly two value parameters, and the `setValue()` function must have exactly three. To migrate, remove the `operator` modifier or change the function signature.

Deprecation cycle:

- 2.2.20: report a warning for `operator` `getValue()` and `setValue()` functions with too many value parameters
- 2.4.0: raise the warning to an error

Prohibit inconsistent type arguments in generic calls

Issue: KTLC-373

Component: Core language

Incompatible change type: source

Short summary: When you specify type arguments in a generic call, the compiler now reports an error if one type argument violates an upper-bound constraint that depends on another type argument. If type parameters depend on each other, use type arguments that match those constraints, for example `Container<Alpha, AlphaKey>()` instead of `Container<Alpha, BetaKey>()`.

Deprecation cycle:

- 2.3.0: report a warning when explicit type arguments in a generic call violate upper-bound constraints between type parameters
- 2.4.0: raise the warning to an error

Deprecate references to the `javaClass` property

Issue: KTLC-375

Component: Kotlin/JVM

Incompatible change type: source

Short summary: Kotlin 2.4.0 deprecates property references to the `javaClass` property to reduce confusion with `::class.java`. Use `.javaClass` to get the runtime Java class of an object, or `::class.java` to get a Java class reference.

Deprecation cycle:

- 2.4.0: report a warning for property references to the `javaClass` property

Report errors for implicit enum constructor calls that require opt-in

Issue: KTLC-359

Component: Core language

Incompatible change type: source

Short summary: Kotlin now reports an error when an enum entry implicitly calls an enum primary constructor that requires opt-in. To migrate, add `@OptIn` to the enum class or to each enum entry that calls the constructor.

Deprecation cycle:

- 2.2.20: report a warning when an enum entry implicitly calls an enum primary constructor that requires opt-in
- 2.4.0: raise the warning to an error

Forbid `inline` modifier on enum entries

Issue: KTLC-361

Component: Core language

Incompatible change type: source

Short summary: Kotlin now reports an error when you use the `inline` modifier on an enum entry.

Deprecation cycle:

- 2.3.0: report a warning when the `inline` modifier is used on an enum entry
- 2.4.0: raise the warning to an error

Prohibit array literals outside annotation calls and parameter defaults

Issue: KTLC-369

Component: Core language

Incompatible change type: source

Short summary: Using array literals outside annotation calls and default values for annotation parameters now results in an error. To migrate, use `arrayOf(...)`, for example `Roles(arrayOf("admin", "user"))` instead of `Roles(["admin", "user"])`.

Deprecation cycle:

- 2.3.0: report a warning for array literals outside annotation calls and default values for annotation parameters
- 2.4.0: raise the warning to an error

Prohibit `_root_ide_package_` in CLI compiler mode

Issue: KTLC-378

Component: Compiler

Incompatible change type: source

Short summary: Using the IDE-only `_root_ide_package_` qualifier in CLI compiler mode now results in an error.

Deprecation cycle:

- 2.3.20: report a warning for `_root_ide_package_` references in CLI compiler mode
- 2.4.0: raise the warning to an error

Correct equality for function references with vararg conversions

Issue: KTLC-385

Component: Kotlin/JVM

Incompatible change type: behavioral

Short summary: Kotlin/JVM now treats function references with different conversions as unequal. Previously, Kotlin/JVM ignored vararg conversion in equality checks when the same function reference also used another conversion, so `getDefault(::foo) == getDefaultAndVararg(::foo)` could return `true` even though only one side used vararg conversion.

Deprecation cycle:

- 2.4.0: introduce the new behavior

Enforce opt-in for companion object access

Issue: KTLC-386

Component: Core language

Incompatible change type: source

Short summary: Kotlin now reports an opt-in error when a class name reference resolves to a companion object that requires opt-in. For example, `val p = C` requires opt-in if `C` resolves to a companion object marked with an opt-in annotation.

Deprecation cycle:

- 2.3.20: report a warning when companion object access requires opt-in
- 2.4.0: raise the warning to an error for `ERROR`-level opt-in requirements

Report type mismatches from supertypes with nested generic arguments

Issue: KTLC-372

Component: Core language

Incompatible change type: source

Short summary: Kotlin now reports an error when the compiler detects a type mismatch involving a supertype with nested generic arguments. Previously, the compiler could miss this mismatch, which later failed with a `ClassCastException`. To migrate, use a type argument that matches the receiver's generic type, or remove the explicit type argument so the compiler can infer it.

Deprecation cycle:

- 2.4.0: report an error for type mismatches involving supertypes with nested generic arguments

Prohibit inferred types with inaccessible declarations

Issue: KTLC-363

Component: Core language

Incompatible change type: source

Short summary: Using an inferred type that contains a declaration inaccessible in the current scope now results in an error.

Deprecation cycle:

- 2.3.0: report a warning when an inferred type contains a declaration that isn't accessible in the current scope
- 2.4.0: raise the warning to an error

Standard library

Deprecate `kotlin.io.readLine()` function

Issue: KTLC-394

Component: kotlin-stdlib

Incompatible change type: source

Short summary: The `kotlin.io.readLine()` function is deprecated. Use the `readln()` function instead of `readLine()!!`, and the `readlnOrNull()` function instead of `readLine()`.

Deprecation cycle:

- 2.4.0: report a warning when using `kotlin.io.readLine()`

Deprecate `AbstractCoroutineContextKey` and related APIs

Issue: KT-84970

Component: kotlin-stdlib

Incompatible change type: source

Short summary: The `AbstractCoroutineContextKey` class and its related APIs were experimental since Kotlin 1.3 and proved to be error-prone. For this reason, this class and the related `getPolymorphicElement()` and `minusPolymorphicKey()` functions are deprecated.

Deprecation cycle:

- 2.4.0: report a warning when using the deprecated APIs

Change `Random.nextDouble()` contract for infinite bounds

Issue: KT-84368

Component: kotlin-stdlib

Incompatible change type: behavioral

Short summary: The documented contract for `Random.nextDouble(until)` now requires the `until` bound to be finite. Use a finite bound instead.

Deprecation cycle:

- 2.4.0: enable the new behavior

Tools

Deprecate legacy Kotlin/JS compiler type selection APIs

Issue: KT-64275, KT-84753

Component: Gradle

Incompatible change type: source

Short summary: Kotlin 2.4.0 removes deprecated Gradle APIs related to selecting the legacy Kotlin/JS compiler type.

Additionally, the `KotlinJsCompilerType` enum and the `KotlinProjectExtension.js()` overloads with a compiler type parameter are deprecated. To migrate, remove the compiler type argument from the `js()` target declaration and use the `js {}` block instead.

Deprecation cycle:

- 1.8.0: deprecate legacy Kotlin/JS compiler type constants
- 2.4.0: remove the deprecated legacy compiler type APIs and report a warning when using `KotlinJsCompilerType` or `KotlinProjectExtension.js()` overloads with a compiler type parameter

Deprecate `sourceSets` in the Kotlin Android extension

Issue: KT-74451

Component: Gradle

Incompatible change type: source

Short summary: The `sourceSets` property in `KotlinAndroidProjectExtension` is deprecated. To migrate, configure source sets through the Android Gradle plugin's `android { sourceSets { ... } }` block instead.

Deprecation cycle:

- 2.4.0: report a warning when accessing `sourceSets` from `KotlinAndroidProjectExtension`

Remove consumable configurations for Kotlin/Native Apple frameworks

Issue: KT-74503, KT-82230

Component: Gradle

Incompatible change type: source

Short summary: Kotlin 2.4.0 removes generated consumable Gradle configurations that expose Kotlin/Native Apple frameworks as outgoing artifacts.

Deprecation cycle:

- 2.4.0: remove consumable configurations for Kotlin/Native Apple frameworks

Remove deprecated task, compilation, and DSL APIs from the Kotlin Gradle plugin

Issue: KT-85509

Component: Gradle

Incompatible change type: source

Short summary: Kotlin 2.4.0 removes the following deprecated Kotlin Gradle plugin APIs:

Compile task configuration APIs:

- `KotlinJvmCompile.parentKotlinOptions`
- `KotlinJvmCompile.moduleName`
- `KotlinJvmFactory.createKotlinJvmOptions()`
- `BaseKotlinCompile.moduleName` from `KotlinCompile` and `Kotlin2JsCompile` tasks

Kotlin Multiplatform hierarchy and target APIs:

- `DeprecatedKotlinTargetHierarchyDsl`
- `KotlinMultiplatformExtension.targetHierarchy`
- `KotlinTargetComponent.sourcesArtifacts`
- `KotlinTarget.sourceSets`
- `KotlinHierarchyBuilder.withoutCompilations()`
- `KotlinHierarchyBuilder.filterCompilations()`
- `KotlinHierarchyBuilder.withWasm()`
- `KotlinCompilation.defaultSourceSetName`

Kotlin compilation task APIs:

- `KotlinCompilation.compileKotlinTaskProvider`
- `KotlinCompilation.compileKotlinTask`

Kotlin dependency handler APIs:

- `KotlinDependencyHandler.enforcedPlatform()`
- `KotlinDependencyHandler.platform()` Other deprecated task and extension APIs:
- `KaptExtension.processors`
- `KotlinTest.excludes`
- `KotlinTest.fileResolver`
- `KotlinTest.execHandleFactory`
- `IncrementalSyncTask.destinationDir`

To migrate, remove usages of these APIs and use the replacements suggested by the deprecation diagnostics.

Deprecation cycle:

- 2.4.0: remove the deprecated APIs

Deprecate explicit shrunk classpath snapshot configuration

Issue: KT-75837

Component: Build tools API

Incompatible change type: source

Short summary: The `shrunkClasspathSnapshot` configuration parameter in `ClasspathSnapshotBasedIncrementalCompilationApproachParameters` is deprecated. The shrunk classpath snapshot is an internal incremental compilation cache, so the compiler now creates and manages it automatically under the incremental compiler metadata `workingDirectory`. To migrate, use the automatically managed snapshot file, instead of passing a value to `shrunkClasspathSnapshot`.

Deprecation cycle:

- 2.4.0: report a warning when using `shrunkClasspathSnapshot`

Remove redundant ABI validation Gradle DSL elements

Issue: KT-80685

Component: Gradle

Incompatible change type: source

Short summary: Kotlin 2.4.0 simplifies the ABI validation Gradle DSL and removes redundant configuration entries. To migrate, configure report settings directly in `abiValidation {}` instead of `abiValidation { legacyDump { ... } }`, remove `abiValidation { klib { enabled = ... } }`, and use `keepLocallyUnsupportedTargets` instead of `klib.keepUnsupportedTargets`.

Deprecation cycle:

- 2.4.0: remove redundant ABI validation DSL elements

Deprecate obsolete Compose compiler Gradle plugin options

Issue: KT-85343

Component: Gradle

Incompatible change type: source

Short summary: In Kotlin 2.4.0, the following deprecated Compose compiler Gradle plugin options now report an error when used:

- `generateFunctionKeyMetaClasses`
- `enableIntrinsicRemember`
- `enableNonSkippingGroupOptimization`
- `enableStrongSkippingMode`
- `stabilityConfigurationFile`
- `ComposeFeatureFlag.StrongSkipping`
- `ComposeFeatureFlag.IntrinsicRemember`

Use `featureFlags` instead of the deprecated feature options, and `stabilityConfigurationFiles` instead of `stabilityConfigurationFile`.

Deprecation cycle:

- 2.0.20: report warnings for `enableIntrinsicRemember`, `enableNonSkippingGroupOptimization`, and `enableStrongSkippingMode`
- 2.1.0: report a warning for `stabilityConfigurationFile`
- 2.4.0: raise the warnings to errors

Report errors for obsolete Kotlin/Native Gradle task APIs

Issue: KT-85510

Component: Gradle

Incompatible change type: source

Short summary: The following deprecated Kotlin/Native Gradle task APIs now report an error when used:

`AbstractKotlinNativeCompile` properties:

- `additionalCompilerOptions`
- `languageSettings`
- `progressiveMode`

`KotlinNativeCompile` properties:

- `moduleName`
- `konanDataDir`
- `konanHome`
- `languageVersion`
- `apiVersion`
- `enabledLanguageFeatures`
- `optInAnnotationsInUse`
- `additionalCompilerOptions`

`CInteropProcess` properties:

- `outputFile`
- `konanDataDir`
- `konanHome`
- `defFile`

`KotlinNativeLink` properties:

- `languageSettings`
- `additionalCompilerOptions`
- `konanDataDir`
- `konanHome`

Additionally, the `KotlinNativeLink.compilation` property is removed.

Deprecation cycle:

- 2.4.0: report an error for the deprecated Kotlin/Native Gradle task APIs, remove the `KotlinNativeLink.compilation` property

Report warnings for case mismatches in compiler argument values

Issue: KT-86059

Component: Build tools API

Incompatible change type: source

Short summary: Compiler arguments that accept a fixed set of values previously handled letter case inconsistently: some accepted any letter case, while others required an exact match. The Build tools API now accepts any letter case for these values but reports a warning, for example `Case mismatch for -module-kind: expected 'commonjs', got 'CommonJS'`. To migrate, use the letter case listed for the argument in the compiler reference.

Deprecation cycle:

- 2.4.20: report a warning when the letter case of a compiler argument value doesn't match the expected value

Basic syntax overview

This is a collection of basic syntax elements with examples. At the end of every section, you'll find a link to a detailed description of the related topic.

You can also learn all the Kotlin essentials with the free Kotlin Core track by JetBrains Academy.

Package definition and imports

Package specification should be at the top of the source file:

```
package my.demo

import kotlin.text.*

// ...
```

It is not required to match directories and packages: source files can be placed arbitrarily in the file system.

See Packages.

Program entry point

An entry point of a Kotlin application is the `main` function:

```
fun main() {
    println("Hello world!")
}
```

Another form of `main` accepts a variable number of `String` arguments:

```
fun main(args: Array<String>) {
    println(args.contentToString())
}
```

Print to the standard output

`print` prints its argument to the standard output:

```
fun main() {
    print("Hello ")
    print("world!")
}
```

`println` prints its arguments and adds a line break, so that the next thing you print appears on the next line:

```
fun main() {
    println("Hello world!")
    println(42)
}
```

Read from the standard input

The `readln()` function reads from the standard input. This function reads the entire line the user enters as a string.

You can use the `println()`, `readln()`, and `print()` functions together to print messages requesting and showing user input:

```
// Prints a message to request input
println("Enter any word: ")

// Reads and stores the user input. For example: Happiness
val yourWord = readln()

// Prints a message with the input
print("You entered the word: ")
print(yourWord)
// You entered the word: Happiness
```

For more information, see Read standard input.

Functions

A function with two `Int` parameters and `Int` return type:

```
fun sum(a: Int, b: Int): Int {
    return a + b
}

fun main() {
    print("sum of 3 and 5 is ")
    println(sum(3, 5))
}
```

A function body can be an expression. Its return type is inferred:

```
fun sum(a: Int, b: Int) = a + b

fun main() {
    println("sum of 19 and 23 is ${sum(19, 23)}")
}
```

A function that returns no meaningful value:

```
fun printSum(a: Int, b: Int): Unit {
    println("sum of $a and $b is ${a + b}")
}

fun main() {
    printSum(-1, 8)
}
```

`Unit` return type can be omitted:

```
fun printSum(a: Int, b: Int) {
    println("sum of $a and $b is ${a + b}")
}

fun main() {
    printSum(-1, 8)
}
```

See Functions.

Variables

In Kotlin, you declare a variable starting with a keyword, `val` or `var`, followed by the name of the variable.

Use the `val` keyword to declare variables that are assigned a value only once. These are immutable, read-only local variables that can't be reassigned a different value after initialization:

```
fun main() {
    // Declares the variable x and initializes it with the value of 5
    val x: Int = 5
    // 5
    println(x)
}
```

Use the `var` keyword to declare variables that can be reassigned. These are mutable variables, and you can change their values after initialization:

```
fun main() {
    // Declares the variable x and initializes it with the value of 5
    var x: Int = 5
    // Reassigns a new value of 6 to the variable x
    x += 1
    // 6
    println(x)
}
```

Kotlin supports type inference and automatically identifies the data type of a declared variable. When declaring a variable, you can omit the type after the variable name:

```
fun main() {
    // Declares the variable x with the value of 5;`Int` type is inferred
    val x = 5
    // 5
    println(x)
}
```

You can use variables only after initializing them. You can either initialize a variable at the moment of declaration or declare a variable first and initialize it later. In the second case, you must specify the data type:

```
fun main() {
    // Initializes the variable x at the moment of declaration; type is not required
    val x = 5
    // Declares the variable c without initialization; type is required
    val c: Int
    // Initializes the variable c after declaration
    c = 3
    // 5
    // 3
    println(x)
    println(c)
}
```

You can declare variables at the top level:

```
val PI = 3.14
var x = 0

fun incrementX() {
    x += 1
}
// x = 0; PI = 3.14
// incrementX()
// x = 1; PI = 3.14

fun main() {
    println("x = $x; PI = $PI")
    incrementX()
    println("incrementX()")
    println("x = $x; PI = $PI")
}
```

For information about declaring properties, see Properties.

Creating classes and instances

To define a class, use the `class` keyword:

```
class Shape
```

Properties of a class can be listed in its declaration or body:

```
class Rectangle(val height: Double, val length: Double) {
    val perimeter = (height + length) * 2
}
```

The default constructor with parameters listed in the class declaration is available automatically:

```
class Rectangle(val height: Double, val length: Double) {
    val perimeter = (height + length) * 2
}
fun main() {
    val rectangle = Rectangle(5.0, 2.0)
    println("The perimeter is ${rectangle.perimeter}")
}
```

Inheritance between classes is declared by a colon (`:`). Classes are `final` by default; to make a class inheritable, mark it as `open` :

```
open class Shape

class Rectangle(val height: Double, val length: Double): Shape() {
    val perimeter = (height + length) * 2
}
```

For more information about constructors and inheritance, see Classes and Objects and instances.

Comments

Just like most modern languages, Kotlin supports single-line (or *end-of-line*) and multi-line (*block*) comments:

```
// This is an end-of-line comment

/* This is a block comment
   on multiple lines. */
```

Block comments in Kotlin can be nested:

```
/* The comment starts here
/* contains a nested comment */
and ends here. */
```

See Documenting Kotlin Code for information on the documentation comment syntax.

String templates

```
fun main() {
    var a = 1
    // simple name in template:
    val s1 = "a is $a"

    a = 2
    // arbitrary expression in template:
    val s2 = "${s1.replace("is", "was")}, but now is $a"
    println(s2)
}
```

See String templates for details.

Conditional expressions

```
fun maxOf(a: Int, b: Int): Int {
    if (a > b) {
        return a
    } else {
        return b
    }
}

fun main() {
    println("max of 0 and 42 is ${maxOf(0, 42)}")
}
```

In Kotlin, `if` can also be used as an expression:

```
fun maxOf(a: Int, b: Int) = if (a > b) a else b

fun main() {
    println("max of 0 and 42 is ${maxOf(0, 42)}")
}
```

See `if` -expressions.

for loop

```
fun main() {
    val items = listOf("apple", "banana", "kiwifruit")
    for (item in items) {
        println(item)
    }
}
```

or:

```
fun main() {
    val items = listOf("apple", "banana", "kiwifruit")
    for (index in items.indices) {
        println("item at $index is ${items[index]}")
    }
}
```

See for loop.

while loop

```
fun main() {
    val items = listOf("apple", "banana", "kiwifruit")
    var index = 0
    while (index < items.size) {
        println("item at $index is ${items[index]}")
        index++
    }
}
```

See while loop.

when expression

```
fun describe(obj: Any): String =
    when (obj) {
        1          → "One"
        "Hello"    → "Greeting"
        is Long    → "Long"
        !is String → "Not a string"
        else       → "Unknown"
    }

fun main() {
    println(describe(1))
    println(describe("Hello"))
    println(describe(1000L))
    println(describe(2))
    println(describe("other"))
}
```

See when expressions and statements.

Ranges

Check if a number is within a range using `in` operator:

```
fun main() {
    val x = 10
    val y = 9
    if (x in 1..y+1) {
        println("fits in range")
    }
}
```

Check if a number is out of range:

```
fun main() {
    val list = listOf("a", "b", "c")

    if (-1 !in 0..list.lastIndex) {
        println("-1 is out of range")
    }
    if (list.size !in list.indices) {
        println("list size is out of valid list indices range, too")
    }
}
```

Iterate over a range:

```
fun main() {
    for (x in 1..5) {
        print(x)
    }
}
```

Or over a progression:

```
fun main() {
    for (x in 1..10 step 2) {
        print(x)
    }
    println()
    for (x in 9 downTo 0 step 3) {
        print(x)
    }
}
```

See Ranges and progressions.

Collections

Iterate over a collection:

```
fun main() {
    val items = listOf("apple", "banana", "kiwifruit")
    for (item in items) {
        println(item)
    }
}
```

Check if a collection contains an object using `in` operator:

```
fun main() {
    val items = setOf("apple", "banana", "kiwifruit")
    when {
        "orange" in items → println("juicy")
        "apple" in items → println("apple is fine too")
    }
}
```

Use lambda expressions to filter and map collections:

```
fun main() {
    val fruits = listOf("banana", "avocado", "apple", "kiwifruit")
    fruits
      .filter { it.startsWith("a") }
      .sortedBy { it }
      .map { it.uppercase() }
      .forEach { println(it) }
}
```

See Collections overview.

Nullable values and null checks

A reference must be explicitly marked as nullable when a `null` value is possible. Nullable type names have `?` at the end. For example, `Int?` .

Return `null` if `str` does not hold an integer:

```
fun parseInt(str: String): Int? {
    return str.toIntOrNull()
}
```

Use a function returning nullable value:

```
fun parseInt(str: String): Int? {
    return str.toIntOrNull()
}

fun printProduct(arg1: String, arg2: String) {
    val x = parseInt(arg1)
    val y = parseInt(arg2)

    // Using `x * y` yields error because they may hold nulls.
    if (x ≠ null && y ≠ null) {
        // x and y are automatically cast to non-nullable after null check
        println(x * y)
    }
    else {
        println("'$arg1' or '$arg2' is not a number")
    }
}

fun main() {
    printProduct("6", "7")
    printProduct("a", "7")
    printProduct("a", "b")
}
```

or:

```
fun parseInt(str: String): Int? {
    return str.toIntOrNull()
}

fun printProduct(arg1: String, arg2: String) {
    val x = parseInt(arg1)
    val y = parseInt(arg2)

    // ...
    if (x == null) {
        println("Wrong number format in arg1: '$arg1'")
        return
    }
    if (y == null) {
        println("Wrong number format in arg2: '$arg2'")
        return
    }

    // x and y are automatically cast to non-nullable after null check
    println(x * y)
}

fun main() {
    printProduct("6", "7")
    printProduct("a", "7")
    printProduct("99", "b")
}
```

See Null-safety.

Type checks and automatic casts

The `is` operator checks if an expression is an instance of a type. If an immutable local variable or property is checked for a specific type, there's no need to cast it explicitly:

```
fun getStringLength(obj: Any): Int? {
    if (obj is String) {
        // `obj` is automatically cast to `String` in this branch
        return obj.length
    }

    // `obj` is still of type `Any` outside of the type-checked branch
    return null
}

fun main() {
    fun printLength(obj: Any) {
        println("Getting the length of '$obj'. Result: ${getStringLength(obj) ?: "Error: The object is
not a string"} ")
    }
    printLength("Incomprehensibilities")
    printLength(1000)
    printLength(listOf(Any()))
}
```

or:

```
fun getStringLength(obj: Any): Int? {
    if (obj !is String) return null

    // `obj` is automatically cast to `String` in this branch
    return obj.length
}

fun main() {
    fun printLength(obj: Any) {
        println("Getting the length of '$obj'. Result: ${getStringLength(obj) ?: "Error: The object is
not a string"} ")
    }
    printLength("Incomprehensibilities")
    printLength(1000)
    printLength(listOf(Any()))
}
```

or even:

```
fun getStringLength(obj: Any): Int? {
    // `obj` is automatically cast to `String` on the right-hand side of `&&`
    if (obj is String && obj.length >= 0) {
        return obj.length
    }

    return null
}

fun main() {
    fun printLength(obj: Any) {
        println("Getting the length of '$obj'. Result: ${getStringLength(obj) ?: "Error: The object is
not a string"} ")
    }
    printLength("Incomprehensibilities")
    printLength("")
    printLength(1000)
}
```

See Classes and Type casts.

Keywords and operators

Hard keywords

The following tokens are always interpreted as keywords and cannot be used as identifiers:

- `as`
  - is used for type casts.
  - specifies an alias for an import
- `as?` is used for safe type casts.
- `break` terminates the execution of a loop.
- `class` declares a class.
- `continue` proceeds to the next step of the nearest enclosing loop.
- `do` begins a do/while loop (a loop with a postcondition).
- `else` defines the branch of an if expression that is executed when the condition is false.
- `false` specifies the 'false' value of the Boolean type.
- `for` begins a for loop.
- `fun` declares a function.
- `if` begins an if expression.
- `in`
  - specifies the object being iterated in a for loop.
  - is used as an infix operator to check that a value belongs to a range, a collection, or another entity that defines a 'contains' method.

    - is used in when expressions for the same purpose.
    - marks a type parameter as contravariant.
- `!in`
    - is used as an operator to check that a value does NOT belong to a range, a collection, or another entity that defines a 'contains' method.
    - is used in when expressions for the same purpose.
- `interface` declares an interface.
- `is`
    - checks that a value has a certain type.
    - is used in when expressions for the same purpose.
- `!is`
    - checks that a value does NOT have a certain type.
    - is used in when expressions for the same purpose.
- `null` is a constant representing an object reference that doesn't point to any object.
- `object` declares a class and its instance at the same time.
- `package` specifies the package for the current file.
- `return` returns from the nearest enclosing function or anonymous function.
- `super`
    - refers to the superclass implementation of a method or property.
    - calls the superclass constructor from a secondary constructor.
- `this`
    - refers to the current receiver.
    - calls another constructor of the same class from a secondary constructor.
- `throw` throws an exception.
- `true` specifies the 'true' value of the Boolean type.
- `try` begins an exception-handling block.
- `typealias` declares a type alias.
- `typeof` is reserved for future use.
- `val` declares a read-only property or local variable.
- `var` declares a mutable property or local variable.
- `when` begins a when expression (executes one of the given branches).
- `while` begins a while loop (a loop with a precondition).

Soft keywords

The following tokens act as keywords in the context in which they are applicable, and they can be used as identifiers in other contexts:

- `by`
  - delegates the implementation of an interface to another object.
  - delegates the implementation of the accessors for a property to another object.
- `catch` begins a block that handles a specific exception type.
- `constructor` declares a primary or secondary constructor.
- `delegate` is used as an annotation use-site target.
- `dynamic` references a dynamic type in Kotlin/JS code.
- `field`
  - declares an explicit backing field.
  - is used as an annotation use-site target.
- `file` is used as an annotation use-site target.
- `finally` begins a block that is always executed when a try block exits.
- `get`
  - declares the getter of a property.
  - is used as an annotation use-site target.
- `import` imports a declaration from another package into the current file.
- `init` begins an initializer block.
- `param` is used as an annotation use-site target.
- `property` is used as an annotation use-site target.
- `receiver` is used as an annotation use-site target.
- `set`
  - declares the setter of a property.
  - is used as an annotation use-site target.
- `setparam` is used as an annotation use-site target.
- `value` with the `class` keyword declares an inline class.
- `where` specifies the constraints for a generic type parameter.

Modifier keywords

The following tokens act as keywords in modifier lists of declarations, and they can be used as identifiers in other contexts:

- `abstract` marks a class or member as abstract.

- `actual` denotes a platform-specific implementation in multiplatform projects.
- `annotation` declares an annotation class.
- `companion` declares a companion object.
- `const` marks a property as a compile-time constant.
- `crossinline` forbids non-local returns in a lambda passed to an inline function.
- `data` instructs the compiler to generate canonical members for a class.
- `enum` declares an enumeration.
- `expect` marks a declaration as platform-specific, expecting an implementation in platform modules.
- `external` marks a declaration as implemented outside of Kotlin (accessible through JNI or in JavaScript).
- `final` forbids overriding a member.
- `infix` allows calling a function using infix notation.
- `inline` tells the compiler to inline a function and the lambdas passed to it at the call site.
- `inner` allows referring to an outer class instance from a nested class.
- `internal` marks a declaration as visible in the current module.
- `lateinit` allows initializing a non-nullable property outside of a constructor.
- `noinline` turns off inlining of a lambda passed to an inline function.
- `open` allows subclassing a class or overriding a member.
- `operator` marks a function as overloading an operator or implementing a convention.
- `out` marks a type parameter as covariant.
- `override` marks a member as an override of a superclass member.
- `private` marks a declaration as visible in the current class or file.
- `protected` marks a declaration as visible in the current class and its subclasses.
- `public` marks a declaration as visible anywhere.
- `reified` marks a type parameter of an inline function as accessible at runtime.
- `sealed` declares a sealed class (a class with restricted subclassing).
- `suspend` marks a function or lambda as suspending (usable as a coroutine).
- `tailrec` marks a function as tail-recursive (allowing the compiler to replace recursion with iteration).
- `vararg` allows passing a variable number of arguments for a parameter.

Special identifiers

The following identifiers are defined by the compiler in specific contexts, and they can be used as regular identifiers in other contexts:

- `field` is used inside a property accessor to refer to the backing field of the property.
- `it` is used inside a lambda to refer to its parameter implicitly.

Operators and special symbols

Kotlin supports the following operators and special symbols:

- `+`, `-`, `*`, `/`, `%` - mathematical operators
  - `*` is also used to pass an array to a vararg parameter.
- `=`
  - assignment operator.
  - is used to specify default values for parameters.
- `+=`, `-=`, `*=`, `/=`, `%=` - augmented assignment operators.
- `++`, `--` - increment and decrement operators.
- `&&`, `||`, `!` - logical 'and', 'or', 'not' operators (for bitwise operations, use the corresponding infix functions instead).
- `==`, `!=` - equality operators (translated to calls of `equals()` for non-primitive types).
- `===`, `!==` - referential equality operators.
- `<`, `>`, `<=`, `>=` - comparison operators (translated to calls of `compareTo()` for non-primitive types).
- `[`, `]` - indexed access operator (translated to calls of `get` and `set`).
- `!!` asserts that an expression is non-nullable.
- `?.` performs a safe call (calls a method or accesses a property if the receiver is non-nullable).
- `?:` takes the right-hand value if the left-hand value is null (the elvis operator).
- `::` creates a member reference or a class reference.
- `.`
  - accesses members, including nested classes and enum entries.
  - defines and calls extensions.
  - qualifies names and packages.
  - separates the integer and fractional parts of a floating-point literal.
- `..`, `..<` create ranges.
- `:` separates a name from a type in a declaration.
- `?` marks a type as nullable.
- `->`
  - separates the parameters and body of a lambda expression.
  - separates the parameters and return type declaration in a function type.
  - separates the condition and body of a when expression branch.
- `@`
  - introduces an annotation.
  - introduces or references a loop label.

- introduces or references a lambda label.
- references a 'this' expression from an outer scope.
- references an outer superclass.

- `;` separates multiple statements on the same line.
- `$` references a variable or expression in a string template.
- `_`
  - substitutes an unused parameter in a lambda expression.
  - substitutes an unused parameter in a destructuring declaration.

For operator precedence, see this reference in Kotlin grammar.

Packages and imports

In a Kotlin project, code is organized using packages and imports:

- A **package** is a container for one or more Kotlin files. Files are linked to a package using a `package` header.
- An **import** is a directive that makes entities from other packages available in the current file.

Package headers

A source file may start with a package header:

```
package org.example

fun printMessage() { /*...*/ }
class Message(val text: String) { /*...*/ }
```

All contents of the source file, such as classes and functions, belong to this package. Their fully qualified name combines the package name with the entity's name. In this example:

- The fully qualified name of `printMessage()` is `org.example.printMessage`.
- The fully qualified name of `Message` is `org.example.Message`.

If a file has no package header, its contents belong to the root package.

Imports

To use an entity from a file in a different package, use an `import` directive. In addition to the default imports, each file may declare its own imports.

Import a single entity

Import a specific entity so you can use it without qualification:

```
// Message is accessible without qualification
import org.example.Message

fun main() {
    val message = Message("Hello")
    println(message.text)
}
```

Import the contents of a scope

Star imports, ending in an asterisk `*`, import all named entities inside the corresponding scope:

```
// Everything in org.example is accessible
import org.example.*

fun main() {
    printMessage()
    val message = Message("Hi")
}
```

If you import an entity with both a star import and an explicit import, the explicit import takes priority during overload resolution.

Resolve name clashes with aliases

If two imported entities have the same name, use the `as` keyword to locally rename one of them:

```
// Message refers to org.example.Message
import org.example.Message

// TestMessage refers to org.test.Message
import org.test.Message as TestMessage

fun main() {
    val a = Message("from example")
    val b = TestMessage("from test")
}
```

What you can import

The `import` keyword is not limited to classes. You can import any of the following entities, whether they come from a package, a class, an object, or an enum:

- Top-level functions and properties declared directly inside a package:

  ```
  import org.example.printMessage // Top-level function
  import org.example.VERSION      // Top-level property
  ```

- Functions and properties from object declarations:

  ```
  import org.example.Config.DEFAULT_TIMEOUT // Property from an object
  import org.example.Config.loadSettings    // Function from an object
  ```

- Members of a companion object, referenced through the enclosing class name:

```
import org.example.MyClass.create // Refers to MyClass.Companion.create
```

- Enum constants:

```
import org.example.Color.RED
import org.example.Color.GREEN
```

- Nested classes:

```
import org.example.Outer.Nested
```

Default imports

Kotlin includes the following imports by default:

- kotlin.*
- kotlin.annotation.*
- kotlin.collections.*
- kotlin.comparisons.*
- kotlin.io.*
- kotlin.ranges.*
- kotlin.sequences.*
- kotlin.text.*
- kotlin.math.*

Kotlin imports additional packages depending on the target platform:

- JVM:
  - java.lang.*
  - kotlin.jvm.*
- JS:
  - kotlin.js.*

Visibility and imports

The ability to import an entity depends on its visibility modifiers:

- `public` entities can be imported anywhere.
- `internal` entities can be imported only within the same module.
- `protected` entities cannot be imported.
- Top-level `private` entities are only accessible within their declaring file.
- Other `private` entities cannot be imported.

Annotations

Annotations are tags that you can use to attach metadata to elements in your code. Tools and frameworks process this metadata during compilation and runtime, and perform different actions based on it.

You can annotate your code to simplify and automate common tasks, such as generating boilerplate code, enforcing coding standards or writing documentation.

> If you want to develop your own annotation processors, you can use the Kotlin Symbol Processing (KSP) API.

Declaration

Annotations are a special type of class. To declare an annotation, use the `annotation` keyword before the class declaration:

```
annotation class Fancy
```

Additional attributes of the annotation can be specified by annotating the annotation class with meta-annotations:

- `@Target` specifies the possible kinds of elements which can be annotated with the annotation (such as classes, functions, properties, and expressions);
- `@Retention` specifies whether the annotation is stored in the compiled class files and whether it's visible through reflection at runtime (by default, both are true);
- `@Repeatable` allows using the same annotation on a single element multiple times;
- `@MustBeDocumented` specifies that the annotation is part of the public API and should be included in the class or method signature shown in the generated API documentation.

```
@Target(AnnotationTarget.CLASS, AnnotationTarget.FUNCTION,
        AnnotationTarget.TYPE_PARAMETER, AnnotationTarget.VALUE_PARAMETER,
        AnnotationTarget.EXPRESSION)
@Retention(AnnotationRetention.SOURCE)
@MustBeDocumented
annotation class Fancy
```

Usage

```
@Fancy class Foo {
    @Fancy fun baz(@Fancy foo: Int): Int {
        return (@Fancy 1)
    }
}
```

If you need to annotate the primary constructor of a class, you need to add the `constructor` keyword to the constructor declaration, and add the annotations before it:

```
class Foo @Inject constructor(dependency: MyDependency) { ... }
```

You can also annotate property accessors:

```
class Foo {
    var x: MyDependency? = null
        @Inject set
}
```

Constructors

Annotations can have constructors that take parameters.

```
annotation class Special(val why: String)

@Special("example") class Foo {}
```

Allowed parameter types are:

- Types that correspond to Java primitive types (Int, Long etc.)
- Strings
- Classes (`Foo::class`)
- Enums
- Other annotations
- Arrays of the types listed above

Annotation parameters cannot have nullable types, because the JVM does not support storing `null` as a value of an annotation attribute.

If an annotation is used as a parameter of another annotation, its name is not prefixed with the `@` character:

```
annotation class ReplaceWith(val expression: String)

annotation class Deprecated(
        val message: String,
        val replaceWith: ReplaceWith = ReplaceWith(""))

@Deprecated("This function is deprecated, use === instead", ReplaceWith("this === other"))
```

If you need to specify a class as an argument of an annotation, use a Kotlin class (KClass). The Kotlin compiler will automatically convert it to a Java class, so that the Java code can access the annotations and arguments normally.

```
import kotlin.reflect.KClass

annotation class Ann(val arg1: KClass<*>, val arg2: KClass<out Any>)

@Ann(String::class, Int::class) class MyClass
```

Instantiation

In Java, an annotation type is a form of an interface, so you can implement it and use an instance. As an alternative to this mechanism, Kotlin lets you call a constructor of an annotation class in arbitrary code and similarly use the resulting instance.

```
annotation class InfoMarker(val info: String)

fun processInfo(marker: InfoMarker): Unit = TODO()

fun main(args: Array<String>) {
    if (args.isNotEmpty())
        processInfo(getAnnotationReflective(args))
    else
        processInfo(InfoMarker("default"))
}
```

Learn more about instantiation of annotation classes in this KEEP.

Lambdas

Annotations can also be used on lambdas. They will be applied to the `invoke()` method into which the body of the lambda is generated. This is useful for frameworks like Quasar, which uses annotations for concurrency control.

```
annotation class Suspendable

val f = @Suspendable { Fiber.sleep(10) }
```

Annotation use-site targets

When you're annotating a property or a primary constructor parameter, there are multiple Java elements that are generated from the corresponding Kotlin element, and therefore multiple possible locations for the annotation in the generated Java bytecode. To specify how exactly the annotation should be generated, use the following syntax:

```
class Example(@field:Ann val foo,    // annotate only the Java field
              @get:Ann val bar,      // annotate only the Java getter
              @param:Ann val quux)   // annotate only the Java constructor parameter
```

The same syntax can be used to annotate the entire file. To do this, put an annotation with the target `file` at the top level of a file, before the package directive or before all imports if the file is in the default package:

```
@file:JvmName("Foo")

package org.jetbrains.demo
```

If you have multiple annotations with the same target, you can avoid repeating the target by adding brackets after the target and putting all the annotations inside the brackets (except for the `all` meta-target):

```
class Example {
     @set:[Inject VisibleForTesting]
     var collaborator: Collaborator
}
```

The full list of supported use-site targets is:

- `file`
- `field`

- `property` (annotations with this target are not visible to Java)
- `get` (property getter)
- `set` (property setter)
- `all` (a meta-target for properties, see the `all` meta-target section for more information)
- `receiver` (receiver parameter of an extension function or property)

  To annotate the receiver parameter of an extension function, use the following syntax:

  ```
  fun @receiver:Fancy String.myExtension() { ... }
  ```

- `param` (constructor parameter)
- `setparam` (property setter parameter)
- `delegate` (the field storing the delegate instance for a delegated property)

Defaults when no use-site targets are specified

If you don't specify a use-site target, the compiler chooses the target according to the `@Target` annotation of the annotation you use. If there are multiple applicable targets, the compiler chooses one or more of them in the following order:

- The constructor parameter target (`param`).
- The property target (`property`).
- The field target (`field`), if it's applicable and the property target (`property`) isn't.

If none of `param` , `property` , or `field` are applicable, the annotation is invalid, and you need to specify a use-site target explicitly.

Let's use the `@Email` annotation from Jakarta Bean Validation:

```
@Target(value={METHOD,FIELD,ANNOTATION_TYPE,CONSTRUCTOR,PARAMETER,TYPE_USE})
public @interface Email { }
```

With this annotation, consider the following example:

```
data class User(val username: String,
                // @Email is now equivalent to @param:Email @field:Email
                @Email val email: String) {
    // @Email is still equivalent to @field:Email
    @Email val secondaryEmail: String? = null
}
```

In this example, the `@Email` annotation applies to both the constructor parameter and the field targets for the `email` property because the property:

- Is declared in the primary constructor.
- Has no custom getter or setter, so the compiler generates a backing field.

The `@Email` annotation only applies to the field target for the `secondaryEmail` property because the property:

- Isn't declared in the primary constructor.
- Has no custom getter or setter, so the compiler generates a backing field.

`all` meta-target

The `all` target makes it easier to apply the same annotation not only to the parameter and the property or field, but also to the corresponding getter and setter.

Specifically, the annotation marked with `all` is propagated, if applicable:

- To the constructor parameter (`param`) if the property is defined in the primary constructor.
- To the property itself (`property`).
- To the backing field (`field`) if the property has one.
- To the getter (`get`).
- To the setter parameter (`setparam`) if the property is defined as `var` .
- To the Java-only target `RECORD_COMPONENT` if the class has the `@JvmRecord` annotation.

Let's use the `@Email` annotation from Jakarta Bean Validation, which is defined as follows:

```
@Target(value={METHOD,FIELD,ANNOTATION_TYPE,CONSTRUCTOR,PARAMETER,TYPE_USE})
public @interface Email { }
```

In the example below, this `@Email` annotation is applied to all relevant targets:

```
data class User(
    val username: String,
    // Applies @Email to param, field, and get
    @all:Email val email: String,
    // Applies @Email to param, field, get, and setparam
    @all:Email var name: String,
) {
    // Applies @Email to field and getter (not param since it's not in the constructor)
    @all:Email val secondaryEmail: String? = null
}
```

You can use the `all` meta-target with any property, both inside and outside the primary constructor.

Limitations

The `all` target comes with some limitations:

- It does not propagate an annotation to types, potential extension receivers, or context receivers or parameters.
- It cannot be used with multiple annotations:

  ```
  @all:[A B] // forbidden, use @all:A @all:B
  val x: Int = 5
  ```

- It cannot be used with delegated properties.

Java annotations

Java annotations are 100% compatible with Kotlin:

```
import org.junit.Test
import org.junit.Assert.*
import org.junit.Rule
import org.junit.rules.*

class Tests {
    // apply @Rule annotation to property getter
    @get:Rule val tempFolder = TemporaryFolder()

    @Test fun simple() {
        val f = tempFolder.newFile()
        assertEquals(42, getTheAnswer())
    }
}
```

Since the order of parameters for an annotation written in Java is not defined, you can't use a regular function call syntax for passing the arguments. Instead, you need to use the named argument syntax:

```
// Java
public @interface Ann {
    int intValue();
    String stringValue();
}
```

```
// Kotlin
@Ann(intValue = 1, stringValue = "abc") class C
```

Just like in Java, a special case is the `value` parameter; its value can be specified without an explicit name:

```
// Java
public @interface AnnWithValue {
    String value();
}
```

```
// Kotlin
@AnnWithValue("abc") class C
```

Arrays as annotation parameters

If the `value` argument in Java has an array type, it becomes a `vararg` parameter in Kotlin:

```
// Java
public @interface AnnWithArrayValue {
    String[] value();
}
```

```
// Kotlin
@AnnWithArrayValue("abc", "foo", "bar") class C
```

For other arguments that have an array type, you need to use the array literal syntax or `arrayOf(...)`:

```
// Java
public @interface AnnWithArrayMethod {
    String[] names();
}
```

```
@AnnWithArrayMethod(names = ["abc", "foo", "bar"])
class C
```

Accessing properties of an annotation instance

Values of an annotation instance are exposed as properties to Kotlin code:

```
// Java
public @interface Ann {
    int value();
}
```

```
// Kotlin
fun foo(ann: Ann) {
    val i = ann.value
}
```

Ability to not generate JVM 1.8+ annotation targets

If a Kotlin annotation has `TYPE` among its Kotlin targets, the annotation maps to `java.lang.annotation.ElementType.TYPE_USE` in its list of Java annotation targets. This is just like how the `TYPE_PARAMETER` Kotlin target maps to the `java.lang.annotation.ElementType.TYPE_PARAMETER` Java target. This is an issue for Android clients with API levels less than 26, which don't have these targets in the API.

To avoid generating the `TYPE_USE` and `TYPE_PARAMETER` annotation targets, use the new compiler argument `-Xno-new-java-annotation-targets`.

Repeatable annotations

Just like in Java, Kotlin has repeatable annotations, which can be applied to a single code element multiple times. To make your annotation repeatable, mark its declaration with the `@kotlin.annotation.Repeatable` meta-annotation. This will make it repeatable both in Kotlin and Java. Java repeatable annotations are also supported from the Kotlin side.

The main difference with the scheme used in Java is the absence of a *containing annotation*, which the Kotlin compiler generates automatically with a predefined name. For an annotation in the example below, it will generate the containing annotation `@Tag.Container`:

```
@Repeatable
annotation class Tag(val name: String)

// The compiler generates the @Tag.Container containing annotation
```

You can set a custom name for a containing annotation by applying the `@kotlin.jvm.JvmRepeatable` meta-annotation and passing an explicitly declared containing annotation class as an argument:

```
@JvmRepeatable(Tags::class)
annotation class Tag(val name: String)

annotation class Tags(val value: Array<Tag>)
```

To extract Kotlin or Java repeatable annotations via reflection, use the `KAnnotatedElement.findAnnotations()` function.

Learn more about Kotlin repeatable annotations in this KEEP.

Visibility modifiers

Classes, objects, interfaces, constructors, and functions, as well as properties and their setters, can have *visibility modifiers*. Getters always have the same visibility as their properties.

There are four visibility modifiers in Kotlin: `private`, `protected`, `internal`, and `public`. The default visibility is `public`.

On this page, you'll learn how the modifiers apply to different types of declaring scopes.

Packages

Functions, properties, classes, objects, and interfaces can be declared at the "top-level" directly inside a package:

```
// file name: example.kt
package foo

fun baz() { ... }
class Bar { ... }
```

- If you don't use a visibility modifier, `public` is used by default, which means that your declarations will be visible everywhere.
- If you mark a declaration as `private`, it will only be visible inside the file that contains the declaration.
- If you mark it as `internal`, it will be visible everywhere in the same module.
- The `protected` modifier is not available for top-level declarations.

To use a visible top-level declaration from another package, you should import it.

Examples:

```
// file name: example.kt
package foo

private fun foo() { ... } // visible inside example.kt

public var bar: Int = 5 // property is visible everywhere
    private set         // setter is visible only in example.kt

internal val baz = 6    // visible inside the same module
```

Class members

For members declared inside a class:

- `private` means that the member is visible inside this class only (including all its members).
- `protected` means that the member has the same visibility as one marked as `private`, but that it is also visible in subclasses.

- `internal` means that any client *inside this module* who sees the declaring class sees its `internal` members.
- `public` means that any client who sees the declaring class sees its `public` members.

> In Kotlin, an outer class does not see private members of its inner classes.

If you override a `protected` or an `internal` member and do not specify the visibility explicitly, the overriding member will also have the same visibility as the original.

Examples:

```
open class Outer {
    private val a = 1
    protected open val b = 2
    internal open val c = 3
    val d = 4  // public by default

    protected class Nested {
        public val e: Int = 5
    }
}

class Subclass : Outer() {
    // a is not visible
    // b, c and d are visible
    // Nested and e are visible

    override val b = 5   // 'b' is protected
    override val c = 7   // 'c' is internal
}

class Unrelated(o: Outer) {
    // o.a, o.b are not visible
    // o.c and o.d are visible (same module)
    // Outer.Nested is not visible, and Nested::e is not visible either
}
```

Constructors

Use the following syntax to specify the visibility of the primary constructor of a class:

> You need to add an explicit `constructor` keyword.

```
class C private constructor(a: Int) { ... }
```

Here the constructor is `private`. By default, all constructors are `public`, which effectively amounts to them being visible everywhere the class is visible (this means that a constructor of an `internal` class is only visible within the same module).

For sealed classes, constructors are `protected` by default. For more information, see Sealed classes.

Local declarations

Local variables, functions, and classes can't have visibility modifiers.

Modules

The `internal` visibility modifier means that the member is visible within the same module. More specifically, a module is a set of Kotlin files compiled together, for example:

- An IntelliJ IDEA module.
- A Maven project.
- A Gradle source set (with the exception that the `test` source set can access the internal declarations of `main`).

Coding conventions

Commonly known and easy-to-follow coding conventions are vital for any programming language. Here we provide guidelines on the code style and code organization for projects that use Kotlin.

Configure style in IDE

Two most popular IDEs for Kotlin - IntelliJ IDEA and Android Studio provide powerful support for code styling. You can configure them to automatically format your code in consistence with the given code style.

Apply the style guide

1. Go to **Settings/Preferences | Editor | Code Style | Kotlin**.
2. Click **Set from...**.
3. Select **Kotlin style guide**.

Verify that your code follows the style guide

1. Go to **Settings/Preferences | Editor | Inspections | General**.
2. Switch on **Incorrect formatting** inspection. Additional inspections that verify other issues described in the style guide (such as naming conventions) are enabled by default.

For more information, see the Migrate to Kotlin code style with IntelliJ IDEA guide.

Source code organization

Directory structure

In pure Kotlin projects, the recommended directory structure follows the package structure with the common root package omitted. For example, if all the code in the project is in the `org.example.kotlin` package and its subpackages, files with the `org.example.kotlin` package should be placed directly under the source root, and files in `org.example.kotlin.network.socket` should be in the `network/socket` subdirectory of the source root.

> On JVM: In projects where Kotlin is used together with Java, Kotlin source files should reside in the same source root as the Java source files, and follow the same directory structure: each file should be stored in the directory corresponding to each package statement.

Source file names

If a Kotlin file contains a single class or interface (potentially with related top-level declarations), its name should be the same as the name of the class, with the `.kt` extension appended. It applies to all types of classes and interfaces. If a file contains multiple classes, or only top-level declarations, choose a name describing what the file contains, and name the file accordingly. Use upper camel case, where the first letter of each word is capitalized. For example, `ProcessDeclarations.kt`.

The name of the file should describe what the code in the file does. Therefore, you should avoid using meaningless words such as `Util` in file names.

Multiplatform projects

In multiplatform projects, files with top-level declarations in platform-specific source sets should have a suffix associated with the name of the source set. For example:

- **jvm**Main/kotlin/Platform. **jvm** .kt
- **android**Main/kotlin/Platform. **android** .kt
- **ios**Main/kotlin/Platform. **ios** .kt

As for the common source set, files with top-level declarations should not have a suffix. For example, `commonMain/kotlin/Platform.kt`.

Technical details

We recommend following this file naming scheme in multiplatform projects due to JVM limitations: it doesn't allow top-level members (functions, properties).

To work around this, the Kotlin JVM compiler creates wrapper classes (so-called "file facades") that contain top-level member declarations. File facades have an internal name derived from the file name.

In turn, JVM doesn't allow several classes with the same fully qualified name (FQN). This might lead to situations when a Kotlin project cannot be compiled to JVM:

```
root
├─ commonMain/kotlin/myPackage/Platform.kt // contains 'fun count() { }'
├─ jvmMain/kotlin/myPackage/Platform.kt // contains 'fun multiply() { }'
```

Here both `Platform.kt` files are in the same package, so the Kotlin JVM compiler produces two file facades, both of which have FQN `myPackage.PlatformKt`. This produces the "Duplicate JVM classes" error.

The simplest way to avoid that is renaming one of the files according to the guideline above. This naming scheme helps avoid clashes while retaining code readability.

There are two scenarios where these recommendations may seem redundant, but we still advise to follow them:

- Non-JVM platforms don't have issues with duplicating file facades. However, this naming scheme can help you keep file naming consistent.
- On JVM, if source files don't have top-level declarations, the file facades aren't generated, and you won't face naming clashes.

  However, this naming scheme can help you avoid situations when a simple refactoring or an addition could include a top-level function and result in the same "Duplicate JVM classes" error.

Source file organization

Placing multiple declarations (classes, top-level functions or properties) in the same Kotlin source file is encouraged as long as these declarations are closely related to each other semantically, and the file size remains reasonable (not exceeding a few hundred lines).

In particular, when defining extension functions for a class which are relevant for all clients of this class, put them in the same file with the class itself. When defining extension functions that make sense only for a specific client, put them next to the code of that client. Avoid creating files just to hold all extensions of some class.

Class layout

The contents of a class should go in the following order:

1. Property declarations and initializer blocks
2. Secondary constructors
3. Method declarations
4. Companion object

Do not sort the method declarations alphabetically or by visibility, and do not separate regular methods from extension methods. Instead, put related stuff together, so that someone reading the class from top to bottom can follow the logic of what's happening. Choose an order (either higher-level stuff first, or vice versa) and stick to it.

Put nested classes next to the code that uses those classes. If the classes are intended to be used externally and aren't referenced inside the class, put them in the end, after the companion object.

Interface implementation layout

When implementing an interface, keep the implementing members in the same order as members of the interface (if necessary, interspersed with additional private methods used for the implementation).

Overload layout

Always put overloads next to each other in a class.

Naming rules

Package and class naming rules in Kotlin are quite simple:

- Names of packages are always lowercase and do not use underscores (`org.example.project`). Using multi-word names is generally discouraged, but if you do need to use multiple words, you can either just concatenate them together or use camel case (`org.example.myProject`).
- Names of classes and objects use upper camel case:

```
open class DeclarationProcessor { /*...*/ }

object EmptyDeclarationProcessor : DeclarationProcessor() { /*...*/ }
```

Function names

Names of functions, properties, and local variables start with a lowercase letter and use camel case without underscores:

```
fun processDeclarations() { /*...*/ }
var declarationCount = 1
```

Names for class-like functions

There are two exceptions where function names should follow class-naming convention instead. Functions of this kind are usually defined at the top level.

- Factory functions that create class instances can have the same name as the abstract return type:

```
interface Foo { /*...*/ }

class FooImpl : Foo { /*...*/ }

fun Foo(): Foo { return FooImpl() }
```

- `@Composable` functions that return `Unit`:

```
@Composable fun TabHeader { /*...*/ }
```

Names for test methods

In tests (and **only** in tests), you can use method names with spaces enclosed in backticks. Note that such method names are only supported by Android runtime from API level 30. Underscores in method names are also allowed in test code.

```
class MyTestCase {
    @Test fun `ensure everything works`() { /*...*/ }

    @Test fun ensureEverythingWorks_onAndroid() { /*...*/ }
}
```

Property names

Names of constants (properties marked with `const`, or top-level or object `val` properties with no custom `get` function that hold deeply immutable data) should use all uppercase, underscore-separated names following the screaming snake case convention:

```
const val MAX_COUNT = 8
val USER_NAME_FIELD = "UserName"
```

Names of top-level or object properties which hold objects with behavior or mutable data should use camel case names:

```
val mutableCollection: MutableSet<String> = HashSet()
```

Names of properties holding references to singleton objects can use the same naming style as `object` declarations:

```
val PersonComparator: Comparator<Person> = /* ... */
```

For enum constants, it's OK to use either all uppercase, underscore-separated (screaming snake case) names (`enum class Color { RED, GREEN }`) or upper camel case names, depending on the usage.

Names for backing properties

If a class has two properties which are conceptually the same but one is part of a public API and another is an implementation detail, use an underscore as the prefix for the name of the private property:

```
class C {
    private val _elementList = mutableListOf<Element>()

    val elementList: List<Element>
        get() = _elementList
}
```

Choose good names

The name of a class is usually a noun or a noun phrase explaining what the class *is*: `List` , `PersonReader` .

The name of a method is usually a verb or a verb phrase saying what the method *does*: `close` , `readPersons` . The name should also suggest if the method is mutating the object or returning a new one. For instance, `sort` is sorting a collection in place, while `sorted` is returning a sorted copy of the collection.

The names should make it clear what the purpose of the entity is, so it's best to avoid using meaningless words (`Manager` , `Wrapper`) in names.

When using an acronym as part of a declaration name, follow these rules:

- For two-letter acronyms, use uppercase for both letters. For example, `IOStream` .
- For acronyms longer than two letters, capitalize only the first letter. For example, `XmlFormatter` or `HttpInputStream` .

Formatting

Indentation

Use four spaces for indentation. Do not use tabs.

For curly braces, put the opening brace at the end of the line where the construct begins, and the closing brace on a separate line aligned horizontally with the opening construct.

```
if (elements != null) {
    for (element in elements) {
        // ...
    }
}
```

In Kotlin, semicolons are optional, and therefore line breaks are significant. The language design assumes Java-style braces, and you may encounter surprising behavior if you try to use a different formatting style.

Horizontal whitespace

- Put spaces around binary operators (`a + b`). Exception: don't put spaces around the "range to" operator (`0..i`).
- Do not put spaces around unary operators (`a++`).
- Put spaces between control flow keywords (`if` , `when` , `for` , and `while`) and the corresponding opening parenthesis.
- Do not put a space before an opening parenthesis in a primary constructor declaration, method declaration or method call.

```
class A(val x: Int)

fun foo(x: Int) { ... }

fun bar() {
    foo(1)
}
```

- Never put a space after `(` , `[` , or before `]` , `)` .
- Never put a space around `.` or `?.` : `foo.bar().filter { it > 2 }.joinToString()` , `foo?.bar()` .
- Put a space after `//` : `// This is a comment` .
- Do not put spaces around angle brackets used to specify type parameters: `class Map<K, V> { ... }` .
- Do not put spaces around `::` : `Foo::class` , `String::length` .
- Do not put a space before `?` used to mark a nullable type: `String?` .

As a general rule, avoid horizontal alignment of any kind. Renaming an identifier to a name with a different length should not affect the formatting of either the declaration or any of the usages.

Colon

Put a space before `:` in the following scenarios:

- When it's used to separate a type and a supertype.
- When delegating to a superclass constructor or a different constructor of the same class.
- After the `object` keyword.

Don't put a space before `:` when it separates a declaration and its type.

Always put a space after `:` .

```
abstract class Foo<out T : Any> : IFoo {
    abstract fun foo(a: Int): T
}

class FooImpl : Foo() {
    constructor(x: String) : this(x) { /*...*/ }

    val x = object : IFoo { /*...*/ }
}
```

Class headers

Classes with a few primary constructor parameters can be written in a single line:

```
class Person(id: Int, name: String)
```

Classes with longer headers should be formatted so that each primary constructor parameter is in a separate line with indentation. Also, the closing parenthesis should be on a new line. If you use inheritance, the superclass constructor call, or the list of implemented interfaces should be located on the same line as the parenthesis:

```
class Person(
    id: Int,
    name: String,
    surname: String
) : Human(id, name) { /*...*/ }
```

For multiple interfaces, the superclass constructor call should be located first and then each interface should be located in a different line:

```
class Person(
    id: Int,
    name: String,
    surname: String
) : Human(id, name),
    KotlinMaker { /*...*/ }
```

For classes with a long supertype list, put a line break after the colon and align all supertype names horizontally:

```
class MyFavouriteVeryLongClassHolder :
    MyLongHolder<MyFavouriteVeryLongClass>(),
    SomeOtherInterface,
    AndAnotherOne {

    fun foo() { /*...*/ }
}
```

To clearly separate the class header and body when the class header is long, either put a blank line following the class header (as in the example above), or put the opening curly brace on a separate line:

```
class MyFavouriteVeryLongClassHolder :
    MyLongHolder<MyFavouriteVeryLongClass>(),
    SomeOtherInterface,
    AndAnotherOne
{
    fun foo() { /*...*/ }
}
```

Use regular indent (four spaces) for constructor parameters. This ensures that properties declared in the primary constructor have the same indentation as properties declared in the body of a class.

Modifiers order

If a declaration has multiple modifiers, always put them in the following order:

```
public / protected / private / internal
expect / actual
final / open / abstract / sealed / const
external
override
lateinit
tailrec
vararg
suspend
inner
enum / annotation / fun // as a modifier in `fun interface`
companion
inline / value
infix
operator
data
```

Place all annotations before modifiers:

```
@Named("Foo")
private val foo: Foo
```

Unless you're working on a library, omit redundant modifiers (for example, `public`).

Annotations

Place annotations on separate lines before the declaration to which they are attached, and with the same indentation:

```
@Target(AnnotationTarget.PROPERTY)
annotation class JsonExclude
```

Annotations without arguments may be placed on the same line:

```
@JsonExclude @JvmField
var x: String
```

A single annotation without arguments may be placed on the same line as the corresponding declaration:

```
@Test fun foo() { /*...*/ }
```

File annotations

File annotations are placed after the file comment (if any), before the `package` statement, and are separated from `package` with a blank line (to emphasize the fact that they target the file and not the package).

```
/** License, copyright and whatever */
@file:JvmName("FooBar")

package foo.bar
```

Functions

If the function signature doesn't fit on a single line, use the following syntax:

```
fun longMethodName(
    argument: ArgumentType = defaultValue,
    argument2: AnotherArgumentType,
): ReturnType {
    // body
}
```

Use regular indent (four spaces) for function parameters. It helps ensure consistency with constructor parameters.

Prefer using an expression body for functions with the body consisting of a single expression.

```
fun foo(): Int {     // bad
    return 1
}

fun foo() = 1        // good
```

Expression bodies

If the function has an expression body whose first line doesn't fit on the same line as the declaration, put the `=` sign on the first line and indent the expression body by four spaces.

```
fun f(x: String, y: String, z: String) =
    veryLongFunctionCallWithManyWords(andLongParametersToo(), x, y, z)
```

Properties

For very simple read-only properties, consider one-line formatting:

```
val isEmpty: Boolean get() = size == 0
```

For more complex properties, always put `get` and `set` keywords on separate lines:

```
val foo: String
    get() { /*...*/ }
```

For properties with an initializer, if the initializer is long, add a line break after the `=` sign and indent the initializer by four spaces:

```
private val defaultCharset: Charset? =
    EncodingRegistry.getInstance().getDefaultCharsetForPropertiesFiles(file)
```

Control flow statements

If the condition of an `if` or `when` statement is multiline, always use curly braces around the body of the statement. Indent each subsequent line of the condition by four spaces relative to the statement start. Put the closing parentheses of the condition together with the opening curly brace on a separate line:

```
if (!component.isSyncing &&
    !hasAnyKotlinRuntimeInScope(module)
) {
    return createKotlinNotConfiguredPanel(module)
}
```

This helps align the condition and statement bodies.

Put the `else`, `catch`, `finally` keywords, as well as the `while` keyword of a `do-while` loop, on the same line as the preceding curly brace:

```
if (condition) {
    // body
} else {
    // else part
}

try {
    // body
} finally {
    // cleanup
}
```

In a `when` statement, if a branch is more than a single line, consider separating it from adjacent case blocks with a blank line:

```
private fun parsePropertyValue(propName: String, token: Token) {
    when (token) {
        is Token.ValueToken ->
            callback.visitValue(propName, token.value)

        Token.LBRACE -> { // ...
        }
    }
}
```

Put short branches on the same line as the condition, without braces.

```
when (foo) {
    true -> bar() // good
    false -> { baz() } // bad
}
```

Method calls

In long argument lists, put a line break after the opening parenthesis. Indent arguments by four spaces. Group multiple closely related arguments on the same line.

```
drawSquare(
    x = 10, y = 10,
    width = 100, height = 100,
    fill = true
)
```

Put spaces around the `=` sign separating the argument name and value.

Wrap chained calls

When wrapping chained calls, put the `.` character or the `?.` operator on the next line, with a single indent:

```
val anchor = owner
    ?.firstChild!!
    .siblings(forward = true)
    .dropWhile { it is PsiComment || it is PsiWhiteSpace }
```

The first call in the chain should usually have a line break before it, but it's OK to omit it if the code makes more sense that way.

Lambdas

In lambda expressions, spaces should be used around the curly braces, as well as around the arrow which separates the parameters from the body. If a call takes a single lambda, pass it outside parentheses whenever possible.

```
list.filter { it > 10 }
```

If assigning a label for a lambda, do not put a space between the label and the opening curly brace:

```
fun foo() {
    ints.forEach lit@{
        // ...
    }
}
```

When declaring parameter names in a multiline lambda, put the names on the first line, followed by the arrow and the newline:

```
appendCommaSeparated(properties) { prop ->
    val propertyValue = prop.get(obj)  // ...
}
```

If the parameter list is too long to fit on a line, put the arrow on a separate line:

```
foo {
    context: Context,
    environment: Env
    ->
    context.configureEnv(environment)
}
```

Trailing commas

A trailing comma is a comma symbol after the last item in a series of elements:

```
class Person(
    val firstName: String,
    val lastName: String,
    val age: Int, // trailing comma
)
```

Using trailing commas has several benefits:

- It makes version-control diffs cleaner – as all the focus is on the changed value.
- It makes it easy to add and reorder elements – there is no need to add or delete the comma if you manipulate elements.

- It simplifies code generation, for example, for object initializers. The last element can also have a comma.

Trailing commas are entirely optional – your code will still work without them. The Kotlin style guide encourages the use of trailing commas at the declaration site and leaves it at your discretion for the call site.

To enable trailing commas in the IntelliJ IDEA formatter, go to **Settings/Preferences | Editor | Code Style | Kotlin**, open the **Other** tab and select the **Use trailing comma** option.

Enumerations

```
enum class Direction {
    NORTH,
    SOUTH,
    WEST,
    EAST, // trailing comma
}
```

Value arguments

```
fun shift(x: Int, y: Int) { /*...*/ }
shift(
    25,
    20, // trailing comma
)
val colors = listOf(
    "red",
    "green",
    "blue", // trailing comma
)
```

Class properties and parameters

```
class Customer(
    val name: String,
    val lastName: String, // trailing comma
)
class Customer(
    val name: String,
    lastName: String, // trailing comma
)
```

Function value parameters

```
fun powerOf(
    number: Int,
    exponent: Int, // trailing comma
) { /*...*/ }
constructor(
    x: Comparable<Number>,
    y: Iterable<Number>, // trailing comma
) {}
fun print(
    vararg quantity: Int,
    description: String, // trailing comma
) {}
```

Parameters with optional type (including setters)

```
val sum: (Int, Int, Int) -> Int = fun(
    x,
    y,
    z, // trailing comma
): Int {
    return x + y + x
}
println(sum(8, 8, 8))
```

Indexing suffix

```
class Surface {
    operator fun get(x: Int, y: Int) = 2 * x + 4 * y - 10
}
fun getZValue(mySurface: Surface, xValue: Int, yValue: Int) =
    mySurface[
        xValue,
        yValue, // trailing comma
    ]
```

Parameters in lambdas

```
fun main() {
    val x = {
            x: Comparable<Number>,
            y: Iterable<Number>, // trailing comma
        ->
        println("1")
    }
    println(x)
}
```

when entry

```
fun isReferenceApplicable(myReference: KClass<*>) = when (myReference) {
    Comparable::class,
    Iterable::class,
    String::class, // trailing comma
        -> true
    else -> false
}
```

Collection literals (in annotations)

```
annotation class ApplicableFor(val services: Array<String>)
@ApplicableFor([
    "serializer",
    "balancer",
    "database",
    "inMemoryCache", // trailing comma
])
fun run() {}
```

Type arguments

```
fun <T1, T2> foo() {}
fun main() {
    foo<
            Comparable<Number>,
            Iterable<Number>, // trailing comma
            >()
}
```

Type parameters

```
class MyMap<
        MyKey,
        MyValue, // trailing comma
        > {}
```

Destructuring declarations

```
data class Car(val manufacturer: String, val model: String, val year: Int)
val myCar = Car("Tesla", "Y", 2019)
val (
    manufacturer,
    model,
    year, // trailing comma
) = myCar
val cars = listOf<Car>()
fun printMeanValue() {
    var meanValue: Int = 0
    for ((
        _,
        _,
        year, // trailing comma
    ) in cars) {
        meanValue += year
    }
    println(meanValue/cars.size)
}
printMeanValue()
```

Documentation comments

For longer documentation comments, place the opening `/**` on a separate line and begin each subsequent line with an asterisk:

```
/**
 * This is a documentation comment
 * on multiple lines.
 */
```

Short comments can be placed on a single line:

```
/** This is a short documentation comment. */
```

Generally, avoid using `@param` and `@return` tags. Instead, incorporate the description of parameters and return values directly into the documentation comment, and add links to parameters wherever they are mentioned. Use `@param` and `@return` only when a lengthy description is required which doesn't fit into the flow of the main text.

```
// Avoid doing this:

/**
 * Returns the absolute value of the given number.
 * @param number The number to return the absolute value for.
 * @return The absolute value.
 */
fun abs(number: Int): Int { /*...*/ }

// Do this instead:

/**
 * Returns the absolute value of the given [number].
 */
fun abs(number: Int): Int { /*...*/ }
```

Avoid redundant constructs

In general, if a certain syntactic construction in Kotlin is optional and highlighted by the IDE as redundant, you should omit it in your code. Do not leave unnecessary syntactic elements in code just "for clarity".

Unit return type

If a function returns Unit, the return type should be omitted:

```
fun foo() { // ": Unit" is omitted here

}
```

Semicolons

Omit semicolons whenever possible.

String templates

Don't use curly braces when inserting a simple variable into a string template. Use curly braces only for longer expressions:

```
println("$name has ${children.size} children")
```

Use multi-dollar string interpolation to treat the dollar sign chars `$` as string literals:

```
val KClass<*>.jsonSchema : String
    get() = $$"""
        {
            "$schema": "https://json-schema.org/draft/2020-12/schema",
            "$id": "https://example.com/product.schema.json",
            "$dynamicAnchor": "meta",
            "title": "$${simpleName ?: qualifiedName ?: "unknown"}",
            "type": "object"
        }
        """
```

Idiomatic use of language features

Immutability

Prefer using immutable data to mutable. Always declare local variables and properties as `val` rather than `var` if they are not modified after initialization.

Always use immutable collection interfaces (`Collection` , `List` , `Set` , `Map`) to declare collections which are not mutated. When using factory functions to create collection instances, always use functions that return immutable collection types when possible:

```
// Bad: use of a mutable collection type for value which will not be mutated
fun validateValue(actualValue: String, allowedValues: HashSet<String>) { ... }

// Good: immutable collection type used instead
fun validateValue(actualValue: String, allowedValues: Set<String>) { ... }

// Bad: arrayListOf() returns ArrayList<T>, which is a mutable collection type
val allowedValues = arrayListOf("a", "b", "c")

// Good: listOf() returns List<T>
val allowedValues = listOf("a", "b", "c")
```

Default parameter values

Prefer declaring functions with default parameter values to declaring overloaded functions.

```
// Bad
fun foo() = foo("a")
fun foo(a: String) { /*...*/ }

// Good
fun foo(a: String = "a") { /*...*/ }
```

Type aliases

If you have a functional type or a type with type parameters which is used multiple times in a codebase, prefer defining a type alias for it:

```
typealias MouseClickHandler = (Any, MouseEvent) -> Unit
typealias PersonIndex = Map<String, Person>
```

If you use a private or internal type alias for avoiding name collision, prefer the `import ... as ...` mentioned in Packages and Imports.

Lambda parameters

In lambdas which are short and not nested, it's recommended to use the `it` convention instead of declaring the parameter explicitly. In nested lambdas with parameters, always declare parameters explicitly.

Returns in a lambda

Avoid using multiple labeled returns in a lambda. Consider restructuring the lambda so that it will have a single exit point. If that's not possible or not clear enough, consider converting the lambda into an anonymous function.

Do not use a labeled return for the last statement in a lambda.

Named arguments

Use the named argument syntax when a method takes multiple parameters of the same primitive type, or for parameters of `Boolean` type, unless the meaning of all parameters is absolutely clear from context.

```
drawSquare(x = 10, y = 10, width = 100, height = 100, fill = true)
```

Conditional statements

Prefer using the expression form of `try`, `if`, and `when`.

```
return if (x) foo() else bar()
```

```
return when(x) {
    0 -> "zero"
    else -> "nonzero"
}
```

The above is preferable to:

```
if (x)
    return foo()
else
    return bar()
```

```
when(x) {
    0 -> return "zero"
    else -> return "nonzero"
}
```

if versus when

Prefer using `if` for binary conditions instead of `when`. For example, use this syntax with `if`:

```
if (x == null) ... else ...
```

Instead of this one with `when`:

```
when (x) {
    null -> // ...
    else -> // ...
}
```

Prefer using `when` if there are three or more options.

Guard conditions in when expression

Use parentheses when combining multiple boolean expressions in `when` expressions or statements with guard conditions:

```
when (status) {
    is Status.Ok if (status.info.isEmpty() || status.info.id == null) -> "no information"
}
```

Instead of:

```
when (status) {
    is Status.Ok if status.info.isEmpty() || status.info.id == null -> "no information"
}
```

Nullable Boolean values in conditions

If you need to use a nullable `Boolean` in a conditional statement, use `if (value == true)` or `if (value == false)` checks.

Loops

Prefer using higher-order functions (`filter` , `map` etc.) to loops. Exception: `forEach` (prefer using a regular `for` loop instead, unless the receiver of `forEach` is nullable or `forEach` is used as part of a longer call chain).

When making a choice between a complex expression using multiple higher-order functions and a loop, understand the cost of the operations being performed in each case and keep performance considerations in mind.

Loops on ranges

Use the `..<` operator to loop over an open-ended range:

```
for (i in 0..n - 1) { /*...*/ }  // bad
for (i in 0..<n) { /*...*/ }  // good
```

Strings

Prefer string templates to string concatenation.

Prefer multiline strings to embedding `\n` escape sequences into regular string literals.

To maintain indentation in multiline strings, use `trimIndent` when the resulting string does not require any internal indentation, or `trimMargin` when internal indentation is required:

```
fun main() {
    println("""
     Not
     trimmed
     text
     """
    )

    println("""
     Trimmed
     text
     """.trimIndent()
    )

    println()

    val a = """Trimmed to margin text:
            |if(a > 1) {
            |    return a
            |}""".trimMargin()

   println(a)
}
```

Learn the difference between Java and Kotlin multiline strings.

Functions vs properties

In some scenarios, functions with no arguments might be interchangeable with read-only properties. Although the semantics are similar, there are some stylistic conventions on when to prefer one to another.

Prefer a property over a function when the underlying algorithm:

- Does not throw.
- Is cheap to calculate (or cached on the first run).
- Returns the same result over invocations if the object state hasn't changed.

Extension functions

Use extension functions liberally. Every time you have a function that works primarily on an object, consider making it an extension function accepting that object as a receiver. To minimize API pollution, restrict the visibility of extension functions as much as it makes sense. As necessary, use local extension functions, member extension functions, or top-level extension functions with private visibility.

Infix functions

Declare a function as `infix` only when it works on two objects which play a similar role. Good examples: `and`, `to`, `zip`. Bad example: `add`.

Do not declare a method as `infix` if it mutates the receiver object.

Factory functions

If you declare a factory function for a class, avoid giving it the same name as the class itself. Prefer using a distinct name, making it clear why the behavior of the factory function is special. Only if there is really no special semantics, you can use the same name as the class.

```
class Point(val x: Double, val y: Double) {
    companion object {
        fun fromPolar(angle: Double, radius: Double) = Point(...)
    }
}
```

If you have an object with multiple overloaded constructors that don't call different superclass constructors and can't be reduced to a single constructor including parameters with default values, prefer to replace the overloaded constructors with factory functions.

Platform types

A public function/method returning an expression of a platform type must declare its Kotlin type explicitly:

```
fun apiCall(): String = MyJavaApi.getProperty("name")
```

Any property (package-level or class-level) initialized with an expression of a platform type must declare its Kotlin type explicitly:

```
class Person {
    val name: String = MyJavaApi.getProperty("name")
}
```

A local value initialized with an expression of a platform type may or may not have a type declaration:

```
fun main() {
    val name = MyJavaApi.getProperty("name")
    println(name)
}
```

Scope functions apply/with/run/also/let

Kotlin provides a set of functions to execute a block of code in the context of a given object: `let`, `run`, `with`, `apply`, and `also`. For the guidance on choosing the right scope function for your case, refer to Scope Functions.

Coding conventions for libraries

When writing libraries, it's recommended to follow an additional set of rules to ensure API stability:

- Always explicitly specify member visibility (to avoid accidentally exposing declarations as public API).
- Always explicitly specify function return types and property types (to avoid accidentally changing the return type when the implementation changes).
- Provide KDoc comments for all public members, except for overrides that do not require any new documentation (to support generating documentation for the library).

Learn more about best practices and ideas to consider when writing an API for your library in the Library authors' guidelines.

Idioms

A collection of random and frequently used idioms in Kotlin. If you have a favorite idiom, contribute it by sending a pull request.

Create DTOs (POJOs/POCOs)

```
data class Customer(val name: String, val email: String)
```

provides a `Customer` class with the following functionality:

- getters (and setters in case of `var`s) for all properties
- `equals()`
- `hashCode()`
- `toString()`
- `copy()`
- `component1()`, `component2()`, ..., for all properties (see Data classes)

Default values for function parameters

```
fun foo(a: Int = 0, b: String = "") { ... }
```

Filter a list

```
val positives = list.filter { x -> x > 0 }
```

Or alternatively, even shorter:

```
val positives = list.filter { it > 0 }
```

Learn the difference between Java and Kotlin filtering.

Check the presence of an element in a collection

```
if ("john@example.com" in emailsList) { ... }

if ("jane@example.com" !in emailsList) { ... }
```

String interpolation

```
println("Name $name")
```

Learn the difference between Java and Kotlin string concatenation.

Read standard input safely

```
// Reads a string and returns null if the input can't be converted into an integer. For example: Hi
there!
val wrongInt = readln().toIntOrNull()
println(wrongInt)
// null

// Reads a string that can be converted into an integer and returns an integer. For example: 13
val correctInt = readln().toIntOrNull()
println(correctInt)
// 13
```

For more information, see Read standard input.

Instance checks

```
when (x) {
    is Foo → ...
    is Bar → ...
    else   → ...
}
```

Read-only list

```
val list = listOf("a", "b", "c")
```

Read-only map

```
val map = mapOf("a" to 1, "b" to 2, "c" to 3)
```

Access a map entry

```
println(map["key"])
map["key"] = value
```

Traverse a map or a list of pairs

```
for ((k, v) in map) {
    println("$k → $v")
}
```

`k` and `v` can be any convenient names, such as `name` and `age`.

Iterate over a range

```
for (i in 1..100) { ... }  // closed-ended range: includes 100
for (i in 1..<100) { ... } // open-ended range: does not include 100
for (x in 2..10 step 2) { ... }
for (x in 10 downTo 1) { ... }
(1..10).forEach { ... }
```

Lazy property

```
val p: String by lazy { // the value is computed only on first access
    // compute the string
}
```

Extension functions

```
fun String.spaceToCamelCase() { ... }

"Convert this to camelcase".spaceToCamelCase()
```

Create a singleton

```
object Resource {
    val name = "Name"
}
```

Use inline value classes for type-safe values

```
@JvmInline
value class EmployeeId(private val id: String)

@JvmInline
value class CustomerId(private val id: String)
```

If you accidentally mix up `EmployeeId` and `CustomerId`, a compilation error is triggered.

The `@JvmInline` annotation is only needed for JVM backends.

Instantiate an abstract class

```
abstract class MyAbstractClass {
    abstract fun doSomething()
    abstract fun sleep()
}

fun main() {
    val myObject = object : MyAbstractClass() {
        override fun doSomething() {
            // ...
        }

        override fun sleep() { // ...
        }
    }
    myObject.doSomething()
}
```

If-not-null shorthand

```
val files = File("Test").listFiles()

println(files?.size) // size is printed if files is not null
```

If-not-null-else shorthand

```
val files = File("Test").listFiles()

// For simple fallback values:
println(files?.size ?: "empty") // if files is null, this prints "empty"

// To calculate a more complicated fallback value in a code block, use `run`
val filesSize = files?.size ?: run {
    val someSize = getSomeSize()
    someSize * 2
}
println(filesSize)
```

Execute an expression if null

```
val values = ...
val email = values["email"] ?: throw IllegalStateException("Email is missing!")
```

Get first item of a possibly empty collection

```
val emails = ... // might be empty
val mainEmail = emails.firstOrNull() ?: ""
```

Learn the difference between Java and Kotlin first item getting.

Execute if not null

```
val value = ...

value?.let {
    ... // execute this block if not null
}
```

Map nullable value if not null

```
val value = ...

val mapped = value?.let { transformValue(it) } ?: defaultValue
// defaultValue is returned if the value or the transform result is null.
```

Return on when statement

```
fun transform(color: String): Int {
    return when (color) {
        "Red" -> 0
        "Green" -> 1
        "Blue" -> 2
        else -> throw IllegalArgumentException("Invalid color param value")
    }
}
```

try-catch expression

```
fun test() {
    val result = try {
        count()
    } catch (e: ArithmeticException) {
        throw IllegalStateException(e)
    }

    // Working with result
}
```

if expression

```
val y = if (x == 1) {
    "one"
} else if (x == 2) {
    "two"
} else {
    "other"
}
```

Builder-style usage of methods that return Unit

```
fun arrayOfMinusOnes(size: Int): IntArray {
    return IntArray(size).apply { fill(-1) }
}
```

Single-expression functions

```
fun theAnswer() = 42
```

This is equivalent to

```
fun theAnswer(): Int {
    return 42
}
```

This can be effectively combined with other idioms, leading to shorter code. For example, with the `when` expression:

```
fun transform(color: String): Int = when (color) {
    "Red" -> 0
    "Green" -> 1
    "Blue" -> 2
    else -> throw IllegalArgumentException("Invalid color param value")
}
```

Call multiple methods on an object instance (with)

```
class Turtle {
    fun penDown()
    fun penUp()
    fun turn(degrees: Double)
    fun forward(pixels: Double)
}

val myTurtle = Turtle()
with(myTurtle) { //draw a 100 pix square
    penDown()
    for (i in 1..4) {
        forward(100.0)
        turn(90.0)
    }
    penUp()
}
```

Configure properties of an object (apply)

```
val myRectangle = Rectangle().apply {
    length = 4
    breadth = 5
    color = 0xFAFAFA
}
```

This is useful for configuring properties that aren't present in the object constructor.

Java 7's try-with-resources

```
val stream = Files.newInputStream(Paths.get("/some/file.txt"))
stream.buffered().reader().use { reader →
    println(reader.readText())
}
```

Generic function that requires the generic type information

```
//  public final class Gson {
//      ...
//      public <T> T fromJson(JsonElement json, Class<T> classOfT) throws JsonSyntaxException {
//      ...

inline fun <reified T: Any> Gson.fromJson(json: JsonElement): T = this.fromJson(json, T::class.java)
```

Swap two variables

```
var a = 1
var b = 2
a = b.also { b = a }
```

Mark code as incomplete (TODO)

Kotlin's standard library has a `TODO()` function that will always throw a `NotImplementedError`. Its return type is `Nothing` so it can be used regardless of expected type. There's also an overload that accepts a reason parameter:

```
fun calcTaxes(): BigDecimal = TODO("Waiting for feedback from accounting")
```

IntelliJ IDEA's kotlin plugin understands the semantics of `TODO()` and automatically adds a code pointer in the TODO tool window.

What's next?

- Learn how to perform typical tasks with strings in Java and Kotlin.
- Learn how to perform typical tasks with collections in Java and Kotlin.
- Learn how to handle nullability in Java and Kotlin.

Types overview

In Kotlin, everything is an object in the sense that you can call member functions and properties on any variable. While certain types have an optimized internal representation as primitive values at runtime (such as numbers, characters, and booleans), they appear and behave like regular classes to you.

This section describes the basic types used in Kotlin:

- Numbers and their unsigned counterparts
- Booleans
- Characters
- Strings
- Arrays

To learn about other Kotlin types, such as `Nothing`, `Any`, and `Unit`, look through the Kotlin API reference:

- `Any`
- `Nothing`
- `Unit`

Kotlin also has non-denotable types. They are the types that you can't write directly in the Kotlin code. Instead, the compiler uses them internally, for example, for interoperability with other languages. Kotlin creates non-denotable types to represent type information that is more precise than what Kotlin source syntax allows.

Even though you can't declare non-denotable types yourself, you may encounter them in compiler diagnostics, IDE tooltips, or inferred type displays. Learn more about non-denotable types in:

- Platform types
- Intersection types
- Integer literal types
- Captured types
- Kotlin language specification: Type system

Learn how to perform type checks and casts in Kotlin.

Numbers

The Kotlin number types represent:

- Integer values (Byte, Short, Int, and Long)
- Floating-point values (Float and Double)

Use number types to store and process numeric data, for example, in arithmetic, counters, measurements, and other calculations.

Choose a number type

In most cases, you can refer to the following rules to determine the correct number type for your task:

- Use `Int` for whole numbers.
- Use `Long` for whole numbers outside the `Int` range.
- Use `Double` for decimal numbers.
- Use `Float` when lower precision is acceptable or required.
- Use `Byte` and `Short` when an API or data format requires them.

Kotlin also provides Unsigned integer types as a Beta feature.

Integer types

Kotlin provides four integer types with different sizes and value ranges:

Type	Size (bits)	Min value	Max value
`Byte`	8	-128	127
`Short`	16	-32768	32767
`Int`	32	-2,147,483,648 (-231)	2,147,483,647 (231 - 1)
`Long`	64	-9,223,372,036,854,775,808 (-263)	9,223,372,036,854,775,807 (263 - 1)

Declare integer values

Kotlin supports the following literal forms for integer values:

- Decimals: `123`
- Hexadecimals: `0x0F`
- Binaries: `0b00001011`

Kotlin does not support octal literals.

To declare a numeric value, specify the type explicitly:

```
val one: Int = 1

// Use underscores to improve readability
val oneBillion: Long = 1_000_000_000
val hexBytes: Int = 0x7F_EC_DE_5E
val bytes: Int = 0b01010010_01101001_10010100_10010010

val oneByte: Byte = 1
val oneShort: Short = 1
```

You can also append the `L` suffix, to declare a `Long` value:

```
val oneLong = 1L
```

When you declare a numeric type explicitly, the compiler checks that the value fits in the range of that type:

```
// Value fits in Byte
val oneByte: Byte = 1

// Error: the value does not fit in Byte
val tooBig: Byte = 128
```

When you do not specify a numeric type, Kotlin infers `Int` if the value fits in the `Int` range. Otherwise, Kotlin infers `Long`:

```
val million = 1_000_000 // Int
val threeBillion = 3_000_000_000 // Long
```

If a value can be absent, use nullable types:

```
val maybeAbsent: Int? = null
```

Floating-point types

For numbers with a fractional part, Kotlin provides `Float` and `Double`.

Floating-point types follow the IEEE 754 standard. `Float` reflects the *single precision*. `Double` reflects the *double precision*.

Floating-point types differ in size and precision:

Type	Size (bits)	Significant bits	Exponent bits	Decimal digits
`Float`	32	24	8	6-7
`Double`	64	53	11	15-16

Declare floating-point values

To declare a floating-point literal, include a decimal point (`.`) or use exponent notation:

```
val pi = 3.14
val avogadro = 6.02214076e23
```

By default, Kotlin infers floating-point literals as `Double`. To declare a `Float`, add the `f` or `F` suffix:

```
val pi = 3.14 // Double
val eFloat = 2.7182817f // Float
```

Kotlin rounds a `Float` literal that contains more precision than `Float` can store.

If a value can be absent, use nullable types:

```
val maybeAbsent: Double? = null
```

Arithmetic operations

Kotlin supports the standard arithmetic operations on numbers: `+`, `-`, `*`, `/`, and `%`.

Use these operators to perform common calculations:

```
fun main() {
    println(1 + 2) // 3
    println(2_500_000_000L - 1L) // 2499999999
    println(3.14 * 2.71) // 8.5094
    println(10.0 / 3) // 3.3333333333333335
}
```

The result type depends on the types of the operands. Learn more in Mixed numeric expressions.

> You can override these operators in custom number classes. For more information, see Operator overloading.

Integer division

Division between integer values always returns an integer result. The compiler discards the fractional part:

```
fun main() {
    val intValue = 5 / 2
    println(intValue) // 2

    val longValue = 5L / 2
    println(longValue) // 2
}
```

To return a floating-point result, make at least one operand a `Float` or `Double`:

```
fun main() {
    val a = 5 / 2.0
    println(a) // 2.5

    val b = 5 / 2.toDouble()
    println(b) // 2.5
}
```

Type conversion

Numeric types are not subtypes of one another. Kotlin requires explicit conversions to avoid silent data loss and unexpected behavior.

For example, a function that expects `Double` cannot accept an `Int` or a `Float` value without conversion:

```
fun main() {
    fun printDouble(x: Double) {
        print(x)
    }

    val x = 1.0
    val xInt = 1
    val xFloat = 1.0f
    val one: Double = 1 // Error: initializer type mismatch

    printDouble(x) // OK
    printDouble(xInt) // Error: argument type mismatch
    printDouble(xFloat) // Error: argument type mismatch
}
```

All number types support conversions to other number types. To convert a number to another type, use an explicit conversion function:

- `toByte()`
- `toShort()`
- `toInt()`
- `toLong()`
- `toFloat()`
- `toDouble()`

For example, the following code converts an `Int` value to `Double`:

```
fun main() {
    val intValue: Int = 1
    val doubleValue = intValue.toDouble()

    println(doubleValue) // 1.0
}
```

When you convert a floating-point value to an integer type, the compiler discards the fractional part:

```
fun main() {
    val d: Double = 1.5
    val l: Long = d.toLong()

    println(l) // 1
}
```

Mixed numeric expressions

Kotlin does not support implicit conversion for assignments or function arguments. However, you can combine different numeric types in arithmetic expressions. In such cases, Kotlin determines a result type based on the operand types, and arithmetic operators handle the conversion automatically:

```
val intNumber: Int = 1
val longNumber: Long = 1000
val result = intNumber + longNumber // 1001, Long
```

If you try to assign the result to a smaller type, the compiler reports an error:

```
val intNumber: Int = 1
val longNumber: Long = 1000
val result: Int = intNumber + longNumber
// Error: Initializer type mismatch
```

Integer literal types

During type inference, Kotlin treats unsuffixed integer literals as a special Integer Literal Type (ILT) until the surrounding context determines a specific type:

```
fun List<Any>.log() {
    println(joinToString(" | ") { it::class.simpleName ?: "Unknown" })
}

fun main() {
    listOf(1, 2).log()
    // Int | Int

    listOf(1L, 2L).log()
    // Long | Long

    // Compiler interprets 1 as an ILT and resolves it to Long
    listOf(1, 2L).log()
    // Long | Long

    // .toInt() converts the literal to Int
    listOf(1.toInt(), 2L).log()
    // Int | Long
}
```

It's especially easy to miss with the `Int` and `Long` values because they have the same string representation at runtime. To avoid this, specify the expected type or convert values explicitly:

```
fun List<Any>.log() {
    println(joinToString(" | ") { it::class.simpleName ?: "Unknown" })
}

fun main() {
    val longValues: List<Long> = listOf(1, 2L)
    longValues.log()
    // Long | Long

    val numberValues: List<Number> = listOf(1.toInt(), 2L)
    numberValues.log()
    // Int | Long
}
```

You can also use an explicit type to catch unintended type inference:

```
fun main() {
    val intValues: List<Int> = listOf(1, 2L)
    // Error: initializer type mismatch
}
```

Learn more about Integer literal types.

Data overflow

Numeric types can represent only values within their defined ranges.

If the result of an operation falls outside that range, overflow occurs. If you convert a value to a smaller numeric type, the converted value may not preserve the original numeric value.

This behavior can affect the result of your code even when the compiler accepts it.

Overflow in operations

Each integer type can store only values within its defined range. When the result of an arithmetic operation exceeds that range, *data overflow* occurs:

```
fun main(){
    val intNumber: Int = 2147483647
    // Max Int value is 2147483647
    println(intNumber + 1) // -2147483648
}
```

Here, the result wraps around because the value no longer fits in `Int`.

The compiler does not automatically produce an error when integer overflow occurs.

Overflow in negation

Overflow can also occur during negation. For example, you cannot represent the positive counterpart of `Int.MIN_VALUE` as an `Int`.

```
fun main(){
    val min = Int.MIN_VALUE
    println(-min) // -2147483648
}
```

Narrowing conversions

When you convert a value to a smaller integer type, the result may not preserve the original numeric value:

```
fun main() {
    val large: Int = 130
    val narrowed: Byte = large.toByte()

    println(narrowed) // -126
}
```

However, since floating-point types follow the IEEE 754 Standard, very large results can become `Infinity`:

```
fun main() {
    println(Double.MAX_VALUE * 2) // Infinity
}
```

Bitwise operations

Kotlin provides *bitwise operations* for `Int` and `Long`. These operations are represented by a set of infix functions and `inv()`.

```
fun main() {
    val x = 1

    println(x shl 2) // 4
    println(x and 0x000FF000) // 0
}
```

Bitwise operations include:

- `shl()` – signed shift left
- `shr()` – signed shift right
- `ushr()` – unsigned shift right
- `and()` – bitwise AND
- `or()` – bitwise OR
- `xor()` – bitwise XOR
- `inv()` – bitwise inversion

Floating-point number comparison

In Kotlin, floating-point comparison depends on the static type of the operands.

When the operands are statically known to be `Float` or `Double`, operations on the numbers and the range that they form follow the IEEE 754 Standard for Floating-Point Arithmetic.

However, in generic use cases (such as `Any`, `Comparable<...>`, or `Collection<T>`), behavior differs for operands that are not statically typed as floating-point numbers. In these cases, Kotlin uses the `equals()` and `compareTo()` implementations for `Float` and `Double`.

As a result:

- `NaN` is considered equal to itself
- `NaN` is considered greater than any other element including `POSITIVE_INFINITY`
- `-0.0` is considered less than `0.0`

The following example shows the difference between operands statically typed as floating-point numbers and operands used through generic types:

```
//sampleStart
fun generalizedEquals(a: Any, b: Any): Boolean {
    return a == b
}

fun main() {
    // Operands statically typed as floating-point numbers
    println(Double.NaN == Double.NaN) // false
    println(0.0 == -0.0) // true

    // Operands used through a non-floating-point static type
    println(generalizedEquals(Double.NaN, Double.NaN)) // true
    println(generalizedEquals(0.0, -0.0)) // false
}
```

Boxing and caching numbers on the JVM

On the JVM, non-nullable numeric values are usually stored using primitive types, such as `int`, `long`, or `double`. However, when you use generic types or nullable numeric types like `Int?`, the value is boxed and represented as an object.

The JVM applies a memory optimization technique to small numbers by caching their boxed representations. As a result, boxed numbers with the same value can be referentially equal.

For example, the JVM caches boxed `Integer` values in the range `-128` to `127`. Therefore, the following code returns `true`:

```
fun main() {
    val score: Int = 100
    val savedScore: Int? = score
    val displayedScore: Int? = score

    println(savedScore === displayedScore) // true
}
```

For values outside the cached range, boxed values are separate objects. In that case, they are not referentially equal, even if their values are structurally equal. For this reason, use `==` to compare numeric values:

```
fun main() {
    val score: Int = 10000
    val savedScore: Int? = score
    val displayedScore: Int? = score

    println(savedScore === displayedScore) // false
    println(savedScore == displayedScore) // true
}
```

Unsigned integer types

In addition to integer types, Kotlin provides the following types for unsigned integer numbers:

Type	Size (bits)	Min value	Max value
`UByte`	8	0	255
`UShort`	16	0	65,535
`UInt`	32	0	4,294,967,295 (232 - 1)
`ULong`	64	0	18,446,744,073,709,551,615 (264 - 1)

Unsigned types support most of the operations of their signed counterparts.

Unsigned numbers are implemented as inline classes with a single storage property that contains the corresponding signed counterpart type of the same width. If you want to convert between unsigned and signed integer types, make sure you update your code so that any function calls and operations support the new type.

Unsigned arrays and ranges

Unsigned arrays and operations on them are in Beta. They can be changed incompatibly at any time. Opt-in is required (see the details below).

Same as for primitives, each unsigned type has a corresponding type that represents arrays of that type:

- `UByteArray`: an array of unsigned bytes.
- `UShortArray`: an array of unsigned shorts.
- `UIntArray`: an array of unsigned ints.
- `ULongArray`: an array of unsigned longs.

Same as for signed integer arrays, they provide a similar API to the `Array` class without boxing overhead.

When you use unsigned arrays, you receive a warning that indicates that this feature is not stable yet. To remove the warning, opt-in with the `@ExperimentalUnsignedTypes` annotation. It's up to you to decide if your clients have to explicitly opt-in into usage of your API, but keep in mind that unsigned arrays are not a stable feature, so an API that uses them can be broken by changes in the language. Learn more about opt-in requirements.

Ranges and progressions are supported for `UInt` and `ULong` by classes `UIntRange`, `UIntProgression`, `ULongRange`, and `ULongProgression`. Together with the unsigned integer types, these classes are stable.

Unsigned integers literals

To make unsigned integers easier to use, you can append a suffix to an integer literal indicating a specific unsigned type (similarly to `F` for `Float` or `L` for `Long`):

- `u` and `U` letters signify unsigned literals without specifying the exact type. If no expected type is provided, the compiler uses `UInt` or `ULong` depending on the size of the literal:

```
val b: UByte = 1u  // UByte, expected type provided
val s: UShort = 1u // UShort, expected type provided
val l: ULong = 1u  // ULong, expected type provided

val a1 = 42u // UInt: no expected type provided, constant fits in UInt
val a2 = 0xFFFF_FFFF_FFFFu // ULong: no expected type provided, constant doesn't fit in UInt
```

- `uL` and `UL` explicitly specify that literal should be an unsigned long:

```
val a = 1UL // ULong, even though no expected type provided and the constant fits into UInt
```

Use cases

The main use case of unsigned numbers is utilizing the full bit range of an integer to represent positive values. For example, to represent hexadecimal constants that do not fit in signed types such as color in 32-bit `AARRGGBB` format:

```
data class Color(val representation: UInt)

val yellow = Color(0xFFCC00CCu)
```

You can use unsigned numbers to initialize byte arrays without explicit `toByte()` literal casts:

```
val byteOrderMarkUtf8 = ubyteArrayOf(0xEFu, 0xBBu, 0xBFu)
```

Another use case is interoperability with native APIs. Kotlin allows representing native declarations that contain unsigned types in the signature. The mapping won't substitute unsigned integers with signed ones keeping the semantics unaltered.

Non-goals

While unsigned integers can only represent positive numbers and zero, it's not a goal to use them where application domain requires non-negative integers. For example, as a type of collection size or collection index value.

There are a couple of reasons:

- Using signed integers can help to detect accidental overflows and signal error conditions, such as `List.lastIndex` being -1 for an empty list.
- Unsigned integers cannot be treated as a range-limited version of signed ones because their range of values is not a subset of the signed integers range. Neither signed nor unsigned integers are subtypes of each other.

Booleans

The `Boolean` type represents logical values: `true` and `false`.

Use `Boolean` values in functions that answer yes-or-no questions, and in the `while`, `if`, and `when` conditions.

Declare a `Boolean` variable

To declare a `Boolean` variable, assign it `true` or `false`.

You can specify the `Boolean` type explicitly or let Kotlin infer it from the value:

```
val isTrue: Boolean = true
val isFalse = false // Kotlin infers Boolean
```

If a value can be `null`, use `Boolean?`:

```
val isEnabled: Boolean? = null
```

You cannot assign an integer value to a `Boolean` variable. In Kotlin, `0` and `1` are not `Boolean` values.

Produce `Boolean` values

You can use comparison expressions and functions to produce `Boolean` values:

```
fun main() {
    val number = 10
    val isPositive = number > 0
    println(isPositive) // true

    val language = "Kotlin"
    val isEmpty = language.isEmpty()
    println(isEmpty) // false
}
```

You can use the results in conditions and other expressions as well:

```
fun main() {
    val number = 10
    val isPositive = number > 0 // true

    if (isPositive) {
        println("The number is positive.")
    }
}
```

`Boolean` operations

Kotlin provides operators and infix functions for working with `Boolean` values. You can use them to invert a `Boolean` value or combine multiple `Boolean` values into a single result.

Negation (NOT)

The NOT operator inverts a `Boolean` value.

To use NOT, place the `!` operator before a `Boolean` value:

```
val isOn = true
val isOff = !isOn // isOff is false
```

Logical AND

The AND operator returns `true` only if both operands are `true`.

To use logical AND, place the `&&` operator between operands:

```
val a = false && false // false
val b = false && true // false
val c = true && false // false
val d = true && true  // true
```

If the first operand is `false`, the `&&` operator skips the second operand. To evaluate both operands, use the `and` infix function instead.

Logical OR

The OR operator returns `true` if at least one operand is `true`.

To use logical OR, place the `||` operator between operands:

```
val a = false || false // false
val b = false || true  // true
val c = true || false  // true
val d = true || true   // true
```

If the first operand is `true`, the `||` operator skips the second operand. To evaluate both operands, use the `or` infix function instead.

Exclusive OR (XOR)

The exclusive OR (XOR) operation returns `true` if the operands have different values.

To use XOR, write `xor` between operands:

```
val a = false xor false // false
val b = false xor true  // true
val c = true xor false  // true
val d = true xor true   // false
```

`xor` is an infix function, not an operator.

Learn more about `Boolean` functions in the API Reference.

Operator precedence

If an expression contains multiple logical operations and no parentheses to specify the evaluation order, Kotlin applies precedence rules. Operations with higher precedence are evaluated before operations with lower precedence.

For the `Boolean` operations described in this section, the precedence order is as follows:

1. `!`

2. `xor` (and other infix functions)
3. `&&`
4. `||`

In the following example, the compiler evaluates `&&` before `||`:

```
fun main() {
    val result = true || false && false
    println(result) // true
}
```

To make evaluation order explicit, use parentheses:

```
fun main() {
    val result = (true || false) && false
    println(result) // false
}
```

`Boolean` in conditions

`if`, `when`, and `while` evaluate `Boolean` expressions to direct program flow.

`if` expressions

```
fun main() {
    val number = 4
    val isEven = number % 2 == 0

    // Condition already has the `Boolean` type
    // You do not need to compare it to `true` or `false`
    if (isEven) {
        println("The number is even.")
    } else {
        println("The number is odd.")
    }
}
```

`when` expressions

```
fun main() {
    val number = 3

    when {
        number > 0 -> println("The number is positive.")
        number < 0 -> println("The number is negative.")
        else -> println("The number is zero.")
    }
}
```

`while` loops

```
fun main() {
    var isCalculating = true

    while (isCalculating) {
        println("Calculating...")
        isCalculating = false
    }
}
```

Characters

The `Char` type represents a single character as a UTF-16 code unit.

Use `Char` for individual character values, such as letters, digits, punctuation marks, or whitespace. For sequences of characters, use `String`.

> `Char` is not a numeric type, but each character has a numeric Unicode value that you can access. See Character conversion.

Syntax

To declare a character, enclose the value in single quotes (`' '`). You can specify the `Char` type explicitly or let Kotlin infer it from the value:

```
val letter: Char = 'a'

// Kotlin infers Char because the values are written in single quotes
val digit = '1'
val symbol = '!'
val space = ' '
val separator = ':'
```

A character literal must contain exactly one character. Otherwise, the Kotlin compiler reports an error:

```
val invalid = 'AB' // Error
val invalidEmpty = '' // Error
```

Nullable values

To store a nullable value, use `Char?`:

```
val maybeAbsent: Char? = null
```

> On the JVM, nullable `Char` values are boxed when needed. The same applies to numeric types.

Unicode support

Kotlin represents `Char` values as UTF-16 code units. This means that a single `Char` stores one UTF-16 code unit, not necessarily one complete Unicode character.

Basic Multilingual Plane

A single `Char` can store values in the range from `\u0000` to `\uFFFF`. This range covers the Basic Multilingual Plane (BMP) that includes characters for almost all modern languages and a large number of symbols.

To specify a character by the Unicode value, use `\u` followed by four-digit hexadecimal value from the Unicode table:

```
val unicodeNumber = '\u0031' // Equals '1'
```

Supplementary characters

Unicode characters outside the BMP, such as emojis and some historic scripts, cannot be represented by a single `Char`. In UTF-16, they are encoded as a *surrogate pair*, where two `Char` values together represent one Unicode character in a `String`:

```
fun main() {
    val emoji = "🥦"

    println(emoji.length) // 2
    println(emoji[0])     // First surrogate
    println(emoji[1])     // Second surrogate
}
```

To handle 32-bit symbols individually, use Unicode code points stored as `Int` values.

Escape sequences

Use escape sequences for special characters that are difficult to write directly in source code or have a special meaning.

Every escape sequence begins with a backslash (`\`).

Supported sequence	Description
`\t`	Tab
`\b`	Backspace
`\n`	New Line (LF)
`\r`	Carriage Return (CR)
`\'`	Single quotation mark

Supported sequence	Description
`\"`	Double quotation mark
`\\`	Backslash
`\$`	Dollar sign

For example:

```
val newLine = '\n'
val dollar = '\$'
val backslash = '\\'
```

Operations

`Char` supports comparison, inspection, case conversion, and explicit numeric conversion.

Character comparison

To compare `Char` values, use standard comparison operators such as `==`, `!=`, `<`, `>`, `<=`, and `>=`.

Kotlin compares `Char` values by their numeric Unicode values and returns a `Boolean` value:

```
val before = 'a' < 'b' // true
val after = 'c' > 'd' // false
val different = 'A' == 'a' // false
val equal = 'A' == 'A' // true
```

Character processing

Kotlin provides functions for inspection and case conversion of character values. For example:

```
fun main() {
    val myChar = 'A'
    // Checks if the character represents a digit
    println(myChar.isDigit()) // false
    // Checks if the character represents an uppercase letter
    println(myChar.isUpperCase()) // true
    // Returns a lowercase version
    println(myChar.lowercaseChar()) // 'a'
}
```

Learn more about available functions in the API Reference.

Character arithmetic

You can create another character value by adding or subtracting an integer:

```
fun main() {
    val a = 'a'

    println(a + 1)  // b
    println(a + 2)  // c
    println(a - 32) // A
}
```

These operations follow Unicode values, not language-specific alphabet rules.

You can also use the increment (`++`) and decrement (`--`) operators in the prefix and postfix forms with mutable variables:

```
fun main() {
    var a = 'A'

    a += 10
    println(a)   // 'K'

    println(++a) // 'L'  prefix increment
    println(a++) // 'L'  postfix increment
    println(a)   // 'M'

    println(--a) // 'L'  prefix decrement
    println(a--) // 'L'  postfix decrement
    println(a)   // 'K'
}
```

Character conversion

To convert `Char` to a numeric type, use explicit conversion:

- Use `.code` to get the numeric Unicode value of a character:

```
fun main() {
    val letter = 'A'
    println(letter.code) // 65
}
```

- If a character represents a decimal digit, use `digitToInt()` :

```
fun main() {
    val digit = '7'
    println(digit.digitToInt()) // 7
}
```

If the character may not be a valid digit, use `digitToIntOrNull()` .

Strings

The `String` type represents a sequence of characters. You can use it for text values, such as words, sentences, messages, or structured text.

The `String` type is immutable. After you create a `String` object, its contents stay the same for the rest of its lifetime. Any operation that appears to modify the string actually creates a new string.

Declare strings

To declare a `String` literal, enclose the value in double quotes (`""`). You can specify the `String` type explicitly or let Kotlin infer it from the value:

```
val name: String = "Kotlin"
val message = "Hello, world!" // Kotlin infers String
```

Double-quoted string literals support escape sequences such as `\n` or `\t` :

```
val message = "Hello,\nworld!"
val quote = "Kotlin says, \"Hi\"."
```

Multiline strings

To store text that consists of multiple lines or contains quotes that you don't want to escape, use a multiline string enclosed in triple quotes (`""" """`):

```
val text = """
Hello,
Kotlin
"""

val quote = """Kotlin says, "Hi"."""
```

Multiline strings don't support escape sequences. Kotlin treats these characters as regular text.

Multiline strings preserve line breaks and indentations as written in the source code. This behavior is useful when you want the runtime value to match the text layout in your file.

In the following example, the spaces before each line are part of the resulting string:

```
val text = """
    Hello,
    Kotlin
"""
```

To remove common leading indentation, use the `trimIndent()` function. It detects the common minimal indent of non-empty lines and removes it:

```
fun main() {
    val text = """
        Hello,
        Kotlin
    """.trimIndent()

    println(text)
}
```

To control indentation removal more explicitly, use the `trimMargin()` function. It removes everything before and including the margin prefix on each line:

```
fun main() {
    val text = """
        |Hello,
        |Kotlin
    """.trimMargin()

    println(text)
}
```

By default, the `trimMargin()` function uses a pipe symbol (`|`) as the margin prefix, but you can pass another character as a parameter. For example: `trimMargin(">")` .

When you process a string with functions like `trimIndent()` or `trimMargin()` , the resulting string uses only newline (`\n`) separators, regardless of the platform.

String templates

String templates let you embed variables and expressions directly inside a `String` literal. This process is called *interpolation*. You can use string templates in both regular and multiline strings.

To insert a variable into a string, use the `$` symbol:

```
fun main() {
    val name = "Kotlin"
    println("Hello, $name")
    // Hello, Kotlin
}
```

To insert an expression into a string or to place a variable directly next to other text, use `${}` :

```
fun main() {
    val text = "abc"
    println("The length of $text is ${text.length}")
    // The length of abc is 3

    val language = "Kotlin"
    println("${language}Lang")
    // KotlinLang
}
```

You can also combine strings with the `+` operator. However, string templates are usually easier to read and more idiomatic.

Template expressions can also contain double-quoted strings without escaping:

```
// Double-quoted string
val test = "${"test".uppercase()}"

// Multiline string
val result = """
Result: ${"OK".lowercase()}
"""
```

Nullable values in string templates

If an interpolated expression or variable evaluates to `null`, the Kotlin compiler inserts the text `null` into the resulting string. To replace `null` with another value, use the Elvis operator (`?:`):

```
fun main(){
    val text: String? = null

    println("Hello, $text")
    // Hello, null

    println("Hello, ${text ?: "Kotlin"}")
    // Hello, Kotlin
}
```

Multi-dollar string interpolation

In regular string templates, a single dollar sign (`$`) starts interpolation. If you need to include literal dollar signs in a string, use **multi-dollar string interpolation**.

Multi-dollar string interpolation allows you to specify how many consecutive dollar signs are required to trigger interpolation. Dollar signs below that number are treated as literal characters.

For example, when you use `$$` before a string literal, interpolation begins only with two consecutive dollar signs:

```
val KClass<*>.jsonSchema : String
    get() = $$"""
    {
      "$schema": "https://json-schema.org/draft/2020-12/schema",
      "$id": "https://example.com/product.schema.json",
      "$dynamicAnchor": "meta",
      "title": "$${simpleName ?: qualifiedName ?: "unknown"}",
      "type": "object"
    }
    """
```

If you use single-dollar string interpolation, multi-dollar string interpolation doesn't affect your code. You can continue using a single `$` and apply multi-dollar signs when needed.

Basic string operations

Kotlin provides a range of operations for working with strings. This section introduces some of the most commonly used operations.

Learn more about all available functions in the API Reference.

Get string length

To get the number of characters in a string, use the `length` property:

```
fun main (){
    val language = "Kotlin"
    println(language.length)
    // 6
}
```

Access characters

You can access an individual character in a string with the indexing operator (`[]`):

```
fun main (){
    val language = "Kotlin"

    println(language[0])
    // K
    println(language[5])
    // n
}
```

A string index starts at zero. If you try to access an index outside the valid range, Kotlin throws an exception.

You can also iterate over the characters in a string:

```
fun main(){
    for (char in "Kotlin") {
      println(char)
    }
}
```

Extract parts of a string

To extract parts of a string, use one of the following functions:

- `substring()` to return a new string with the selected part of the original text.
- `subSequence()` to return a `CharSequence` with the selected part of the original text.

For example:

```
fun main() {
//sampleStart
    val text = "Kotlin"
    println(text.substring(1))
    // otlin
    println(text.substring(1, 5))
    // otli
    println(text.subSequence(1, 5))
    // otli
}
```

Since the `String` type is immutable, these functions don't modify the original string.

Compare strings

You can check whether two strings have the same content with the `==` operator:

```
fun main(){
    println("kotlin" == "kotlin")
    // true

    println("kotlin" == "Kotlin")
    // false
}
```

You can also compare strings lexicographically (character by character) with the `compareTo()` function. It scans both strings until it finds the first differing pair of characters and returns:

- `0` when the strings are equal.
- A value less than `0` when the receiver is smaller than the argument.
- A value greater than `0` when the receiver is greater than the argument.

```
fun main() {
//sampleStart
    println("abc".compareTo("abd") < 0)
    // true

    println("abc".compareTo("ABC") > 0)
    // true

    // Pass true to ignore case differences
    println("abc".compareTo("ABC", ignoreCase = true) == 0)
    // true
}
```

Work with string content

If you want to change the content of a string, create a modified copy of it with functions like `.trim()`, `.replace()`, `.uppercase()`, and `.lowercase()`:

```
fun main() {
    val text = "  Hello, Kotlin  "

    println(text.trim())
    // Hello, Kotlin

    println(text.replace("Kotlin", "world"))
    //   Hello, world

    println(text.uppercase())
    //   HELLO, KOTLIN

    println(text.lowercase())
    //   hello, kotlin
}
```

You can also inspect the string content with the `contains()`, `startsWith()`, and `endsWith()` functions:

```
fun main() {
    val domain = "kotlinlang.org"

    // Checks if the string contains "."
    println(domain.contains("."))
    // true

    // Checks if the string starts with "kotlin"
    println(domain.startsWith("kotlin"))
    // true

    // Checks if the string ends with ".org"
    println(domain.endsWith(".org"))
    // true
}
```

Split strings

You can divide a string into parts around a delimiter with the `split()` function:

```
fun main() {
    val numbers = "one, two, three"
    println(numbers.split(", "))
    // [one, two, three]
}
```

If you want to split a string into individual lines, use the `lines()` function:

```
fun main() {
    val numbers = "one\ntwo\nthree"
    println(numbers.lines())
    // [one, two, three]
}
```

Build and format strings

For most formatting tasks in Kotlin, use string templates.

When you concatenate strings with the `+` operator, Kotlin creates a new `String` object for each operation. However, this approach may not be beneficial in loops or when you assemble many pieces. To avoid such issues, you can use the `buildString()` function or `StringBuilder`. They collect all pieces in a single mutable buffer and produce only one string at the end.

Use the `buildString()` function when the logic that determines what to append is complex. For example, when you have multiple conditions that contribute a different fragment. With `buildString()`, you don't handle the buffer directly. The function creates a `StringBuilder` internally, runs your block, and returns the resulting string.

```
fun main() {

    val hasErrors = true
    val hasWarnings = true
    val isComplete = false

    // buildString creates an empty buffer
    val status = buildString {
        // Appends "Errors found" to the buffer
        if (hasErrors) append("Errors found")
        if (hasWarnings) {
            // The buffer is not empty, appends "; "
            if (isNotEmpty()) append("; ")
            // Appends "Warnings found"
            append("Warnings found")
        }
        // isComplete = false, nothing to append
        if (isComplete) {
            if (isNotEmpty()) append("; ")
            append("Completed")
        }
        // The buffer is not empty, skips the fallback
        if (isEmpty()) append("OK")
    }

    println(status)
    // Errors found; Warnings found
}
```

Use `StringBuilder` when you need the buffer as an explicit value. For example, to change the existing text:

```
fun main() {
    val text = "Hello, Kotlin"
    val builder = StringBuilder(text)

    builder.replace(7, 13, "world")
    println(builder.toString())
    // Hello, world
}
```

On the JVM, you can also format a string with the `String.format()` function:

```
val text = String.format("Hello, %s", "Kotlin")
```

Use the `String.format()` function only when you specifically need formatter-style specifiers on the JVM. Learn more about format specifiers in the Java Class Formatter documentation.

String conversion

Often you may use strings to represent values of other types, such as numbers, `Boolean` values, or identifiers from the input. Kotlin provides functions for converting values to strings and for parsing strings into other types.

To return a string representation of a value, use the `toString()` function:

```
val number = 10
val text = number.toString()
```

In string templates and string concatenation, Kotlin converts values to strings automatically.

To convert a string to another type, use the corresponding parsing functions:

- For integer values: `toByte()`, `toShort()`, `toInt()`, `toLong()`
- For floating-point values: `toDouble()`, `toFloat()`
- For booleans: `toBoolean()`, `toBooleanStrict()`

These functions return a value of the requested type if the string has a valid format. If the input may be invalid, use the `OrNull` variants. These functions return `null` instead of throwing an exception making them safe for user input or data that you don't fully control:

```
val toInt = "10".toInt() // 10

// 1000000000000 exceeds maximum value of Int
val toIntInvalid = "1000000000000".toIntOrNull()

val toBoolean = "true".toBooleanStrict() // true
val toBooleanInvalid = "yes".toBooleanStrictOrNull() // null
```

Arrays

An array is a data structure that holds a fixed number of values of the same type or its subtypes. Array elements are ordered and accessed by index.

Kotlin provides the `Array<T>` class and primitive-type arrays.

When to use arrays

Use arrays for interoperability with Java APIs or low-level requirements. For example, if you have performance requirements beyond what is needed for regular applications, or you need to build custom data structures.

For most use cases, prefer collections instead.

Functionality	Arrays	Collections
Size	Fixed	Depends on the type
Read-only variant	No, always mutable	Yes (`List` and `Set`)
Adding and removing elements	No native support. Allocate and copy to a new array	Yes (mutable collections)
Structural equality with `==`	No, compares references. Use `.contentEquals()` instead	Yes
Primitive values	Primitive-type arrays store values without boxing	Usually boxed

Functionality	Arrays	Collections
Java interoperability	Maps to `T[]`	Maps to `java.util.List` and `java.util.Set`
Functional-style filtering and transformations	Limited	Extensive

Learn how to convert arrays to collections.

Create arrays

To create arrays, you can use:

- The `arrayOf()`, `arrayOfNulls()`, or `emptyArray()` functions.
- The `Array` constructor.

> Declaring an array with `val` only prevents reassigning the variable but doesn't make the contents read-only. Elements are mutable in both `val` and `var` arrays. The distinction only affects the reference, not the contents. For a read-only view, use collections instead.

Array with values

To create a typed array from a known set of values, use the `arrayOf()` function. Kotlin infers the type automatically:

```
fun main() {
    val simpleArray = arrayOf(1, 2, 3) // Array<Int>
    println(simpleArray.joinToString())
    // 1, 2, 3
}
```

Empty array

To create an array with no elements, use the `emptyArray()` function. You can specify the type of elements on the left-hand or right-hand side of the assignment:

```
val emptyArrayRight = emptyArray<String>()
val emptyArrayLeft: Array<String> = emptyArray()
```

Learn how to add elements to an array.

Array with nulls

To create an array of a given size filled with `null` elements, use the `arrayOfNulls()` function:

```
fun main() {
    val nullArray: Array<Int?> = arrayOfNulls(3)
    println(nullArray.joinToString())
```

```
    // null, null, null
}
```

Array constructor

The `Array` constructor takes the array size and a function that returns values of array elements:

```
fun main() {
    val zeroes = Array<Int>(3) { 0 }
    println(zeroes.joinToString())
    // 0, 0, 0

    val squares = Array(5) { i -> i * i }
    println(squares.joinToString())
    // 0, 1, 4, 9, 16
}
```

Nested arrays

To create a nested or multidimensional array, use an array of arrays. Nested arrays don't have to be the same type or the same size.

```
fun main() {
    // Creates a two-dimensional array
    val twoDArray = Array(2) { Array<Int>(2) { 0 } }
    println(twoDArray.contentDeepToString())
    // [[0, 0], [0, 0]]

    // Creates a three-dimensional array
    val threeDArray = Array(3) { Array(3) { Array<Int>(3) { 0 } } }
    println(threeDArray.contentDeepToString())
    // [[[0, 0, 0], [0, 0, 0], [0, 0, 0]], [[0, 0, 0], [0, 0, 0], [0, 0, 0]], [[0, 0, 0], [0, 0, 0],
[0, 0, 0]]]
}
```

Primitive-type arrays

If you use the `Array` class with primitive values, the compiler boxes these values into objects. To avoid boxing overhead, you can use dedicated primitive-type arrays. They are not subclasses of the `Array<T>` class, but they provide a similar set of functions and properties.

Kotlin type	Java equivalent
`BooleanArray`	`boolean[]`
`ByteArray`	`byte[]`
`CharArray`	`char[]`
`DoubleArray`	`double[]`

Kotlin type	Java equivalent
`FloatArray`	`float[]`
`IntArray`	`int[]`
`LongArray`	`long[]`
`ShortArray`	`short[]`

Kotlin doesn't have a dedicated `StringArray` type. `String` is not a primitive, so use the `arrayOf()` or `arrayOf<String>()` functions with inferred type instead.

To create a primitive-type array, use one of the following options:

- Constructor functions:

```
fun main() {
    // Creates an Int array of size 5 with the values initialized to zero
    val primitiveTypeArray = IntArray(5)
    println(primitiveTypeArray.joinToString())
    // 0, 0, 0, 0, 0

    // Creates an Int array and takes an initializer function
    val squares = IntArray(5) { i -> i * i }
    println(squares.joinToString())
    // 0, 1, 4, 9, 16
}
```

- Factory functions:

```
fun main() {
    // Creates an Int array with 5 elements
    val numbers = intArrayOf(1, 2, 3, 4, 5)
    println(numbers.joinToString())
    // 1, 2, 3, 4, 5

    // Creates a Char array with 3 elements
    val characters = charArrayOf('K', 't', 'l')
    println(characters.joinToString())
    // K, t, l

    // Creates a Double array with 3 elements
    val doubles = doubleArrayOf(0.22, 4.16, 0.5)
    println(doubles.joinToString())
    // 0.22, 4.16, 0.5
}
```

To convert primitive-type arrays to object-type arrays, use the `.toTypedArray()` function.

To convert object-type arrays to primitive-type arrays, use `.toBooleanArray()`, `.toByteArray()`, `.toCharArray()`, and so on.

Work with arrays

Arrays support many of the same operations as collections, including iteration, searching, sorting, and transformations. In Kotlin, you can work with arrays by using them to pass a variable number of arguments to a function or perform operations on the arrays themselves. Find the most common properties and functions in the following table:

Member	Returns
`size`	The number of elements
`indices`	The range of valid indices
`lastIndex`	The last valid index
`first()` and `last()`	First and last element
`isEmpty()` and `isNotEmpty()`	`true` if array is empty or not empty
`contains()`	`true` if array has the element

Learn more about array properties and functions in the API reference.

This section introduces some of the most commonly used operations.

Access and modify elements

To access and modify elements in an array, use the indexed access operator (`[]`):

```
fun main() {
    val simpleArray = arrayOf(1, 2, 3)
    val twoDArray = Array(2) { Array<Int>(2) { 0 } }

    // Accesses the element and modifies it
    simpleArray[0] = 10
    twoDArray[0][0] = 2

    // Prints the modified element
    println(simpleArray[0])
    // 10
    println(twoDArray[0][0])
    // 2
}
```

If you try to access an index outside the bounds of an array, Kotlin throws `ArrayIndexOutOfBoundsException` at runtime.

You can also use the `fill(element, fromIndex, toIndex)` function to replace elements in a range in place. `fromIndex` is inclusive, and `toIndex` is exclusive:

```
fun main() {
    val arr = IntArray(3)
    println(arr.joinToString())
    // 0, 0, 0

   arr.fill(1)
   println(arr.joinToString())
   // 1, 1, 1

   arr.fill(0, 0, 2)
   println(arr.joinToString())
   // 0, 0, 1
}
```

In Kotlin, arrays are *invariant*. This means that `Array<String>` is not a subtype of `Array<Any>`. This prevents possible runtime type failures. To express covariance, use the `Array<out Any>` type projection:

```
fun main() {
    fun printArr(arr: Array<out Any>) {
        for (item in arr) print("$item, ")
    }

    printArr(arrayOf("k", "t", "n"))
    // k, t, n,
}
```

Add and remove elements

Since arrays have a fixed size, they don't support the `.add()` and `.remove()` functions. To perform these operations, you need to create a new array. For that, you can use one of the following options:

- Use the `.copyOf` function:

```
fun main() {
    var arr = intArrayOf(0, 1, 2)

    arr = arr.copyOf(arr.size + 1)
    println(arr.joinToString())
    // 0, 1, 2, 0

    arr[arr.lastIndex] = 3
    println(arr.joinToString())
    // 0, 1, 2, 3
}
```

- Use the `+` or `+=` operators:

```
fun main() {
    var arr = intArrayOf(0, 1, 2)

    arr += 3
    println(arr.joinToString())
    // 0, 1, 2, 3

    arr = arr + intArrayOf(4, 5)
    println(arr.joinToString())
    // 0, 1, 2, 3, 4, 5
}
```

If you need to frequently add or remove elements, use mutable collections instead.

Compare arrays

To compare whether two arrays have the same elements in the same order, use the `.contentEquals()` and `.contentDeepEquals()` functions:

```
fun main() {
    val simpleArray = arrayOf(1, 2, 3)
    val anotherArray = arrayOf(1, 2, 3)

    // Compares contents of arrays
    println(simpleArray.contentEquals(anotherArray))
    // true

    // Using infix notation, compares contents of arrays after an element
    // is changed
    simpleArray[0] = 10
    println(simpleArray contentEquals anotherArray)
    // false
}
```

Don't use equality (`==`) and inequality (`!=`) operators to compare the contents of arrays. These operators check whether the assigned variables point to the same object.

To learn more about why arrays in Kotlin behave this way, see our blog post.

Transform arrays

Kotlin has many useful functions to transform arrays. This section highlights some of them. See the complete list in our API reference.

Sum

To return the sum of all elements in an array, use the `.sum()` function:

```
fun main() {
    val sumArray = arrayOf(1, 2, 3)
    println(sumArray.sum())
    // 6
}
```

The `.sum()` function can only be used with arrays of numeric data types, such as `Int` .

Sort and shuffle

You can sort the elements in the array according to their natural order with the `.sort()` function or randomly shuffle them with the `.shuffle()` function:

```
fun main() {
    val simpleArray = arrayOf(1, 2, 3)

    // Randomly shuffles elements
    simpleArray.shuffle()
    println(simpleArray.joinToString())

    // Sorts elements
    simpleArray.sort()
    println(simpleArray.joinToString())
    // 1, 2, 3
}
```

To get a new sorted array without modifying the original, use the `.sortedArray()` function instead.

Pass variable number of arguments to a function

In Kotlin, you can pass a variable number of arguments to a function via the `vararg` parameter. This is useful when you don't know the number of arguments in advance, like when formatting a message or creating an SQL query.

To pass an array containing a variable number of arguments to a function, use the *spread operator* (`*`). The spread operator passes each element of the array as individual arguments to your chosen function:

```
fun main() {
    val lettersArray = arrayOf("c", "d")
    printAllStrings("a", "b", *lettersArray)
    // abcd
}

fun printAllStrings(vararg strings: String) {
    for (string in strings) {
        print(string)
    }
}
```

For more information, see Variable number of arguments (varargs).

Convert to collections

If you work with different APIs where some use arrays and some use collections, you can convert your arrays to collections and vice versa. For that, use the `.toList()` , `.toSet()` , and `.toMap()` functions. These functions copy the content from your array to the independent copy. They don't reflect subsequent changes to the array.

Convert to List or Set

To convert an array to a `List` or `Set` , use the `.toList()` and `.toSet()` functions:

```
fun main() {
    val simpleArray = arrayOf("a", "b", "c", "c")

    // Converts to a Set
    println(simpleArray.toSet())
    // [a, b, c]

    // Converts to a List
    println(simpleArray.toList())
    // [a, b, c, c]
}
```

Unless you are completely sure that the original array isn't changed or shared elsewhere, don't use `.asList()` and related `as*` functions. These functions wrap the original array instead of copying it. Therefore, changes to the array are reflected in the list and vice versa.

```
fun main() {
    val simpleArray = arrayOf("a", "b", "c")

    val list = simpleArray.asList()
    simpleArray[0] = "d"
    println(list)
    // [d, b, c]
}
```

Convert to Map

To convert an array to a `Map`, use the `.toMap()` function.

You can convert only an array of `Pair<K,V>` to a `Map`. The first value of a `Pair` instance becomes a key, and the second becomes a value. If the same key appears more than once, the last value is used.

This example uses the infix notation to call the `.to` function to create tuples of `Pair`:

```
fun main() {
    val pairArray = arrayOf("apple" to 120, "banana" to 150, "cherry" to 90, "apple" to 140)

    // Converts to a Map
    // Fruits are keys, calorie numbers are values
    // The latest "apple" value overwrites the first one
    println(pairArray.toMap())
    // {apple=140, banana=150, cherry=90}
}
```

Type checks and casts

In Kotlin, you can do two things with types at runtime: check whether an object is a specific type, or convert it to another type. Type **checks** help you confirm the kind of object you're dealing with, while type **casts** attempt to convert the object to another type.

> To learn specifically about **generics** type checks and casts, for example `List<T>`, `Map<K,V>`, see Generics type checks and casts.

Checks with `is` and `!is` operators

Use the `is` operator (or `!is` to negate it) to check if an object matches a type at runtime:

```
fun main() {
    val input: Any = "Hello, Kotlin"

    if (input is String) {
        println("Message length: ${input.length}")
        // Message length: 13
    }

    if (input !is String) { // Same as !(input is String)
        println("Input is not a valid message")
    } else {
        println("Processing message: ${input.length} characters")
        // Processing message: 13 characters
    }
}
```

You can also use `is` and `!is` operators to check if an object matches a subtype:

```
interface Animal {
    val name: String
    fun speak()
}

class Dog(override val name: String) : Animal {
    override fun speak() = println("$name says: Woof!")
}

class Cat(override val name: String) : Animal {
    override fun speak() = println("$name says: Meow!")
}
fun handleAnimal(animal: Animal) {
    println("Handling animal: ${animal.name}")
    animal.speak()

    // Use is operator to check for subtypes
    if (animal is Dog) {
        println("Special care instructions: This is a dog.")
    } else if (animal is Cat) {
        println("Special care instructions: This is a cat.")
    }
}
fun main() {
    val pets: List<Animal> = listOf(
        Dog("Buddy"),
        Cat("Whiskers"),
        Dog("Rex")
    )

    for (pet in pets) {
        handleAnimal(pet)
        println("---")
    }
    // Handling animal: Buddy
    // Buddy says: Woof!
    // Special care instructions: This is a dog.
    // ---
    // Handling animal: Whiskers
    // Whiskers says: Meow!
    // Special care instructions: This is a cat.
    // ---
    // Handling animal: Rex
    // Rex says: Woof!
    // Special care instructions: This is a dog.
    // ---
}
```

This example uses the `is` operator to check if the `Animal` class instance has subtype `Dog` or `Cat` to print the relevant care instructions.

You can check if an object is a supertype of its declared type, but it's not worthwhile because the answer is always true. Every class instance is already an instance of its supertypes.

To identify the type of an object at runtime, see Reflection.

Type casts

To convert the type of an object in Kotlin to another type is called **casting**.

In some cases, the compiler automatically casts objects for you. This is called smart-casting.

If you need to explicitly cast a type, use `as?` or `as` cast operators.

Smart casts

The compiler tracks the type checks and explicit casts for immutable values and inserts implicit (safe) casts automatically:

```
fun logMessage(data: Any) {
    // data is automatically cast to String
    if (data is String) {
        println("Received text: ${data.length} characters")
    }
}

fun main() {
    logMessage("Server started")
    // Received text: 14 characters
    logMessage(404)
}
```

The compiler is even smart enough to know that a cast is safe if a negative check leads to a return:

```
fun logMessage(data: Any) {
    // data is automatically cast to String
    if (data !is String) return

    println("Received text: ${data.length} characters")
}

fun main() {
    logMessage("User signed in")
    // Received text: 14 characters
    logMessage(true)
}
```

Control flow

Smart casts work not only for `if` conditional expressions, but also for `when` expressions:

```
fun processInput(data: Any) {
    when (data) {
        // data is automatically cast to Int
        is Int -> println("Log: Assigned new ID ${data + 1}")
        // data is automatically cast to String
        is String -> println("Log: Received message \"$data\"")
        // data is automatically cast to IntArray
        is IntArray -> println("Log: Processed scores, total = ${data.sum()}")
    }
}

fun main() {
    processInput(1001)
    // Log: Assigned new ID 1002
    processInput("System rebooted")
    // Log: Received message "System rebooted"
    processInput(intArrayOf(10, 20, 30))
    // Log: Processed scores, total = 60
}
```

And for `while` loops:

```
sealed interface Status
data class Ok(val currentRoom: String) : Status
data object Error : Status

class RobotVacuum(val rooms: List<String>) {
    var index = 0

    fun status(): Status =
        if (index < rooms.size) Ok(rooms[index])
        else Error

    fun clean(): Status {
        println("Finished cleaning ${rooms[index]}")
        index++
        return status()
    }
}

fun main() {
        val robo = RobotVacuum(listOf("Living Room", "Kitchen", "Hallway"))

    var status: Status = robo.status()
    while (status is Ok) {
        // The compiler smart casts status to OK type, so the currentRoom
        // property is accessible.
        println("Cleaning ${status.currentRoom}...")
        status = robo.clean()
    }
    // Cleaning Living Room...
    // Finished cleaning Living Room
    // Cleaning Kitchen...
    // Finished cleaning Kitchen
    // Cleaning Hallway...
    // Finished cleaning Hallway
    //sampleEnd
}
```

In this example, the sealed interface `Status` has two implementations: the data class `Ok` and the data object `Error`. Only the `Ok` data class has the `currentRoom` property. When the `while` loop condition evaluates to

true, the compiler smart casts the `status` variable to `Ok` type, making the `currentRoom` property accessible within the loop body.

If you declare a variable of `Boolean` type before using it in your `if`, `when`, or `while` condition, any information collected by the compiler about the variable is accessible in the corresponding block for smart-casting.

This can be useful when you want to do things like extract boolean conditions into variables. Then, you can give the variable a meaningful name, which improves your code readability and makes it possible to reuse the variable later in your code. For example:

```
class Cat {
    fun purr() {
        println("Purr purr")
    }
}
fun petAnimal(animal: Any) {
    val isCat = animal is Cat
    if (isCat) {
        // The compiler can access information about
        // isCat, so it knows that animal was smart-cast
        // to the type Cat.
        // Therefore, the purr() function can be called.
        animal.purr()
    }
}

fun main(){
    val kitty = Cat()
    petAnimal(kitty)
    // Purr purr
}
```

Logical operators

The compiler can perform smart casts on the right-hand side of `&&` or `||` operators if there is a type check (regular or negative) on the left-hand side:

```
// x is automatically cast to String on the right-hand side of `||`
if (x !is String || x.length == 0) return

// x is automatically cast to String on the right-hand side of `&&`
if (x is String && x.length > 0) {
    print(x.length) // x is automatically cast to String
}
```

If you combine type checks for objects with an `and` operator (`&&`), the compiler smart-casts the object to all checked types simultaneously. Learn more in Intersection types.

If you combine type checks for objects with an `or` operator (`||`), a smart cast is made to their closest common supertype:

```
interface Status {
    fun signal() {}
}

interface Ok : Status
interface Postponed : Status
interface Declined : Status

fun signalCheck(signalStatus: Any) {
    if (signalStatus is Postponed || signalStatus is Declined) {
        // signalStatus is smart-cast to a common supertype Status
        signalStatus.signal()
    }
}
```

The common supertype is an **approximation** of a union type. Union types are not currently supported in Kotlin.

Intersection types

When the compiler smart-casts an object through multiple `&&` checks, it infers an *intersection type*. This is an internal type that simultaneously satisfies all the checked constraints:

```
interface Bird {
    fun fly()
}

interface Fish {
    fun swim()
}

fun describe(animal: Any) {
    // Infers the Bird and Fish types
    if (animal is Bird && animal is Fish) {
        // Accesses fly() and swim() without additional checks or casts
        animal.fly()
        animal.swim()
    }
}
```

Intersection types are non-denotable. They only exist in the compiler's internal type system to preserve type information during type checking. You can't write them directly in Kotlin code. You may encounter intersection types in compiler error messages and IDE tooltips, typically displayed as `A & B`. The one exception is `T & Any` that declares a definitely non-nullable type. This syntax is reserved specifically to combine a type parameter with `Any`.

```
fun <T> T.assertNotNull(): T & Any = this ?: throw IllegalStateException("null value")
```

Inline functions

The compiler can smart-cast variables captured within lambda functions that are passed to inline functions.

Inline functions are treated as having an implicit `callsInPlace` contract. This means that any lambda functions passed to an inline function are called in place. Since lambda functions are called in place, the compiler knows that a lambda function can't leak references to any variables contained within its function body.

The compiler uses this knowledge, along with other analyses, to decide whether it's safe to smart-cast any of the captured variables. For example:

```
interface Processor {
    fun process()
}

inline fun inlineAction(f: () -> Unit) = f()

fun nextProcessor(): Processor? = null

fun runProcessor(): Processor? {
    var processor: Processor? = null
    inlineAction {
        // The compiler knows that processor is a local variable and inlineAction()
        // is an inline function, so references to processor can't be leaked.
        // Therefore, it's safe to smart-cast processor.

        // If processor isn't null, processor is smart-cast
        if (processor ≠ null) {
            // The compiler knows that processor isn't null, so no safe call
            // is needed
            processor.process()
        }

        processor = nextProcessor()
    }

    return processor
}
```

Exception handling

Smart cast information is passed on to `catch` and `finally` blocks. This makes your code safer as the compiler tracks whether your object has a nullable type. For example:

```
fun testString() {
    var stringInput: String? = null
    // stringInput is smart-cast to String type
    stringInput = ""
    try {
        // The compiler knows that stringInput isn't null
        println(stringInput.length)
        // 0

        // The compiler rejects previous smart cast information for
        // stringInput. Now stringInput has the String? type.
        stringInput = null

        // Trigger an exception
        if (2 > 1) throw Exception()
        stringInput = ""
    } catch (exception: Exception) {
        // The compiler knows stringInput can be null
        // so stringInput stays nullable.
        println(stringInput?.length)
        // null
    }
}
fun main() {
    testString()
}
```

Smart cast prerequisites

Smart casts work only when the compiler can guarantee that the variable won't change between the check and its usage. They can be used in the following conditions:

`val` local variables	Always, except local delegated properties.
`val` properties	If the property is `private`, `internal`, or if the check is performed in the same module where the property is declared. Smart casts can't be used on `open` properties or properties that have custom getters.
`var` local variables	If the variable is not modified between the check and its usage, is not captured in a lambda that modifies it, and is not a local delegated property.
`var` properties	Never, because the variable can be modified at any time by other code.

`as` and `as?` cast operators

Kotlin has two cast operators: `as` and `as?`. You can use both to cast, but they have different behaviors.

If a cast fails with the `as` operator, a `ClassCastException` is thrown at runtime. That's why it's also called the **unsafe** operator. You can use `as` when casting to a non-null type:

```
fun main() {
    val rawInput: Any = "user-1234"

    // Casts to String successfully
    val userId = rawInput as String
    println("Logging in user with ID: $userId")
    // Logging in user with ID: user-1234

    // Triggers ClassCastException
    val wrongCast = rawInput as Int
    println("wrongCast contains: $wrongCast")
    // Exception in thread "main" java.lang.ClassCastException
}
```

If you use the `as?` operator instead, and the cast fails, the operator returns `null`. That's why it's also called the **safe** operator:

```
fun main() {
    val rawInput: Any = "user-1234"

    // Casts to String successfully
    val userId = rawInput as? String
    println("Logging in user with ID: $userId")
    // Logging in user with ID: user-1234

    // Assigns a null value to wrongCast
    val wrongCast = rawInput as? Int
    println("wrongCast contains: $wrongCast")
    // wrongCast contains: null
}
```

To cast a nullable type safely, use the `as?` operator to prevent triggering a `ClassCastException` if the cast fails.

You *can* use `as` with a nullable type. This allows the result to be `null`, but it still throws a `ClassCastException` if the cast is unsuccessful. For this reason, `as?` is the safer option:

```
fun main() {
    val config: Map<String, Any?> = mapOf(
        "username" to "kodee",
        "alias" to null,
        "loginAttempts" to 3
    )

    // Unsafely casts to a nullable String
    val username: String? = config["username"] as String?
    println("Username: $username")
    // Username: kodee

    // Unsafely casts a null value to a nullable String
    val alias: String? = config["alias"] as String?
    println("Alias: $alias")
    // Alias: null

    // Fails to cast to nullable String and throws ClassCastException
    // val unsafeAttempts: String? = config["loginAttempts"] as String?
    // println("Login attempts (unsafe): $unsafeAttempts")
    // Exception in thread "main" java.lang.ClassCastException

    // Fails to cast to nullable String and returns null
    val safeAttempts: String? = config["loginAttempts"] as? String
    println("Login attempts (safe): $safeAttempts")
    // Login attempts (safe): null
}
```

Up and downcasting

In Kotlin, you can cast objects to supertypes and subtypes.

Casting an object to an instance of its superclass is called **upcasting**. Upcasting doesn't need any special syntax or cast operators. For example:

```
interface Animal {
    fun makeSound()
}

class Dog : Animal {
    // Implements behavior for makeSound()
    override fun makeSound() {
        println("Dog says woof!")
    }
}

fun printAnimalInfo(animal: Animal) {
    animal.makeSound()
}

fun main() {
    val dog = Dog()
    // Upcasts Dog instance to Animal
    printAnimalInfo(dog)
    // Dog says woof!
}
```

In this example, when the `printAnimalInfo()` function is called with a `Dog` instance, the compiler upcasts it to `Animal` because that's the expected parameter type. Since the actual object is still a `Dog` instance, the compiler dynamically resolves the `makeSound()` function from the `Dog` class, printing `"Dog says woof!"`.

You'll often see explicit upcasting in Kotlin APIs where behavior depends on an abstract type. It's also common in Jetpack Compose and UI toolkits, which typically treat all UI elements as supertypes and later operate on specific subclasses:

```
val textView = TextView(this)
    textView.text = "Hello, View!"

    // Upcasts from TextView to View
    val view: View = textView

    // Use View functions
    view.setPadding(20, 20, 20, 20)
    // Activity expects a View type
    setContentView(view)
```

Casting an object to an instance of a subclass is called **downcasting**. Because downcasting can be unsafe, you need to use explicit cast operators. To avoid throwing exceptions on failed casts, we recommend using the safe cast operator `as?`, to return `null` if the cast fails:

```
interface Animal {
    fun makeSound()
}

class Dog : Animal {
    override fun makeSound() {
        println("Dog says woof!")
    }

    fun bark() {
        println("BARK!")
    }
}

fun main() {
    // Creates animal as a Dog instance with Animal
    // type
    val animal: Animal = Dog()

    // Safely downcasts animal to Dog type
    val dog: Dog? = animal as? Dog

    // Uses a safe call to call bark() if dog isn't null
    dog?.bark()
    // "BARK!"
}
```

In this example, `animal` is declared as type `Animal`, but it holds a `Dog` instance. The code safely casts `animal` to `Dog` type and uses a safe call (`?.`) to access the `bark()` function.

You'll use downcasting in serialization when deserializing a base class to a specific subtype. It's also common when working with Java libraries that return supertype objects, which you may need to downcast in Kotlin.

Type aliases

Type aliases provide alternative names for existing types. They can make long or frequently used type expressions shorter and easier to understand.

For example, you can create aliases for generic types, function types, and nested or inner classes:

```
// Generic types
typealias UserIndex = Map<Long, User>
typealias FileTable<K> = MutableMap<K, MutableList<File>>

// Function types
typealias RequestHandler = (Request) -> Response
typealias Predicate<T> = (T) -> Boolean

// Inner and nested classes
class Database {
    inner class Transaction
}
typealias DatabaseTransaction = Database.Transaction
```

A type alias doesn't create a new type. It introduces an alternative name for an existing type. The alias and its underlying type are interchangeable. For example, when you add `typealias Predicate<T>` and use `Predicate<Int>`, the compiler expands it to `(Int) -> Boolean`. You can use a value declared with the alias wherever the underlying type is expected, and the other way around:

```
typealias Predicate<T> = (T) -> Boolean

fun evaluate(predicate: Predicate<Int>) = predicate(42)

fun main() {
    val isPositive: (Int) -> Boolean = { it > 0 }
    println(evaluate(isPositive))
    // true

    val isValid: Predicate<Int> = { it > 0 }
    println(listOf(1, -2).filter(isValid))
    // [1]
}
```

Declare type aliases

You can declare a type alias:

- At the top level of a Kotlin file, as a top-level type alias.
- Inside a class, interface, or object, as a nested type alias.

You can't declare a type alias in a local scope, such as inside a function or lambda expression.

The declaration location determines the scope of a type alias, while its visibility determines which code can access it. By default, a type alias is `public`. A nested type alias is accessible only where its containing class, interface, or object is accessible. For example, a `public` alias inside an `internal` class isn't accessible from outside the module.

A type alias can't expose an underlying type with more restrictive visibility than its own. For example, a `public` type alias can't refer to a `private` class.

Top-level type aliases

A top-level type alias is a package-level declaration. Within the same package, you can refer to an alias by its unqualified name. To use the alias from another package, import the alias or refer to it by its qualified name:

```
// UserId.kt
package org.example.users

typealias UserId = Long

// Refers to the alias within the same package by its unqualified name
fun createUser(id: UserId) {
    // ...
}

// UserService.kt
package org.example.services

import org.example.users.UserId

// Uses the imported alias by its unqualified name
fun findUser(id: UserId) {
    // ...
}

// Uses the fully qualified name
fun deleteUser(id: org.example.users.UserId) {
    // ...
}
```

Nested type aliases

Nested type aliases allow for cleaner, more maintainable code by improving encapsulation, reducing package-level clutter, and simplifying internal implementations. Nested type aliases follow the same scope and name-resolution rules as nested classes.

Declare a type alias inside a class, interface, or object when the alternative name is relevant only in the context of that declaration. This keeps the alias close to the code that uses it and avoids adding another name to the package scope.

Within the containing declaration, you can refer to the alias by its unqualified name. Outside the declaration, qualify the alias with the name of its containing declaration:

```
class UserRepository {
    typealias UserIndex = Map<UserId, User>

    // Refers to the alias by its unqualified name inside UserRepository
    fun saveAll(users: UserIndex) {
        // ...
    }
}

// Refers to the alias by its qualified name outside UserRepository
fun synchronizeUsers(users: UserRepository.UserIndex) {
    // ...
}
```

Nested type aliases aren't supported in Kotlin Multiplatform `expect/actual` declarations.

Type parameters

To use type parameters in a nested type alias, add them to the alias declaration:

```
class Graph<Node> {
    typealias Path<T> = List<T>
}

val cityPath: Graph.Path<String> = listOf("London", "Berlin")
```

In this example, `Path` declares its type parameter `T`. In `Graph.Path<String>`, `String` is the type argument for `T` and is independent of the `Node` type parameter declared by `Graph`.

If you refer to a type parameter declared by its containing class or interface, the compiler reports an error:

```
class Graph<Node> {
    typealias Path = List<Node>
    // Unresolved reference 'Node'.
}
```

Here, `Path` refers to `Node` from `Graph` instead of declaring its own type parameter.

Conditions and loops

Kotlin gives you flexible tools to control your program's flow. Use `if`, `when`, and loops to define clear, expressive logic for your conditions.

If expression

To use `if` in Kotlin, add the condition to check within parentheses `()` and the action to take if the result is true within curly braces `{}`. You can use `else` and `else if` for additional branches and checks.

You can also write `if` as an expression, which lets you assign its returned value directly to a variable. In this form, an `else` branch is required. The `if` expression serves the same purpose as the ternary operator (`condition ? then : else`) found in other languages.

For example:

```
fun main() {
    val heightAlice = 160
    val heightBob = 175

        var taller = heightAlice
    if (heightAlice < heightBob) taller = heightBob

    // Uses an else branch
    if (heightAlice > heightBob) {
        taller = heightAlice
    } else {
        taller = heightBob
    }

    // Uses if as an expression
    taller = if (heightAlice > heightBob) heightAlice else heightBob

    // Uses else if as an expression:
    val heightLimit = 150
    val heightOrLimit = if (heightLimit > heightAlice) heightLimit else if (heightAlice > heightBob)
heightAlice else heightBob

    println("Taller height is $taller")
    // Taller height is 175
    println("Height or limit is $heightOrLimit")
    // Height or limit is 175
    //sampleEnd
}
```

Each branch in an `if` expression can be a block, where the value of the last expression becomes the result:

```
fun main() {
        val heightAlice = 160
    val heightBob = 175

    val taller = if (heightAlice > heightBob) {
        print("Choose Alice\n")
        heightAlice
    } else {
        print("Choose Bob\n")
        heightBob
    }

    println("Taller height is $taller")
    //sampleEnd
}
```

When expressions and statements

`when` is a conditional expression that runs code based on multiple possible values or conditions. It's similar to the `switch` statement in Java, C, and other languages. `when` evaluates its argument and compares the result against each branch in order until one branch condition is satisfied. For example:

```
fun main() {
        val userRole = "Editor"
    when (userRole) {
        "Viewer" -> print("User has read-only access")
        "Editor" -> print("User can edit content")
        else -> print("User role is not recognized")
    }
    // User can edit content
    //sampleEnd
}
```

You can use `when` either as an **expression** or a **statement**. As an expression, `when` returns a value you can use later in your code. As a statement, `when` completes an action without returning a result:

Expression	Statement

`// Returns a string assigned to the`
`// text variable`
`val text = when (x) {`
`    1 -> "x == 1"`
`    2 -> "x == 2"`
`    else -> "x is neither 1 nor 2"`
`}`
	`// Returns no result but triggers a`
	`// print statement`
	`when (x) {`
	`    1 -> print("x == 1")`
	`    2 -> print("x == 2")`
	`    else -> print("x is neither 1 nor 2")`
	`}`

Secondly, you can use `when` with or without a subject. The behavior stays the same either way. Using a subject usually makes your code more readable and maintainable because it clearly shows what you're checking.

With subject `x`	Without subject
`when(x) { ... }`	`when { ... }`

How you use `when` determines whether you need to cover all possible cases in your branches. Covering all possible cases is called being *exhaustive*.

Statements

If you use `when` as a statement, you don't need to cover all possible cases. In this example, some cases aren't covered, so no branch is triggered. However, no error occurs:

```
fun main() {
        val deliveryStatus = "OutForDelivery"
    when (deliveryStatus) {
        // Not all cases are covered
        "Pending" -> print("Your order is being prepared")
        "Shipped" -> print("Your order is on the way")
    }
    //sampleEnd
}
```

Just like with `if`, each branch can be a block, and its value is the value of the last expression in the block.

Expressions

If you use `when` as an expression, you **must** cover all possible cases. The value of the first matching branch becomes the value of the overall expression. If you don't cover all cases, the compiler throws an error.

If your `when` expression has a subject, you can use an `else` branch to make sure that all possible cases are covered, but it isn't mandatory. For example, if your subject is a `Boolean`, `enum class`, `sealed class`, or one of their nullable counterparts, you can cover all cases without an `else` branch:

```
import kotlin.random.Random
enum class Bit {
    ZERO, ONE
}

fun getRandomBit(): Bit {
    return if (Random.nextBoolean()) Bit.ONE else Bit.ZERO
}

fun main() {
    val numericValue = when (getRandomBit()) {
        // No else branch is needed because all cases are covered
        Bit.ZERO -> 0
        Bit.ONE -> 1
    }

    println("Random bit as number: $numericValue")
    // Random bit as number: 0
    //sampleEnd
}
```

> To simplify `when` expressions and reduce repetition, try out context-sensitive resolution (currently in preview). This feature allows you to omit the type name when using enum entries or sealed class members in `when` expressions if the expected type is known.
>
> For more information, see Preview of context-sensitive resolution or the related KEEP proposal.

If your `when` expression **doesn't** have a subject, you **must** have an `else` branch or the compiler throws an error. The `else` branch is evaluated when none of the other branch conditions are satisfied:

```
fun main() {
        val localFileSize = 1200
    val remoteFileSize = 1200

    val message = when {
        localFileSize > remoteFileSize -> "Local file is larger than remote file"
        localFileSize < remoteFileSize -> "Local file is smaller than remote file"
        else -> "Local and remote files are the same size"
    }

    println(message)
    // Local and remote files are the same size
    //sampleEnd
}
```

Other ways to use when

`when` expressions and statements offer different ways to simplify your code, handle multiple conditions, and perform type checks.

Group multiple conditions into a single branch using commas:

```
fun main() {
    val ticketPriority = "High"
        when (ticketPriority) {
        "Low", "Medium" -> print("Standard response time")
        else -> print("High-priority handling")
    }
    //sampleEnd
}
```

Use expressions that evaluate to `true` or `false` as branch conditions:

```
fun main() {
    val storedPin = "1234"
    val enteredPin = 1234

        when (enteredPin) {
        // Expression
        storedPin.toInt() -> print("PIN is correct")
        else -> print("Incorrect PIN")
    }
    //sampleEnd
}
```

Check whether a value is or isn't contained in a range or collection using the `in` or `!in` keywords:

```
fun main() {
    val x = 7
    val validNumbers = setOf(15, 16, 17)

        when (x) {
        in 1..10 -> print("x is in the range")
        in validNumbers -> print("x is valid")
        !in 10..20 -> print("x is outside the range")
        else -> print("none of the above")
    }
    //sampleEnd
}
```

Check a value's type using the `is` or `!is` keywords. Due to smart casts, you can access the member functions and properties of the type directly:

```
fun hasPrefix(input: Any): Boolean = when (input) {
    is String -> input.startsWith("ID-")
    else -> false
}

fun main() {
    val testInput = "ID-98345"
    println(hasPrefix(testInput))
    // true
}
```

Use `when` instead of a traditional `if` - `else` `if` chain. Without a subject, the branch conditions are simply boolean expressions. The first branch with a `true` condition runs:

```
fun Int.isOdd() = this % 2 != 0
fun Int.isEven() = this % 2 == 0

fun main() {
        val x = 5
    val y = 8

    when {
        x.isOdd() -> print("x is odd")
        y.isEven() -> print("y is even")
        else -> print("x+y is odd")
    }
    // x is odd
    //sampleEnd
}
```

Finally, capture the subject in a variable by using the following syntax:

```
fun main() {
    val message = when (val input = "yes") {
        "yes" -> "You said yes"
        "no" -> "You said no"
        else -> "Unrecognized input: $input"
    }

    println(message)
    // You said yes
}
```

The scope of a variable introduced as the subject is restricted to the body of the `when` expression or statement.

Guard conditions

Guard conditions allow you to include more than one condition to the branches of a `when` expression or statement, making complex control flow more explicit and concise. You can use guard conditions with `when` as long as it has a subject.

Place a guard condition after the primary condition in the same branch, separated by `if`:

```
sealed interface Animal {
    data class Cat(val mouseHunter: Boolean) : Animal
    data class Dog(val breed: String) : Animal
}

fun feedDog() = println("Feeding a dog")
fun feedCat() = println("Feeding a cat")

fun feedAnimal(animal: Animal) {
    when (animal) {
        // Branch with only primary condition
        // Calls feedDog() when animal is Dog
        is Animal.Dog -> feedDog()
        // Branch with both primary and guard conditions
        // Calls feedCat() when animal is Cat and not mouseHunter
        is Animal.Cat if !animal.mouseHunter -> feedCat()
        // Prints "Unknown animal" if none of the above conditions match
        else -> println("Unknown animal")
    }
}

fun main() {
    val animals = listOf(
        Animal.Dog("Beagle"),
        Animal.Cat(mouseHunter = false),
        Animal.Cat(mouseHunter = true)
    )

    animals.forEach { feedAnimal(it) }
    // Feeding a dog
    // Feeding a cat
    // Unknown animal
}
```

You can't use guard conditions when you have multiple conditions separated by a comma. For example:

```
0, 1 -> print("x == 0 or x == 1")
```

In a single `when` expression or statement, you can combine branches with and without guard conditions. The code in a branch with a guard condition runs only if both the primary condition and the guard condition evaluate to `true`. If the primary condition doesn't match, the guard condition isn't evaluated.

Since `when` statements don't need to cover all cases, using guard conditions in `when` statements without an `else` branch means that if no conditions match, no code is run.

Unlike statements, `when` expressions must cover all cases. If you use guard conditions in `when` expressions without an `else` branch, the compiler requires you to handle every possible case to avoid runtime errors.

Combine multiple guard conditions within a single branch using the boolean operators `&&` (AND) or `||` (OR). Use parentheses around the boolean expressions to avoid confusion:

```
when (animal) {
    is Animal.Cat if (!animal.mouseHunter && animal.hungry) -> feedCat()
}
```

Guard conditions also support `else if`:

```
when (animal) {
    // Checks if `animal` is `Dog`
    is Animal.Dog -> feedDog()
    // Guard condition that checks if `animal` is `Cat` and not `mouseHunter`
    is Animal.Cat if !animal.mouseHunter -> feedCat()
    // Calls giveLettuce() if none of the above conditions match and animal.eatsPlants is true
    else if animal.eatsPlants -> giveLettuce()
    // Prints "Unknown animal" if none of the above conditions match
    else -> println("Unknown animal")
}
```

Bytecode generation on the JVM

When you compile Kotlin code for JVM 21 or later, the compiler generates an `invokedynamic` instruction for eligible `when` expressions. This produces smaller bytecode, similar to the bytecode produced by Java `switch` statements.

The compiler uses `invokedynamic` with the `SwitchBootstraps.typeSwitch()` method when all the following conditions are met:

- All conditions except for `else` are `is` or `null` checks.
- The `when` expression doesn't contain guard conditions (`if`).
- The conditions don't include types that can't be type-checked directly, such as mutable Kotlin collections (`MutableList`) or function types (`kotlin.Function1` , `kotlin.Function2` , and so on).
- The `when` expression has at least two conditions besides `else` .
- All branches check the same subject of the `when` expression.

For example:

```
open class Shape

class Circle : Shape()
class Rectangle : Shape()
class Triangle : Shape()

fun countCorners(shape: Shape) = when (shape) {
    is Circle -> 0
    is Rectangle -> 4
    is Triangle -> 3
    else -> -1
}
```

The `when (shape)` expression here compiles to a single `invokedynamic` type switch instead of multiple `instanceof` checks in the bytecode.

For loops

Use the `for` loop to iterate through a collection, array, or range:

```
for (item in collection) print(item)
```

The body of a `for` loop can be a block with curly braces `{}` .

```
fun main() {
    val shoppingList = listOf("Milk", "Bananas", "Bread")
        println("Things to buy:")
    for (item in shoppingList) {
        println("- $item")
    }
    // Things to buy:
    // - Milk
    // - Bananas
    // - Bread
    //sampleEnd
}
```

Ranges

To iterate over a range of numbers, use a range expression with `..` and `..<` operators:

```
fun main() {
    println("Closed-ended range:")
    for (i in 1..6) {
        print(i)
    }
    // Closed-ended range:
    // 123456

    println("\nOpen-ended range:")
    for (i in 1..<6) {
        print(i)
    }
    // Open-ended range:
    // 12345

    println("\nReverse order in steps of 2:")
    for (i in 6 downTo 0 step 2) {
        print(i)
    }
    // Reverse order in steps of 2:
    // 6420
}
```

Arrays

If you want to iterate through an array or a list with an index, you can use the `indices` property:

```
fun main() {
    val routineSteps = arrayOf("Wake up", "Brush teeth", "Make coffee")
        for (i in routineSteps.indices) {
        println(routineSteps[i])
    }
    // Wake up
    // Brush teeth
    // Make coffee
    //sampleEnd
}
```

Alternatively, you can use the `.withIndex()` function from the standard library:

```
fun main() {
    val routineSteps = arrayOf("Wake up", "Brush teeth", "Make coffee")
        for ((index, value) in routineSteps.withIndex()) {
        println("The step at $index is \"$value\"")
    }
    // The step at 0 is "Wake up"
    // The step at 1 is "Brush teeth"
    // The step at 2 is "Make coffee"
    //sampleEnd
}
```

Iterators

The `for` loop iterates through anything that provides an iterator. Collections provide iterators by default, whereas ranges and arrays are compiled into index-based loops.

You can create your own iterators by providing a member or extension function called `iterator()` that returns an `Iterator<>`. The `iterator()` function must have a `next()` function and a `hasNext()` function that returns a `Boolean`.

The easiest way to create your own iterator for a class is to inherit from the `Iterable<T>` interface and override the `iterator()`, `next()`, and `hasNext()` functions that are already there. For example:

```
class Booklet(val totalPages: Int) : Iterable<Int> {
    override fun iterator(): Iterator<Int> {
        return object : Iterator<Int> {
            var current = 1
            override fun hasNext() = current <= totalPages
            override fun next() = current++
        }
    }
}

fun main() {
    val booklet = Booklet(3)
    for (page in booklet) {
        println("Reading page $page")
    }
    // Reading page 1
    // Reading page 2
    // Reading page 3
}
```

Learn more about interfaces and inheritance.

Alternatively, you can create the functions from scratch. In this case, add the `operator` keyword to the functions:

```
class Booklet(val totalPages: Int) {
    operator fun iterator(): Iterator<Int> {
        return object {
            var current = 1

            operator fun hasNext() = current <= totalPages
            operator fun next() = current++
        }.let {
            object : Iterator<Int> {
                override fun hasNext() = it.hasNext()
                override fun next() = it.next()
            }
        }
    }
}

fun main() {
    val booklet = Booklet(3)
    for (page in booklet) {
        println("Reading page $page")
    }
    // Reading page 1
    // Reading page 2
    // Reading page 3
}
```

While loops

`while` and `do-while` loops run the code in their body continuously while the condition is satisfied. The difference between them is the condition checking time:

- `while` checks the condition and, if it's satisfied, runs the code in its body and then returns to the condition check.
- `do-while` runs the code in its body and then checks the condition. If it's satisfied, the loop repeats. So, the body of `do-while` runs at least once, regardless of the condition.

For a `while` loop, place the condition to check in parentheses `()` and the body within curly braces `{}`:

```
fun main() {
    var carsInGarage = 0
    val maxCapacity = 3
    while (carsInGarage < maxCapacity) {
        println("Car entered. Cars now in garage: ${++carsInGarage}")
    }
    // Car entered. Cars now in garage: 1
    // Car entered. Cars now in garage: 2
    // Car entered. Cars now in garage: 3

    println("Garage is full!")
    // Garage is full!
}
```

For a `do-while` loop, place the body within curly braces `{}` first before the condition to check in parentheses `()`:

```
import kotlin.random.Random

fun main() {
    var roll: Int
    do {
        roll = Random.nextInt(1, 7)
        println("Rolled a $roll")
    } while (roll ≠ 6)
    // Rolled a 2
    // Rolled a 6

    println("Got a 6! Game over.")
    // Got a 6! Game over.
}
```

Break and continue in loops

Kotlin supports traditional `break` and `continue` operators in loops. See Returns and jumps.

Returns and jumps

Kotlin has three structural jump expressions:

- `return` by default returns from the nearest enclosing function or anonymous function.
- `break` terminates the nearest enclosing loop.
- `continue` proceeds to the next step of the nearest enclosing loop.

All of these expressions can be used as part of larger expressions:

```
val s = person.name ?: return
```

The type of these expressions is the Nothing type.

Break and continue labels

Any expression in Kotlin may be marked with a *label*. Labels have the form of an identifier followed by the `@` sign, such as `abc@` or `fooBar@`. To label an expression, just add a label in front of it.

```
loop@ for (i in 1..100) {
    // ...
}
```

Now, you can qualify a `break` or a `continue` with a label:

```
loop@ for (i in 1..100) {
    for (j in 1..100) {
        if (...) break@loop
    }
}
```

A `break` qualified with a label jumps to the execution point right after the loop marked with that label. A `continue` proceeds to the next iteration of that loop.

In some cases, you can apply `break` and `continue` *non-locally* without explicitly defining labels. Such non-local usages are valid in lambda expressions used in enclosing inline functions.

Return to labels

In Kotlin, functions can be nested using function literals, local functions, and object expressions. A qualified `return` allows you to return from an outer function.

The most important use case is returning from a lambda expression. To return from a lambda expression, label it and qualify the `return`:

```
fun foo() {
    listOf(1, 2, 3, 4, 5).forEach lit@{
        if (it == 3) return@lit // local return to the caller of the lambda - the forEach loop
        print(it)
    }
    print(" done with explicit label")
}

fun main() {
    foo()
}
```

Now, it returns only from the lambda expression. Often it is more convenient to use *implicit labels*, because such a label has the same name as the function to which the lambda is passed.

```
fun foo() {
    listOf(1, 2, 3, 4, 5).forEach {
        if (it == 3) return@forEach // local return to the caller of the lambda - the forEach loop
        print(it)
    }
    print(" done with implicit label")
}

fun main() {
    foo()
}
```

Alternatively, you can replace the lambda expression with an anonymous function. A `return` statement in an anonymous function will return from the anonymous function itself.

```
fun foo() {
    listOf(1, 2, 3, 4, 5).forEach(fun(value: Int) {
        if (value == 3) return  // local return to the caller of the anonymous function - the forEach
loop
        print(value)
    })
    print(" done with anonymous function")
}

fun main() {
    foo()
}
```

Note that the use of local returns in the previous three examples is similar to the use of `continue` in regular loops.

There is no direct equivalent for `break`, but it can be simulated by adding an outer `run` lambda and non-locally returning from it:

```
fun foo() {
    run loop@{
        listOf(1, 2, 3, 4, 5).forEach {
            if (it == 3) return@loop // non-local return from the lambda passed to run
            print(it)
        }
    }
    print(" done with nested loop")
}

fun main() {
    foo()
}
```

The non-local return here is possible since the nested `forEach()` lambda acts as an inline function.

When returning a value, the parser gives preference to the qualified return:

```
return@a 1
```

This means "return `1` at label `@a` " rather than "return a labeled expression `(@a 1)` ".

> In some cases, you can return from a lambda expression without using labels. Such *non-local* returns are located in a lambda but exit the enclosing inline function.

Exception and error handling

Exceptions help your code run more predictably, even when runtime errors occur that could disrupt program execution. Kotlin treats all exceptions as *unchecked* by default. Unchecked exceptions simplify the exception handling process: you can catch exceptions, but you don't need to explicitly handle or declare them.

> Learn more about how Kotlin handles exceptions when interacting with Java, Swift, and Objective-C in the Exception interoperability with Java, Swift, and Objective-C section.

Working with exceptions consists of two primary actions:

- **Throwing exceptions:** indicate when a problem occurs.
- **Catching exceptions:** handle the unexpected exception manually by resolving the issue or notifying the developer or application user.

Exceptions are represented by subclasses of the `Exception` class, which is a subclass of the `Throwable` class. For more information about the hierarchy, see the Exception hierarchy section. Since `Exception` is an `open class`, you can create custom exceptions to suit your application's specific needs.

Throw exceptions

You can manually throw exceptions with the `throw` keyword. Throwing an exception indicates that an unexpected runtime error has occurred in the code. Exceptions are objects, and throwing one creates an instance of an exception class.

You can throw an exception without any parameters:

```
throw IllegalArgumentException()
```

To better understand the source of the problem, include additional information, such as a custom message and the original cause:

```
val cause = IllegalStateException("Original cause: illegal state")

// Throws an IllegalArgumentException if userInput is negative
// Additionally, it shows the original cause, represented by the cause IllegalStateException
if (userInput < 0) {
    throw IllegalArgumentException("Input must be non-negative", cause)
}
```

In this example, an `IllegalArgumentException` is thrown when the user inputs a negative value. You can create custom error messages and keep the original cause (`cause`) of the exception, which will be included in the stack trace.

Throw exceptions with precondition functions

Kotlin offers additional ways to automatically throw exceptions using precondition functions. Precondition functions include:

Precondition function	Use case	Exception thrown
`require()`	Checks user input validity	`IllegalArgumentException`
`check()`	Checks object or variable state validity	`IllegalStateException`
`error()`	Indicates an illegal state or condition	`IllegalStateException`

These functions are suitable for situations where the program's flow cannot continue if specific conditions aren't met. This streamlines your code and makes handling these checks efficient.

require() function

Use the `require()` function to validate input arguments when they are crucial for the function's operation, and the function can't proceed if these arguments are invalid.

If the condition in `require()` is not met, it throws an `IllegalArgumentException` :

```
fun getIndices(count: Int): List<Int> {
    require(count ⩾ 0) { "Count must be non-negative. You set count to $count." }
    return List(count) { it + 1 }
}

fun main() {
    // This fails with an IllegalArgumentException
    println(getIndices(-1))

    // Uncomment the line below to see a working example
    // println(getIndices(3))
    // [1, 2, 3]
}
```

The `require()` function allows the compiler to perform smart casting. After a successful check, the variable is automatically cast to a non-nullable type. These functions are often used for nullability checks to ensure that the variable is not null before proceeding. For example:

```
fun printNonNullString(str: String?) {
    // Nullability check
    require(str ≠ null)
    // After this successful check, 'str' is guaranteed to be
    // non-null and is automatically smart cast to non-nullable String
    println(str.length)
}
```

check() function

Use the `check()` function to validate the state of an object or variable. If the check fails, it indicates a logic error that needs to be addressed.

If the condition specified in the `check()` function is `false`, it throws an `IllegalStateException`:

```
fun main() {
    var someState: String? = null

    fun getStateValue(): String {

        val state = checkNotNull(someState) { "State must be set beforehand!" }
        check(state.isNotEmpty()) { "State must be non-empty!" }
        return state
    }
    // If you uncomment the line below then the program fails with IllegalStateException
    // getStateValue()

    someState = ""

    // If you uncomment the line below then the program fails with IllegalStateException
    // getStateValue()
    someState = "non-empty-state"

    // This prints "non-empty-state"
    println(getStateValue())
}
```

The `check()` function allows the compiler to perform smart casting. After a successful check, the variable is automatically cast to a non-nullable type. These functions are often used for nullability checks to ensure that the variable is not null before proceeding. For example:

```
fun printNonNullString(str: String?) {
    // Nullability check
    check(str != null)
    // After this successful check, 'str' is guaranteed to be
    // non-null and is automatically smart cast to non-nullable String
    println(str.length)
}
```

error() function

The `error()` function is used to signal an illegal state or a condition in the code that logically should not occur. It's suitable for scenarios when you want to throw an exception intentionally in your code, such as when the code encounters an unexpected state. This function is particularly useful in `when` expressions, providing a clear way to handle cases that shouldn't logically happen.

In the following example, the `error()` function is used to handle an undefined user role. If the role is not one of the predefined ones, an `IllegalStateException` is thrown:

```
class User(val name: String, val role: String)

fun processUserRole(user: User) {
    when (user.role) {
        "admin" -> println("${user.name} is an admin.")
        "editor" -> println("${user.name} is an editor.")
        "viewer" -> println("${user.name} is a viewer.")
        else -> error("Undefined role: ${user.role}")
    }
}

fun main() {
    // This works as expected
    val user1 = User("Alice", "admin")
    processUserRole(user1)
    // Alice is an admin.

    // This throws an IllegalStateException
    val user2 = User("Bob", "guest")
    processUserRole(user2)
}
```

Handle exceptions using try-catch blocks

When an exception is thrown, it interrupts the normal execution of the program. You can handle exceptions gracefully with the `try` and `catch` keywords to keep your program stable. The `try` block contains the code that might throw an exception, while the `catch` block catches and handles the exception if it occurs. The exception is caught by the first `catch` block that matches its specific type or a superclass of the exception.

Here's how you can use the `try` and `catch` keywords together:

```
try {
    // Code that may throw an exception
} catch (e: SomeException) {
    // Code for handling the exception
}
```

It's a common approach to use `try-catch` as an expression, so it can return a value from either the `try` block or the `catch` block:

```
fun main() {
    val num: Int = try {

        // If count() completes successfully, its return value is assigned to num
        count()

    } catch (e: ArithmeticException) {

        // If count() throws an exception, the catch block returns -1,
        // which is assigned to num
        -1
    }
    println("Result: $num")
}

// Simulates a function that might throw ArithmeticException
fun count(): Int {

    // Change this value to return a different value to num
    val a = 0

    return 10 / a
}
```

You can handle an exception without using the exception instance. For example, you can provide a fallback value or a generic error message in the `catch` block.

Use an underscore (`_`) instead of the exception parameter name to indicate that the exception instance is intentionally ignored:

```
import java.io.File
import java.io.IOException

fun main() {
    val userSettings = try {
        File("user-settings.json").readText()

    // Catches IOException without using the exception instance
    } catch (_: IOException) {
        // Uses a fallback value if loading the file fails
        "{}"
    }

    println(userSettings)
}
```

You can use multiple `catch` handlers for the same `try` block. You can add as many `catch` blocks as needed to handle different exceptions distinctively. When you have multiple `catch` blocks, it's important to order them from the most specific to the least specific exception, following a top-to-bottom order in your code. This ordering aligns with the program's execution flow.

Consider this example with custom exceptions:

```
open class WithdrawalException(message: String) : Exception(message)
class InsufficientFundsException(message: String) : WithdrawalException(message)

fun processWithdrawal(amount: Double, availableFunds: Double) {
    if (amount > availableFunds) {
        throw InsufficientFundsException("Insufficient funds for the withdrawal.")
    }
    if (amount < 1 || amount % 1 != 0.0) {
        throw WithdrawalException("Invalid withdrawal amount.")
    }
    println("Withdrawal processed")
}

fun main() {
    val availableFunds = 500.0

    // Change this value to test different scenarios
    val withdrawalAmount = 500.5

    try {
        processWithdrawal(withdrawalAmount.toDouble(), availableFunds)

    // The order of catch blocks is important!
    } catch (e: InsufficientFundsException) {
        println("Caught an InsufficientFundsException: ${e.message}")
    } catch (e: WithdrawalException) {
        println("Caught a WithdrawalException: ${e.message}")
    }
}
```

A general catch block handling `WithdrawalException`, catches all exceptions of its type, including specific ones like `InsufficientFundsException`, unless they are caught earlier by a more specific catch block.

The finally block

The `finally` block contains code that always executes, regardless of whether the `try` block completes successfully or throws an exception. With the `finally` block, you can clean up code after the execution of `try` and `catch` blocks. This is especially important when working with resources like files or network connections, as `finally` guarantees they are properly closed or released.

Here is how you would typically use the `try-catch-finally` blocks together:

```
try {
    // Code that may throw an exception
}
catch (e: YourException) {
    // Exception handler
}
finally {
    // Code that is always executed
}
```

The returned value of a `try` expression is determined by the last executed expression in either the `try` or `catch` block. If no exceptions occur, the result comes from the `try` block; if an exception is handled, it comes from the `catch` block. The `finally` block is always executed, but it doesn't change the result of the `try-catch` block.

Let's look at an example to demonstrate:

```
fun divideOrNull(a: Int): Int {

    // The try block is always executed
    // An exception here (division by zero) causes an immediate jump to the catch block
    try {
        val b = 44 / a
        println("try block: Executing division: $b")
        return b
    }

    // The catch block is executed due to the ArithmeticException (division by zero if a ==0)
    catch (e: ArithmeticException) {
        println("catch block: Encountered ArithmeticException $e")
        return -1
    }
    finally {
        println("finally block: The finally block is always executed")
    }
}

fun main() {

    // Change this value to get a different result. An ArithmeticException will return: -1
    divideOrNull(0)
}
```

In Kotlin, the idiomatic way to manage resources that implement the `AutoClosable` interface, such as file streams like `FileInputStream` or `FileOutputStream`, is to use the `.use()` function. This function automatically closes the resource when the block of code completes, regardless of whether an exception is thrown, thereby eliminating the need for a `finally` block. Consequently, Kotlin does not require a special syntax like Java's try-with-resources for resource management.

```
FileWriter("test.txt").use { writer →
    writer.write("some text")
    // After this block, the .use function automatically calls writer.close(), similar to a
finally block
}
```

If your code requires resource cleanup without handling exceptions, you can also use `try` with the `finally` block without `catch` blocks:

```
class MockResource {
    fun use() {
        println("Resource being used")
        // Simulate a resource being used
        // This throws an ArithmeticException if division by zero occurs
        val result = 100 / 0

        // This line is not executed if an exception is thrown
        println("Result: $result")
    }

    fun close() {
        println("Resource closed")
    }
}

fun main() {
    val resource = MockResource()
//sampleStart
    try {

        // Attempts to use the resource
        resource.use()

    } finally {

        // Ensures that the resource is always closed, even if an exception occurs
        resource.close()
    }

    // This line is not printed if an exception is thrown
    println("End of the program")
}
```

As you can see, the `finally` block guarantees that the resource is closed, regardless of whether an exception occurs.

In Kotlin, you have the flexibility to use only a `catch` block, only a `finally` block, or both, depending on your specific needs, but a `try` block must always be accompanied by at least one `catch` block or a `finally` block.

Create custom exceptions

In Kotlin, you can define custom exceptions by creating classes that extend the built-in `Exception` class. This allows you to create more specific error types tailored to your application's needs.

To create one, you can define a class that extends `Exception`:

```
class MyException: Exception("My message")
```

In this example, there is a default error message, "My message", but you can leave it blank if you want.

> Exceptions in Kotlin are stateful objects, carrying information specific to the context of their creation, referred to as the stack trace. Avoid creating exceptions using object declarations. Instead, create a new instance of the exception every time you need one. This way, you can ensure the exception's state accurately reflects the specific context.

Custom exceptions can also be a subclass of any pre-existent exception subclass, like the `ArithmeticException` subclass:

```
class NumberTooLargeException: ArithmeticException("My message")
```

If you want to create subclasses of custom exceptions, you must declare the parent class as `open` because classes are final by default and cannot be subclassed otherwise.

For example:

```
// Declares a custom exception as an open class, making it subclassable
open class MyCustomException(message: String): Exception(message)

// Creates a subclass of the custom exception
class SpecificCustomException: MyCustomException("Specific error message")
```

Custom exceptions behave just like built-in exceptions. You can throw them using the `throw` keyword, and handle them with `try-catch-finally` blocks. Let's look at an example to demonstrate:

```
class NegativeNumberException: Exception("Parameter is less than zero.")
class NonNegativeNumberException: Exception("Parameter is a non-negative number.")

fun myFunction(number: Int) {
    if (number < 0) throw NegativeNumberException()
    else if (number ⩾ 0) throw NonNegativeNumberException()
}

fun main() {

    // Change the value in this function to a get a different exception
    myFunction(1)
}
```

In applications with diverse error scenarios, creating a hierarchy of exceptions can help make the code clearer and more specific. You can achieve this by using an abstract class or a sealed class as a base for common exception features and creating specific subclasses for detailed exception types. Additionally, custom exceptions including parameters with default values offer flexibility, allowing initialization with varied messages, which enables more granular error handling.

Let's look at an example using the sealed class `AccountException` as the base for an exception hierarchy, and class `APIKeyExpiredException`, a subclass, which showcases the use of parameters with default values for improved exception detail:

```
// Creates a sealed class as the base for an exception hierarchy for account-related errors
sealed class AccountException(message: String, cause: Throwable? = null):
Exception(message, cause)

// Creates a subclass of AccountException
class InvalidAccountCredentialsException : AccountException("Invalid account credentials detected")

// Creates a subclass of AccountException, which allows the addition of custom messages and causes
class APIKeyExpiredException(message: String = "API key expired", cause: Throwable? = null)     :
AccountException(message, cause)

// Change values of placeholder functions to get different results
fun areCredentialsValid(): Boolean = true
fun isAPIKeyExpired(): Boolean = true

// Validates account credentials and API key
fun validateAccount() {
    if (!areCredentialsValid()) throw InvalidAccountCredentialsException()
    if (isAPIKeyExpired()) {
        // Example of throwing APIKeyExpiredException with a specific cause
        val cause = RuntimeException("API key validation failed due to network error")
        throw APIKeyExpiredException(cause = cause)
    }
}

fun main() {
    try {
        validateAccount()
        println("Operation successful: Account credentials and API key are valid.")
    } catch (e: AccountException) {
        println("Error: ${e.message}")
        e.cause?.let { println("Caused by: ${it.message}") }
    }
}
```

The Nothing type

In Kotlin, every expression has a type. The type of the expression `throw IllegalArgumentException()` is `Nothing`, a built-in type that is a subtype of all other types, also known as the bottom type. This means `Nothing` can be used as a return type or generic type where any other type is expected, without causing type errors.

`Nothing` is a special type in Kotlin used to represent functions or expressions that never complete successfully, either because they always throw an exception or enter an endless execution path like an infinite loop. You can use `Nothing` to mark functions that are not yet implemented or are designed to always throw an exception, clearly indicating your intentions to both the compiler and code readers. If the compiler infers a `Nothing` type in a function signature, it will warn you. Explicitly defining `Nothing` as the return type can eliminate this warning.

This Kotlin code demonstrates the use of the `Nothing` type, where the compiler marks the code following the function call as unreachable:

```kotlin
class Person(val name: String?)

fun fail(message: String): Nothing {
    throw IllegalArgumentException(message)
    // This function will never return successfully.
    // It will always throw an exception.
}

fun main() {
    // Creates an instance of Person with 'name' as null
    val person = Person(name = null)

    val s: String = person.name ?: fail("Name required")

    // 's' is guaranteed to be initialized at this point
    println(s)
}
```

Kotlin's `TODO()` function, which also uses the `Nothing` type, serves as a placeholder to highlight areas of the code that need future implementation:

```kotlin
fun notImplementedFunction(): Int {
    TODO("This function is not yet implemented")
}

fun main() {
    val result = notImplementedFunction()
    // This throws a NotImplementedError
    println(result)
}
```

As you can see, the `TODO()` function always throws a `NotImplementedError` exception.

Exception classes

Let's explore some common exception types found in Kotlin, which are all subclasses of the `RuntimeException` class:

- `ArithmeticException` : This exception occurs when an arithmetic operation is impossible to perform, like division by zero.

  ```kotlin
  val example = 2 / 0 // throws ArithmeticException
  ```

- `IndexOutOfBoundsException` : This exception is thrown to indicate that an index of some sort, such as an array or string, is out of range.

  ```kotlin
  val myList = mutableListOf(1, 2, 3)
  myList.removeAt(3)  // throws IndexOutOfBoundsException
  ```

To avoid this exception, use a safer alternative, such as the `getOrNull()` function:

```
val myList = listOf(1, 2, 3)
// Returns null, instead of IndexOutOfBoundsException
val element = myList.getOrNull(3)
println("Element at index 3: $element")
```

- `NoSuchElementException` : This exception is thrown when an element that does not exist in a particular collection is accessed. It occurs when using methods that expect a specific element, such as `first()` or `last()` .

```
val emptyList = listOf<Int>()
val firstElement = emptyList.first()  // throws NoSuchElementException
```

To avoid this exception, use a safer alternative, such as the `firstOrNull()` function:

```
val emptyList = listOf<Int>()
// Returns null, instead of NoSuchElementException
val firstElement = emptyList.firstOrNull()
println("First element in empty list: $firstElement")
```

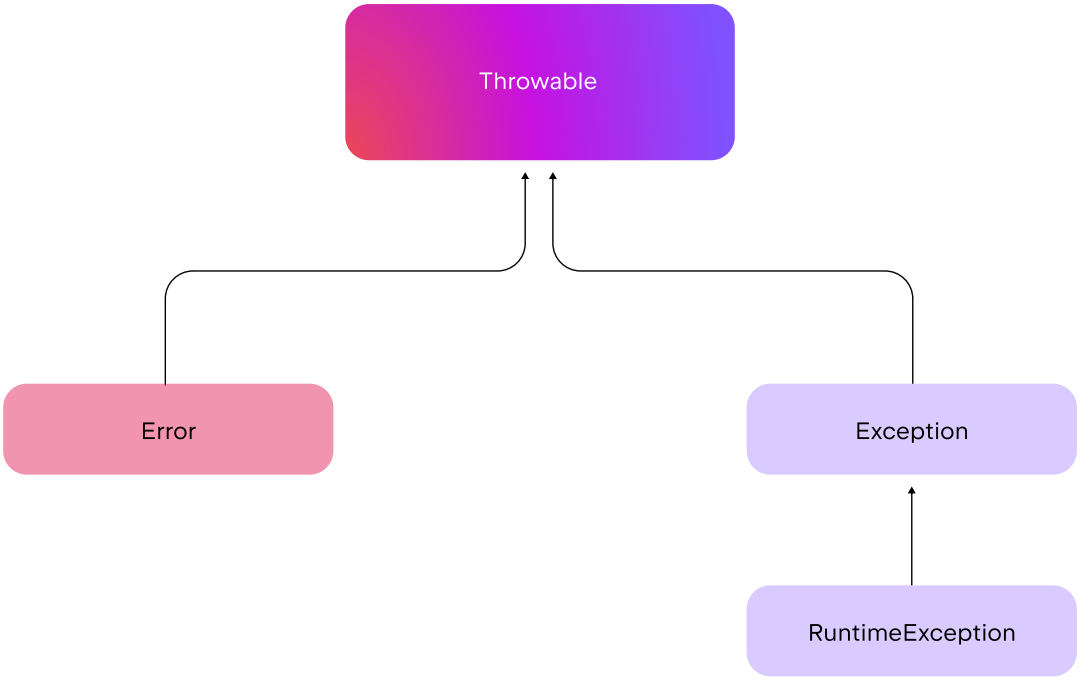
- `NumberFormatException` : This exception occurs when attempting to convert a string to a numeric type, but the string doesn't have an appropriate format.

```
val string = "This is not a number"
val number = string.toInt() // throws NumberFormatException
```

To avoid this exception, use a safer alternative, such as the `toIntOrNull()` function:

```
val nonNumericString = "not a number"
// Returns null, instead of NumberFormatException
val number = nonNumericString.toIntOrNull()
println("Converted number: $number")
```

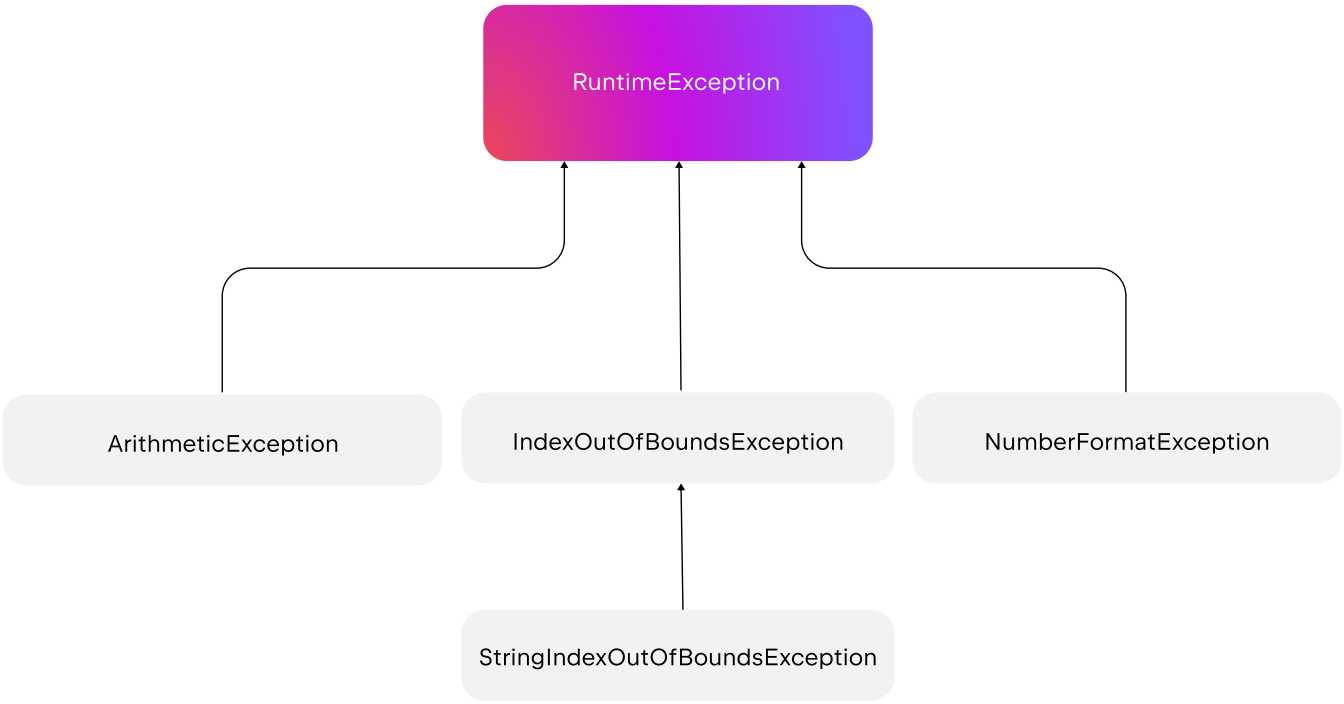
- `NullPointerException` : This exception is thrown when an application attempts to use an object reference that has the `null` value. Even though Kotlin's null safety features significantly reduce the risk of NullPointerExceptions, they can still occur either through deliberate use of the `!!` operator or when interacting with Java, which lacks Kotlin's null safety.



```
val text: String? = null
println(text!!.length)  // throws a NullPointerException
```

While all exceptions are unchecked in Kotlin, and you don't have to catch them explicitly, you still have the flexibility to catch them if desired.

Exception hierarchy



The root of the Kotlin exception hierarchy is the `Throwable` class. It has two direct subclasses, `Error` and `Exception`:

- The `Error` subclass represents serious fundamental problems that an application might not be able to recover from by itself. These are problems that you generally would not attempt to handle, such as `OutOfMemoryError` or `StackOverflowError`.
- The `Exception` subclass is used for conditions that you might want to handle. Subtypes of the `Exception` type, such as the `RuntimeException` and `IOException` (Input/Output Exception), deal with exceptional events in applications.

Exception hierarchy - the Throwable class

`RuntimeException` is usually caused by insufficient checks in the program code and can be prevented programmatically. Kotlin helps prevent common `RuntimeExceptions` like `NullPointerException` and provides compile-time warnings for potential runtime errors, such as division by zero. The following picture demonstrates a hierarchy of subtypes descended from `RuntimeException`:

Hierarchy of RuntimeExceptions

Stack trace

The *stack trace* is a report generated by the runtime environment, used for debugging. It shows the sequence of function calls leading to a specific point in the program, especially where an error or exception occurred.

Let's see an example where the stack trace is automatically printed because of an exception in a JVM environment:

```
fun main() {
//sampleStart
    throw ArithmeticException("This is an arithmetic exception!")
}
```

Running this code in a JVM environment produces the following output:

```
Exception in thread "main" java.lang.ArithmeticException: This is an arithmetic exception!
    at MainKt.main(Main.kt:3)
    at MainKt.main(Main.kt)
```

The first line is the exception description, which includes:

- Exception type: `java.lang.ArithmeticException`
- Thread: `main`
- Exception message: `"This is an arithmetic exception!"`

Each other line that starts with an `at` after the exception description is the stack trace. A single line is called a *stack trace element* or a *stack frame*:

- `at MainKt.main (Main.kt:3)`: This shows the method name (`MainKt.main`) and the source file and line number where the method was called (`Main.kt:3`).
- `at MainKt.main (Main.kt)`: This shows that the exception occurs in the `main()` function of the `Main.kt` file.

Exception interoperability with Java, Swift, and Objective-C

Since Kotlin treats all exceptions as unchecked, it can lead to complications when such exceptions are called from languages that distinguish between checked and unchecked exceptions. To address this disparity in exception handling between Kotlin and languages like Java, Swift, and Objective-C, you can use the `@Throws` annotation. This annotation alerts callers about possible exceptions. For more information, see Calling Kotlin from Java and Interoperability with Swift/Objective-C.

Functions

To declare a function in Kotlin:

- Use the `fun` keyword.
- Specify the parameters in parentheses `()`.
- Include the return type if needed.

For example:

```
// 'double' is the name of the function
// 'x' is a parameter of Int type
// The expected return value is of Int type too
fun double(x: Int): Int {
    return 2 * x
}

fun main() {
    println(double(5))
    // 10
}
```

Function usage

Functions are called using the standard approach:

```
val result = double(2)
```

To call a member or extension function, use a period `.`:

```
// Creates an instance of the Stream class and calls read()
Stream().read()
```

Parameters

Declare function parameters using Pascal notation: `name: Type`. You must separate parameters using commas and give each parameter a type explicitly:

```
fun powerOf(number: Int, exponent: Int): Int { /*...*/ }
```

When you pass an object to a function, the compiler passes a copy of the reference to that object. The copied reference points to the same object, so the function can modify the object's mutable state.

Function parameters are read-only inside the function body (implicitly declared as `val`), so you can't reassign them:

```
class Counter(var value: Int)

fun reset(counter: Counter) {
    counter.value = 0    // Allowed: modifies the object
    counter = Counter(0) // Error: 'val' cannot be reassigned
}
```

You can use a trailing comma when declaring function parameters:

```
fun powerOf(
    number: Int,
    exponent: Int, // trailing comma
) { /*...*/ }
```

Trailing commas help with refactorings and code maintenance: you can move parameters within the declaration without worrying about which is going to be the last one.

Kotlin functions can receive other functions as parameters — and be passed as arguments. For more information, see Higher-order functions and lambdas.

Parameters with default values

You can make a function parameter optional by specifying a default value for it. Kotlin uses the default value when you call the function without providing an argument that corresponds to that parameter. Parameters with default values are also known as *optional parameters*.

Optional parameters reduce the need for multiple overloads, since you don't have to declare different versions of a function just to allow skipping a parameter with a reasonable default.

Set a default value by appending `=` to the parameter declaration:

```
fun read(
    b: ByteArray,
    // The default value of 'off' is 0
    off: Int = 0,
    // The default value of 'len' is calculated
    // as the size of the 'b' array
    len: Int = b.size,
) { /*...*/ }
```

When you declare a parameter **with** a default value before a parameter **without** a default value, you can only use the default value by naming the argument:

```
fun greeting(
    userId: Int = 0,
    message: String,
) { /*...*/ }

fun main() {
    // Uses 0 as the default value for 'userId'
    greeting(message = "Hello!")

    // Error: No value passed for parameter 'message'
    greeting("Hello!")
}
```

Trailing lambdas are an exception to this rule, since the last parameter must correspond to the passed function:

```
fun main () {
//sampleStart
fun greeting(
    userId: Int = 0,
    message: () -> Unit,
)
{ println(userId)
  message() }

// Uses the default value for 'userId'
greeting() { println ("Hello!") }
// 0
// Hello!
}
```

Overriding methods always use the base method's default parameter values. When you override a method that has default parameter values, you must omit the default parameter values from the signature:

```
open class Shape {
    open fun draw(width: Int = 10, height: Int = 5) { /*...*/ }
}

class Rectangle : Shape() {
    // It's not allowed to specify default values here
    // but this function also uses 10 for 'width' and 5 for 'height'
    // by default.
    override fun draw(width: Int, height: Int) { /*...*/ }
}
```

Non-constant expressions as default values

You can assign a parameter a default value that isn't constant. For example, the default can be the result of a function call or a calculation that uses the values of other arguments, like the `len` parameter in this example:

```
fun read(
    b: ByteArray,
    off: Int = 0,
    len: Int = b.size,
) { /*...*/ }
```

Parameters that refer to the values of other parameters must be declared later in the order. In this example, `len` must be declared after `b`.

In general, you can assign any expression as the default value of a parameter. However, default values are only evaluated when the function is called **without** the corresponding parameter and a default value needs to be assigned. For example, this function prints out a line only when it is called without the `print` parameter:

```
fun main() {
    fun read(
        b: Int,
        print: Unit? = println("No argument passed for 'print'")
    ) { println(b) }

    // Prints "No argument passed for 'print'", then "1"
    read(1)
    // Prints only "1"
    read(1, null)
    //sampleEnd
}
```

If the last parameter in a function declaration has a functional type, you can pass the corresponding lambda argument either as a named argument or outside the parentheses:

```
fun main() {
        fun log(
        level: Int = 0,
        code:  Int = 1,
        action: () -> Unit,
    ) { println (level)
        println (code)
        action() }

    // Passes 1 for 'level' and uses the default value 1 for 'code'
    log(1) { println("Connection established") }

    // Uses both default values, 0 for 'level' and 1 for 'code'
    log(action = { println("Connection established") })

    // Equivalent to the previous call, uses both default values
    log { println("Connection established") }
    //sampleEnd
}
```

Named arguments

You can name one or more of a function's arguments when calling it. This can be helpful when a function call has many arguments. In such cases, it's difficult to associate a value with an argument, especially if it's `null` or a boolean value.

When you use named arguments in a function call, you can list them in any order.

Consider the `reformat()` function, which has 4 arguments with default values:

```
fun reformat(
    str: String,
    normalizeCase: Boolean = true,
    upperCaseFirstLetter: Boolean = true,
    divideByCamelHumps: Boolean = false,
    wordSeparator: Char = ' ',
) { /*...*/ }
```

When calling this function, you can name some of the arguments:

```
reformat(
    "String!",
    normalizeCase = false,
    upperCaseFirstLetter = false,
    divideByCamelHumps = true,
    '_'
)
```

You can skip all the arguments with default values:

```
reformat("This is a long String!")
```

You can also skip *some* arguments with default values, rather than omitting them all. However, after the first skipped argument, you must name all subsequent arguments:

```
reformat(
    "This is a short String!",
    upperCaseFirstLetter = false,
    wordSeparator = '_'
)
```

You can pass a variable number of arguments (`vararg`) by naming the corresponding argument. In this example, it's an array:

```
fun mergeStrings(vararg strings: String) { /*...*/ }

mergeStrings(strings = arrayOf("a", "b", "c"))
```

When calling Java functions on the JVM, you can't use the named argument syntax because Java bytecode does not always preserve the names of function parameters.

Return types

When you declare a function with a block body (by putting instructions within curly braces `{}`), you must always specify a return type explicitly. The only exception is when they return `Unit` , in which case specifying the return type is optional.

Kotlin doesn't infer return types for functions with block bodies. Their control flow can be complex, which makes the return type unclear to the reader and sometimes even to the compiler. However, Kotlin can infer the return type for single-expression functions if you don't specify it.

Single-expression functions

When the function body consists of a single expression, you can omit the curly braces and specify the body after an `=` symbol:

```
fun double(x: Int): Int = x * 2
```

Most of the time you don't have to explicitly declare the return type:

```
// Compiler infers that the function returns Int
fun double(x: Int) = x * 2
```

The compiler can sometimes run into problems when inferring return types from single expressions. In such cases, you should add the return type explicitly. For example, functions that are recursive or mutually recursive (calling each other) and functions with typeless expressions like `fun empty() = null` always require a return type.

When you do use an inferred return type, make sure to check the actual result because the compiler may infer a type that is less useful to you. In the example above, if you want the `double()` function to return `Number` instead of `Int`, you have to declare this explicitly.

If you use a `return` statement inside an expression body, you must specify the return type explicitly:

```
fun getDisplayNameOrDefault(userId: String?): String =
    getDisplayName(userId ?: return "default")
```

Unit-returning functions

If a function has a block body (instructions within curly braces `{}`) and does not return a useful value, the compiler assumes its return type is `Unit`. `Unit` is a type that has only one value, also called `Unit`.

You don't have to specify `Unit` as a return type, except for functional type parameters. You never have to return `Unit` explicitly.

For example, you can declare a `printHello()` function without returning `Unit`:

```
// The declaration of the functional type parameter ('action') still
// needs an explicit return type
fun printHello(name: String?, action: () -> Unit) {
    if (name != null)
        println("Hello $name")
    else
        println("Hi there!")

    action()
}

fun main() {
    printHello("Kodee") {
        println("This runs after the greeting.")
    }
    // Hello Kodee
    // This runs after the greeting.

    printHello(null) {
        println("No name provided, but action still runs.")
    }
    // No name provided, but action still runs
}
```

Which is equivalent to this verbose declaration:

```
fun printHello(name: String?, action: () -> Unit): Unit {
    if (name != null)
        println("Hello $name")
    else
        println("Hi there!")

    action()
    return Unit
}
fun main() {
    printHello("Kodee") {
        println("This runs after the greeting.")
    }
    // Hello Kodee
    // This runs after the greeting.

    printHello(null) {
        println("No name provided, but action still runs.")
    }
    // No name provided, but action still runs
}
```

Variable number of arguments (varargs)

To pass a variable number of arguments to a function, you can mark one of its parameters (usually the last one) with the `vararg` modifier. Inside a function, you can use a `vararg` -parameter of type `T` as an array of `T` :

```
fun <T> asList(vararg ts: T): List<T> {
    val result = ArrayList<T>()
    for (t in ts) // ts is an Array
        result.add(t)
    return result
}
```

Then you can pass a variable number of arguments to the function:

```
fun <T> asList(vararg ts: T): List<T> {
    val result = ArrayList<T>()
    for (t in ts) // ts is an Array
        result.add(t)
    return result
}

fun main() {
        val list = asList(1, 2, 3)
    println(list)
    // [1, 2, 3]
    //sampleEnd
}
```

Only one parameter can be marked as `vararg` . If you declare a `vararg` parameter anywhere other than last in the parameter list, you must pass values for the following parameters using named arguments. If a parameter has a function type, you can also pass its value by placing a lambda outside the parentheses.

When you call a `vararg` -function, you can pass arguments individually, as in the example of `asList(1, 2, 3)` . If you already have an array and want to pass its contents to a function as a `vararg` parameter or as a part of it, use the spread operator by prefixing the array name with `*` :

```
fun <T> asList(vararg ts: T): List<T> {
    val result = ArrayList<T>()
    for (t in ts)
        result.add(t)
    return result
}

fun main() {
        val a = arrayOf(1, 2, 3)

    // The function receives the array [-1, 0, 1, 2, 3, 4]
    list = asList(-1, 0, *a, 4)

    println(list)
    // [-1, 0, 1, 2, 3, 4]
    //sampleEnd
}
```

If you want to pass a primitive type array as `vararg`, you need to convert it to a regular (typed) array using the `.toTypedArray()` function:

```
// 'a' is an IntArray, which is a primitive type array
val a = intArrayOf(1, 2, 3)
val list = asList(-1, 0, *a.toTypedArray(), 4)
```

Infix notation

You can declare functions that can be called without parentheses or the period by using the `infix` keyword. This can help make simple function calls in your code easier to read.

```
infix fun Int.shl(x: Int): Int { /*...*/ }

// Calls the function using the general notation
1.shl(2)

// Calls the function using the infix notation
1 shl 2
```

Infix functions must meet the following requirements:

- They must be member functions of a class or extension functions.
- They must have a single parameter.
- The parameter must not accept a variable number of arguments (`vararg`) and must have no default value.

Infix function calls have lower precedence than arithmetic operators, type casts, and the `rangeTo` operator. The following expressions are equivalent:

- `1 shl 2 + 3` is equivalent to `1 shl (2 + 3)`
- `0 until n * 2` is equivalent to `0 until (n * 2)`
- `xs union ys as Set<*>` is equivalent to `xs union (ys as Set<*>)`

On the other hand, an infix function call's precedence is higher than that of the boolean operators `&&` and `||`, `is` - and `in` -checks, and some other operators. These expressions are equivalent as well:

- `a && b xor c` is equivalent to `a && (b xor c)`
- `a xor b in c` is equivalent to `(a xor b) in c`

Note that infix functions always require both the receiver and the parameter to be specified. When you call a method on the current receiver using the infix notation, use `this` explicitly. This ensures unambiguous parsing.

```
class MyStringCollection {
    val items = mutableListOf<String>()

    infix fun add(s: String) {
        println("Adding: $s")
        items += s
    }

    fun build() {
        add("first")      // Correct: ordinary function call
        this add "second" // Correct: infix call with an explicit receiver
        // add "third"    // Compiler error: needs an explicit receiver
    }

    fun printAll() = println("Items = $items")
}

fun main() {
    val myStrings = MyStringCollection()
    // Adds "first" and "second" to the list
    myStrings.build()

    myStrings.printAll()
    // Adding: first
    // Adding: second
    // Items = [first, second]
}
```

Function scope

You can declare Kotlin functions at the top level in a file, meaning you do not need to create a class to hold a function. Functions can also be declared locally as *member functions* or *extension functions*.

Local functions

Kotlin supports local functions, which are functions declared inside other functions. For example, the following code implements the Depth-first search algorithm for a given graph. The local `dfs()` function inside the outer `dfs()` function to hide the implementation and handle recursive calls:

```
class Person(val name: String) {
    val friends = mutableListOf<Person>()
}
class SocialGraph(val people: List<Person>)
fun dfs(graph: SocialGraph) {
    fun dfs(current: Person, visited: MutableSet<Person>) {
        if (!visited.add(current)) return
        println("Visited ${current.name}")
        for (friend in current.friends)
            dfs(friend, visited)
    }
    dfs(graph.people[0], HashSet())
}
fun main() {
    val alice = Person("Alice")
    val bob = Person("Bob")
    val charlie = Person("Charlie")
    alice.friends += bob
    bob.friends += charlie
    charlie.friends += alice
    val network = SocialGraph(listOf(alice, bob, charlie))
    dfs(network)
}
```

A local function can access local variables of outer functions (the closure). In the case above, the `visited` function parameter can be a local variable:

```
class Person(val name: String) {
    val friends = mutableListOf<Person>()
}
class SocialGraph(val people: List<Person>)
fun dfs(graph: SocialGraph) {
    val visited = HashSet<Person>()
    fun dfs(current: Person) {
        if (!visited.add(current)) return
        println("Visited ${current.name}")
        for (friend in current.friends)
            dfs(friend)
    }
    dfs(graph.people[0])
}
fun main() {
    val alice = Person("Alice")
    val bob = Person("Bob")
    val charlie = Person("Charlie")
    alice.friends += bob
    bob.friends += charlie
    charlie.friends += alice
    val network = SocialGraph(listOf(alice, bob, charlie))
    dfs(network)
}
```

Member functions

A member function is a function that is defined inside a class or object:

```
class Sample {
    fun foo() { print("Foo") }
}
```

To call member functions, write the instance or object name, then add a `.` and write the function name:

```
// Creates an instance of the Stream class and calls read()
Stream().read()
```

For more information on classes and overriding members see Classes and Inheritance.

Generic functions

You can specify generic parameters for a function by using angle brackets `<>` before the function name:

```
fun <T> singletonList(item: T): List<T> { /*...*/ }
```

For more information on generic functions, see Generics.

Tail recursive functions

Kotlin supports a style of functional programming known as tail recursion. For some algorithms that would normally use loops, you can use a recursive function instead without the risk of stack overflow. When a function is marked with the `tailrec` modifier and meets the required formal conditions, the compiler optimizes out the recursion, leaving behind a fast and efficient loop based version instead:

```
import kotlin.math.cos
import kotlin.math.abs

// An arbitrary "good enough" precision
val eps = 1E-10

tailrec fun findFixPoint(x: Double = 1.0): Double =
    if (abs(x - cos(x)) < eps) x else findFixPoint(cos(x))
```

This code calculates the fixed point of cosine (a mathematical constant). The function calls `cos()` repeatedly starting at `1.0` until the result no longer changes, yielding a result of `0.7390851332151611` for the specified `eps` precision. The code is equivalent to this more traditional style:

```
import kotlin.math.cos
import kotlin.math.abs

// An arbitrary "good enough" precision
val eps = 1E-10

private fun findFixPoint(): Double {
    var x = 1.0
    while (true) {
        val y = cos(x)
        if (abs(x - y) < eps) return x
        x = cos(x)
    }
}
```

You can apply the `tailrec` modifier to a function only when it calls itself as its final operation. You cannot use tail recursion when there is more code after the recursive call, within `try` / `catch` / `finally` blocks, or when the function is open.

- Higher-order functions and lambdas

Higher-order functions and lambdas

Kotlin functions are first-class, which means they can be stored in variables and data structures, and can be passed as arguments to and returned from other higher-order functions. You can perform any operations on functions that are possible for other non-function values.

To facilitate this, Kotlin, as a statically typed programming language, uses a family of function types to represent functions, and provides a set of specialized language constructs, such as lambda expressions.

Higher-order functions

A higher-order function is a function that takes functions as parameters, or returns a function.

A good example of a higher-order function is the functional programming idiom `fold` for collections. It takes an initial accumulator value and a combining function and builds its return value by consecutively combining the current accumulator value with each collection element, replacing the accumulator value each time:

```
fun <T, R> Collection<T>.fold(
    initial: R,
    combine: (acc: R, nextElement: T) -> R
): R {
    var accumulator: R = initial
    for (element: T in this) {
        accumulator = combine(accumulator, element)
    }
    return accumulator
}
```

In the code above, the `combine` parameter has the function type `(R, T) -> R`, so it accepts a function that takes two arguments of types `R` and `T` and returns a value of type `R`. It is invoked inside the `for` loop, and the return value is then assigned to `accumulator`.

To call `fold`, you need to pass an instance of the function type to it as an argument, and lambda expressions (described in more detail below) are widely used for this purpose at higher-order function call sites:

```
fun main() {
        val items = listOf(1, 2, 3, 4, 5)

    // Lambdas are code blocks enclosed in curly braces.
    items.fold(0, {
        // When a lambda has parameters, they go first, followed by '->'
        acc: Int, i: Int ->
        print("acc = $acc, i = $i, ")
        val result = acc + i
        println("result = $result")
        // The last expression in a lambda is considered the return value:
        result
    })

    // Parameter types in a lambda are optional if they can be inferred:
    val joinedToString = items.fold("Elements:", { acc, i -> acc + " " + i })

    // Function references can also be used for higher-order function calls:
    val product = items.fold(1, Int::times)
    //sampleEnd
    println("joinedToString = $joinedToString")
    println("product = $product")
}
```

Function types

Kotlin uses function types, such as `(Int) -> String`, for declarations that deal with functions: `val onClick: () -> Unit = ...`.

These types have a special notation that corresponds to the signatures of the functions - their parameters and return values:

- All function types have a parenthesized list of parameter types and a return type: `(A, B) -> C` denotes a type that represents functions that take two arguments of types `A` and `B` and return a value of type `C`. The list of parameter types may be empty, as in `() -> A`. The `Unit` return type cannot be omitted.
- Function types can optionally have an additional *receiver* type, which is specified before the dot in the notation: the type `A.(B) -> C` represents functions that can be called on a receiver object `A` with a parameter `B` and return a value `C`. Function literals with receiver are often used along with these types.
- Suspending functions belong to a special kind of function type that have a *suspend* modifier in their notation, such as `suspend () -> Unit` or `suspend A.(B) -> C`.

The function type notation can optionally include names for the function parameters: `(x: Int, y: Int) -> Point`. These names can be used for documenting the meaning of the parameters.

To specify that a function type is nullable, use parentheses as follows: `((Int, Int) -> Int)?`.

Function types can also be combined using parentheses: `(Int) -> ((Int) -> Unit)`.

> The arrow notation is right-associative, `(Int) -> (Int) -> Unit` is equivalent to the previous example, but not to `((Int) -> (Int)) -> Unit`.

You can also give a function type an alternative name by using a type alias:

```
typealias ClickHandler = (Button, ClickEvent) -> Unit
```

Instantiating a function type

There are several ways to obtain an instance of a function type:

- Use a code block within a function literal, in one of the following forms:
  - a lambda expression: `{ a, b -> a + b }`,
  - an anonymous function: `fun(s: String): Int { return s.toIntOrNull() ?: 0 }`

  Function literals with receiver can be used as values of function types with receiver.
- Use a callable reference to an existing declaration:
  - a top-level, local, member, or extension function: `::isOdd`, `String::toInt`,
  - a top-level, member, or extension property: `List<Int>::size`,
  - a constructor: `::Regex`

  These include bound callable references that point to a member of a particular instance: `foo::toString`.
- Use instances of a custom class that implements a function type as an interface:

```
class IntTransformer: (Int) -> Int {
    override operator fun invoke(x: Int): Int = TODO()
}

val intFunction: (Int) -> Int = IntTransformer()
```

The compiler can infer the function types for variables if there is enough information:

```
val a = { i: Int -> i + 1 } // The inferred type is (Int) -> Int
```

Non-literal values of function types with and without a receiver are interchangeable, so the receiver can stand in for the first parameter, and vice versa. For instance, a value of type `(A, B) -> C` can be passed or assigned where a value of type `A.(B) -> C` is expected, and the other way around:

```
fun main() {
        val repeatFun: String.(Int) -> String = { times -> this.repeat(times) }
    val twoParameters: (String, Int) -> String = repeatFun // OK

    fun runTransformation(f: (String, Int) -> String): String {
        return f("hello", 3)
    }
    val result = runTransformation(repeatFun) // OK
    //sampleEnd
    println("result = $result")
}
```

A function type with no receiver is inferred by default, even if a variable is initialized with a reference to an extension function. To alter that, specify the variable type explicitly.

Invoking a function type instance

A value of a function type can be invoked by using its `invoke(...)` operator: `f.invoke(x)` or just `f(x)`.

If the value has a receiver type, the receiver object should be passed as the first argument. Another way to invoke a value of a function type with receiver is to prepend it with the receiver object, as if the value were an extension function: `1.foo(2)`.

Example:

```
fun main() {
        val stringPlus: (String, String) → String = String::plus
    val intPlus: Int.(Int) → Int = Int::plus

    println(stringPlus.invoke("←", "→"))
    println(stringPlus("Hello, ", "world!"))

    println(intPlus.invoke(1, 1))
    println(intPlus(1, 2))
    println(2.intPlus(3)) // extension-like call
    //sampleEnd
}
```

Inline functions

Sometimes it is beneficial to use inline functions, which provide flexible control flow, for higher-order functions.

Lambda expressions and anonymous functions

Lambda expressions and anonymous functions are *function literals*. Function literals are functions that are not declared but are passed immediately as an expression. Consider the following example:

```
max(strings, { a, b → a.length < b.length })
```

The function `max` is a higher-order function, as it takes a function value as its second argument. This second argument is an expression that is itself a function, called a function literal, which is equivalent to the following named function:

```
fun compare(a: String, b: String): Boolean = a.length < b.length
```

You can also create a *suspending lambda expression* using the `suspend` keyword. A suspending lambda has the function type `suspend () -> Unit` and can call other suspending functions:

```
val suspendingTask = suspend { doSuspendingWork() }
```

Lambda expression syntax

The full syntactic form of lambda expressions is as follows:

```
val sum: (Int, Int) → Int = { x: Int, y: Int → x + y }
```

- A lambda expression is always surrounded by curly braces.
- Parameter declarations in the full syntactic form go inside curly braces and have optional type annotations.
- The body goes after the `->`.

- If the inferred return type of the lambda is not `Unit`, the last (or possibly single) expression inside the lambda body is treated as the return value.

If you leave all the optional annotations out, what's left looks like this:

```
val sum = { x: Int, y: Int -> x + y }
```

Passing trailing lambdas

According to Kotlin convention, if the last parameter of a function is a function, then a lambda expression passed as the corresponding argument can be placed outside the parentheses:

```
val product = items.fold(1) { acc, e -> acc * e }
```

Such syntax is also known as *trailing lambda*.

If the lambda is the only argument in that call, the parentheses can be omitted entirely:

```
run { println("...") }
```

it: implicit name of a single parameter

It's very common for a lambda expression to have only one parameter.

If the compiler can parse the signature without any parameters, the parameter does not need to be declared and `->` can be omitted. The parameter will be implicitly declared under the name `it`:

```
ints.filter { it > 0 } // this literal is of type '(it: Int) -> Boolean'
```

Returning a value from a lambda expression

You can explicitly return a value from the lambda using the qualified return syntax. Otherwise, the value of the last expression is implicitly returned.

Therefore, the two following snippets are equivalent:

```
ints.filter {
    val shouldFilter = it > 0
    shouldFilter
}

ints.filter {
    val shouldFilter = it > 0
    return@filter shouldFilter
}
```

This convention, along with passing a lambda expression outside of parentheses, allows for LINQ-style code:

```
strings.filter { it.length == 5 }.sortedBy { it }.map { it.uppercase() }
```

Underscore for unused variables

If the lambda parameter is unused, you can place an underscore instead of its name:

```
map.forEach { (_, value) -> println("$value!") }
```

Destructuring in lambdas

Destructuring in lambdas is described as a part of destructuring declarations.

Anonymous functions

The lambda expression syntax above is missing one thing – the ability to specify the function's return type. In most cases, this is unnecessary because the return type can be inferred automatically. However, if you do need to specify it explicitly, you can use an alternative syntax: an *anonymous function*.

```
fun(x: Int, y: Int): Int = x + y
```

An anonymous function looks very much like a regular function declaration, except its name is omitted. Its body can be either an expression (as shown above) or a block:

```
fun(x: Int, y: Int): Int {
    return x + y
}
```

The parameters and the return type are specified in the same way as for regular functions, except the parameter types can be omitted if they can be inferred from the context:

```
ints.filter(fun(item) = item > 0)
```

The return type inference for anonymous functions works just like for normal functions: the return type is inferred automatically for anonymous functions with an expression body, but it has to be specified explicitly (or is assumed to be `Unit`) for anonymous functions with a block body.

> When passing anonymous functions as parameters, place them inside the parentheses. The shorthand syntax that allows you to leave the function outside the parentheses works only for lambda expressions.

Another difference between lambda expressions and anonymous functions is the behavior of non-local returns. A `return` statement without a label always returns from the function declared with the `fun` keyword. This means that a `return` inside a lambda expression will return from the enclosing function, whereas a `return` inside an anonymous function will return from the anonymous function itself.

Closures

A lambda expression or anonymous function (as well as a local function and an object expression) can access its *closure*, which includes the variables declared in the outer scope. The variables captured in the closure can be modified in the lambda:

```
var sum = 0
ints.filter { it > 0 }.forEach {
    sum += it
}
print(sum)
```

Function literals with receiver

Function types with receiver, such as `A.(B) -> C`, can be instantiated with a special form of function literals – function literals with receiver.

As mentioned above, Kotlin provides the ability to call an instance of a function type with receiver while providing the *receiver object*.

Inside the body of the function literal, the receiver object passed to a call becomes an *implicit* `this`, so that you can access the members of that receiver object without any additional qualifiers, or access the receiver object using a `this` expression.

This behavior is similar to that of extension functions, which also allow you to access the members of the receiver object inside the function body.

Here is an example of a function literal with receiver along with its type, where `plus` is called on the receiver object:

```
val sum: Int.(Int) -> Int = { other -> plus(other) }
```

The anonymous function syntax allows you to specify the receiver type of a function literal directly. This can be useful if you need to declare a variable of a function type with receiver, and then to use it later.

```
val sum = fun Int.(other: Int): Int = this + other
```

Lambda expressions can be used as function literals with receiver when the receiver type can be inferred from the context. One of the most important examples of their usage is type-safe builders:

```
class HTML {
    fun body() { ... }
}

fun html(init: HTML.() -> Unit): HTML {
    val html = HTML()  // create the receiver object
    html.init()        // pass the receiver object to the lambda
    return html
}

html {       // lambda with receiver begins here
    body()   // calling a method on the receiver object
}
```

Type-safe builders

By using well-named functions as builders in combination with function literals with receiver, it is possible to create type-safe, statically-typed builders in Kotlin.

Type-safe builders allow creating Kotlin-based domain-specific languages (DSLs) suitable for building complex hierarchical data structures in a semi-declarative way. Sample use cases for the builders are:

- Generating markup with Kotlin code, such as HTML or XML
- Configuring routes for a web server: Ktor

Consider the following code:

```
package html

fun main() {
        val result = html {
        head {
            title { +"HTML encoding with Kotlin" }
        }
        body {
            h1 { +"HTML encoding with Kotlin" }
            p {
                +"this format can be used as an"
                +"alternative markup to HTML"
            }

            // An element with attributes and text content
            a(href = "http://kotlinlang.org") { +"Kotlin" }

            // Mixed content
            p {
                +"This is some"
                b { +"mixed" }
                +"text. For more see the"
                a(href = "http://kotlinlang.org") {
                    +"Kotlin"
                }
                +"project"
            }
            p {
                +"some text"
                ul {
                    for (i in 1..5)
                        li { +"${i}*2 = ${i*2}" }
                }
            }
        }
    }
    //sampleEnd
    println(result)
}

interface Element {
    fun render(builder: StringBuilder, indent: String)
}

class TextElement(val text: String) : Element {
    override fun render(builder: StringBuilder, indent: String) {
        builder.append("$indent$text\n")
    }
}

@DslMarker
annotation class HtmlTagMarker

@HtmlTagMarker
abstract class Tag(val name: String) : Element {
    val children = arrayListOf<Element>()
    val attributes = hashMapOf<String, String>()

    protected fun <T : Element> initTag(tag: T, init: T.() -> Unit): T {
        tag.init()
        children.add(tag)
        return tag
    }
```

```
    override fun render(builder: StringBuilder, indent: String) {
        builder.append("$indent<$name${renderAttributes()}>\n")
        for (c in children) {
            c.render(builder, indent + "  ")
        }
        builder.append("$indent</$name>\n")
    }

    private fun renderAttributes(): String {
        val builder = StringBuilder()
        for ((attr, value) in attributes) {
            builder.append(" $attr=\"$value\"")
        }
        return builder.toString()
    }

    override fun toString(): String {
        val builder = StringBuilder()
        render(builder, "")
        return builder.toString()
    }
}

abstract class TagWithText(name: String) : Tag(name) {
    operator fun String.unaryPlus() {
        children.add(TextElement(this))
    }
}
class HTML() : TagWithText("html") {
    fun head(init: Head.() -> Unit) = initTag(Head(), init)
    fun body(init: Body.() -> Unit) = initTag(Body(), init)
}

class Head() : TagWithText("head") {
    fun title(init: Title.() -> Unit) = initTag(Title(), init)
}

class Title() : TagWithText("title")

abstract class BodyTag(name: String) : TagWithText(name) {
    fun b(init: B.() -> Unit) = initTag(B(), init)
    fun p(init: P.() -> Unit) = initTag(P(), init)
    fun h1(init: H1.() -> Unit) = initTag(H1(), init)
    fun ul(init: UL.() -> Unit) = initTag(UL(), init)
    fun a(href: String, init: A.() -> Unit) {
        val a = initTag(A(), init)
        a.href = href
    }
}

class Body() : BodyTag("body")
class UL() : BodyTag("ul") {
    fun li(init: LI.() -> Unit) = initTag(LI(), init)
}

class B() : BodyTag("b")
class LI() : BodyTag("li")
class P() : BodyTag("p")
class H1() : BodyTag("h1")

class A : BodyTag("a") {
    var href: String
        get() = attributes["href"]!!
```

```
        set(value) {
            attributes["href"] = value
        }
}

fun html(init: HTML.() -> Unit): HTML {
    val html = HTML()
    html.init()
    return html
}
```

```
<html>
  <head>
    <title>
      HTML encoding with Kotlin
    </title>
  </head>
  <body>
    <h1>
      HTML encoding with Kotlin
    </h1>
    <p>
      this format can be used as an
      alternative markup to HTML
    </p>
    <a href="http://kotlinlang.org">
      Kotlin
    </a>
    <p>
      This is some
      <b>
        mixed
      </b>
      text. For more see the
      <a href="http://kotlinlang.org">
        Kotlin
      </a>
      project
    </p>
    <p>
      some text
      <ul>
        <li>
          1*2 = 2
        </li>
        <li>
          2*2 = 4
        </li>
        <li>
          3*2 = 6
        </li>
        <li>
          4*2 = 8
        </li>
        <li>
          5*2 = 10
        </li>
      </ul>
    </p>
  </body>
</html>
```

How it works

Assume that you need to implement a type-safe builder in Kotlin. First of all, define the model you want to build. In this case, you need to model HTML tags. It is easily done with a bunch of classes. For example, `HTML` is a class that describes the `<html>` tag defining children like `<head>` and `<body>`. (See its declaration below.)

Now, let's recall why you can say something like this in the code:

```
html {
 // ...
}
```

`html` is actually a function call that takes a lambda expression as an argument. This function is defined as follows:

```
fun html(init: HTML.() -> Unit): HTML {
    val html = HTML()
    html.init()
    return html
}
```

This function takes one parameter named `init`, which is itself a function. The type of the function is `HTML.() -> Unit`, which is a *function type with receiver*. This means that you need to pass an instance of type `HTML` (a *receiver*) to the function, and you can call members of that instance inside the function.

The receiver can be accessed through the `this` keyword:

```
html {
    this.head { ... }
    this.body { ... }
}
```

(`head` and `body` are member functions of `HTML`.)

Now, `this` can be omitted, as usual, and you get something that looks very much like a builder already:

```
html {
    head { ... }
    body { ... }
}
```

So, what does this call do? Let's look at the body of `html` function as defined above. It creates a new instance of `HTML`, then it initializes it by calling the function that is passed as an argument (in this example, this boils down to calling `head` and `body` on the `HTML` instance), and then it returns this instance. This is exactly what a builder should do.

The `head` and `body` functions in the `HTML` class are defined similarly to `html`. The only difference is that they add the built instances to the `children` collection of the enclosing `HTML` instance:

```
fun head(init: Head.() -> Unit): Head {
    val head = Head()
    head.init()
    children.add(head)
    return head
}

fun body(init: Body.() -> Unit): Body {
    val body = Body()
    body.init()
    children.add(body)
    return body
}
```

Actually, these two functions do just the same thing, so you can have a generic version, `initTag`:

```
protected fun <T : Element> initTag(tag: T, init: T.() -> Unit): T {
    tag.init()
    children.add(tag)
    return tag
}
```

So, now your functions are very simple:

```
fun head(init: Head.() -> Unit) = initTag(Head(), init)

fun body(init: Body.() -> Unit) = initTag(Body(), init)
```

And you can use them to build `<head>` and `<body>` tags.

One other thing to be discussed here is how you add text to tag bodies. In the example above, you say something like:

```
html {
    head {
        title {+"XML encoding with Kotlin"}
    }
    // ...
}
```

So basically, you just put a string inside a tag body, but there is this little `+` in front of it, so it is a function call that invokes a prefix `unaryPlus()` operation. That operation is actually defined by an extension function `unaryPlus()` that is a member of the `TagWithText` abstract class (a parent of `Title`):

```
operator fun String.unaryPlus() {
    children.add(TextElement(this))
}
```

So, what the prefix `+` does here is wrapping a string into an instance of `TextElement` and adding it to the `children` collection, so that it becomes a proper part of the tag tree.

All this is defined in a package `com.example.html` that is imported at the top of the builder example above. In the last section, you can read through the full definition of this package.

Scope control: @DslMarker

When using DSLs, one might have come across the problem that too many functions can be called in the context. You can call methods of every available implicit receiver inside a lambda and therefore get an inconsistent result, like the tag `head` inside another `head`:

```
html {
    head {
        head {} // should be forbidden
    }
    // ...
}
```

In this example, only members of the nearest implicit receiver `this@head` must be available; `head()` is a member of the outer receiver `this@html`, so it must be illegal to call it.

To address this problem, there is a special mechanism to control receiver scope.

To make the compiler start controlling scopes, you only have to annotate the types of all receivers used in the DSL with the same marker annotation. For instance, for HTML Builders you declare an annotation `@HtmlTagMarker`:

```
@DslMarker
@Target(AnnotationTarget.CLASS)
annotation class HtmlTagMarker
```

An annotation class is called a DSL marker if it is annotated with the `@DslMarker` annotation.

The `@Target` annotation restricts where `@HtmlTagMarker` can be applied. DSL markers only affect scope control when applied to:

- Type declarations (`CLASS`): classes or interfaces used as DSL receivers.
- Type usages (`TYPE`): receiver types in function type signatures.
- Type aliases (`TYPEALIAS`): type aliases that expand to DSL receiver types.

Applying a DSL marker to other targets (such as functions or properties) has no effect on scope control.

> For more details on how DSL marker works, see the corresponding KEEP document.

In our DSL, all the tag classes extend the same superclass `Tag`. It's enough to annotate only the superclass with `@HtmlTagMarker` and after that the Kotlin compiler will treat all the inherited classes as annotated:

```
@HtmlTagMarker
abstract class Tag(val name: String) { ... }
```

You don't have to annotate the `HTML` or `Head` classes with `@HtmlTagMarker` because their superclass is already annotated:

```
class HTML() : Tag("html") { ... }

class Head() : Tag("head") { ... }
```

After you've added this annotation, the Kotlin compiler knows which implicit receivers are part of the same DSL and allows to call members of the nearest receivers only:

```
html {
    head {
        head { } // error: a member of outer receiver
    }
    // ...
}
```

Note that it's still possible to call the members of the outer receiver, but to do that you have to specify this receiver explicitly:

```
html {
    head {
        this@html.head { } // possible
    }
    // ...
}
```

You can also apply the `@DslMarker` annotation directly to function types. This requires including `AnnotationTarget.TYPE` in the annotation targets:

```
@DslMarker
@Target(AnnotationTarget.CLASS, AnnotationTarget.TYPE)
annotation class HtmlTagMarker
```

As a result, the `@DslMarker` annotation can be applied to function types, most commonly to lambdas with receivers. For example:

```
fun html(init: @HtmlTagMarker HTML.() -> Unit): HTML { ... }

fun HTML.head(init: @HtmlTagMarker Head.() -> Unit): Head { ... }

fun Head.title(init: @HtmlTagMarker Title.() -> Unit): Title { ... }
```

When you call these functions, the `@DslMarker` annotation restricts access to outer receivers in the body of a lambda marked with it unless you specify them explicitly:

```
html {
    head {
        title {
            // Access to title, head or other functions of outer receivers is restricted here.
        }
    }
}
```

Only the nearest receiver's members and extensions are accessible within a lambda, preventing unintended interactions between nested scopes.

When both a member of an implicit receiver and a declaration from a context parameter are in a scope with the same name, the compiler reports a warning because the implicit receiver is shadowed by the context parameter. To resolve this, use a `this` qualifier to explicitly call the receiver, or use `contextOf<T>()` to call the context declaration:

```
interface HtmlTag {
    fun setAttribute(name: String, value: String)
}

// Declares a top-level function with the same name,
// which is available through a context parameter
context(tag: HtmlTag)
fun setAttribute(name: String, value: String) { tag.setAttribute(name, value) }

fun test(head: HtmlTag, extraInfo: HtmlTag) {
    with(head) {
        // Introduces a context value of the same type in an inner scope
        context(extraInfo) {
            // Reports a warning:
            // Uses an implicit receiver shadowed by a context parameter
            setAttribute("user", "1234")

            // Calls the receiver's member explicitly
            this.setAttribute("user", "1234")

            // Calls the context declaration explicitly
            contextOf<HtmlTag>().setAttribute("user", "1234")
        }
    }
}
```

Full definition of the com.example.html package

This is how the package `com.example.html` is defined (only the elements used in the example above). It builds an HTML tree. It makes heavy use of extension functions and lambdas with receiver.

```
package com.example.html

interface Element {
    fun render(builder: StringBuilder, indent: String)
}

class TextElement(val text: String) : Element {
    override fun render(builder: StringBuilder, indent: String) {
        builder.append("$indent$text\n")
    }
}

@DslMarker
@Target(AnnotationTarget.CLASS, AnnotationTarget.TYPE)
annotation class HtmlTagMarker

@HtmlTagMarker
abstract class Tag(val name: String) : Element {
    val children = arrayListOf<Element>()
    val attributes = hashMapOf<String, String>()

    protected fun <T : Element> initTag(tag: T, init: T.() -> Unit): T {
        tag.init()
        children.add(tag)
        return tag
    }

    override fun render(builder: StringBuilder, indent: String) {
        builder.append("$indent<$name${renderAttributes()}>\n")
        for (c in children) {
            c.render(builder, indent + "  ")
        }
        builder.append("$indent</$name>\n")
    }

    private fun renderAttributes(): String {
        val builder = StringBuilder()
        for ((attr, value) in attributes) {
            builder.append(" $attr=\"$value\"")
        }
        return builder.toString()
    }

    override fun toString(): String {
        val builder = StringBuilder()
        render(builder, "")
        return builder.toString()
    }
}

abstract class TagWithText(name: String) : Tag(name) {
    operator fun String.unaryPlus() {
        children.add(TextElement(this))
    }
}

class HTML : TagWithText("html") {
    fun head(init: Head.() -> Unit) = initTag(Head(), init)

    fun body(init: Body.() -> Unit) = initTag(Body(), init)
}

class Head : TagWithText("head") {
```

```
    fun title(init: Title.() -> Unit) = initTag(Title(), init)
}

class Title : TagWithText("title")

abstract class BodyTag(name: String) : TagWithText(name) {
    fun b(init: B.() -> Unit) = initTag(B(), init)
    fun p(init: P.() -> Unit) = initTag(P(), init)
    fun h1(init: H1.() -> Unit) = initTag(H1(), init)
    fun a(href: String, init: A.() -> Unit) {
        val a = initTag(A(), init)
        a.href = href
    }
}

class Body : BodyTag("body")
class B : BodyTag("b")
class P : BodyTag("p")
class H1 : BodyTag("h1")

class A : BodyTag("a") {
    var href: String
        get() = attributes["href"]!!
        set(value) {
            attributes["href"] = value
        }
}

fun html(init: HTML.() -> Unit): HTML {
    val html = HTML()
    html.init()
    return html
}
```

Using builders with builder type inference

Kotlin supports *builder type inference* (or builder inference), which can come in useful when you are working with generic builders. It helps the compiler infer the type arguments of a builder call based on the type information about other calls inside its lambda argument.

Consider this example of `buildMap()` usage:

```
fun addEntryToMap(baseMap: Map<String, Number>, additionalEntry: Pair<String, Int>?) {
   val myMap = buildMap {
       putAll(baseMap)
       if (additionalEntry != null) {
           put(additionalEntry.first, additionalEntry.second)
       }
   }
}
```

There is not enough type information here to infer type arguments in a regular way, but builder inference can analyze the calls inside the lambda argument. Based on the type information about `putAll()` and `put()` calls, the compiler can automatically infer type arguments of the `buildMap()` call into `String` and `Number`. Builder inference allows to omit type arguments while using generic builders.

Writing your own builders

Requirements for enabling builder inference

> Before Kotlin 1.7.0, enabling builder inference for a builder function required `-Xenable-builder-inference` compiler option. In 1.7.0 the option is enabled by default.

To let builder inference work for your own builder, make sure its declaration has a builder lambda parameter of a function type with a receiver. There are also two requirements for the receiver type:

1. It should use the type arguments that builder inference is supposed to infer. For example:

```
fun <V> buildList(builder: MutableList<V>.() -> Unit) { ... }
```

> Note that passing the type parameter's type directly like `fun <T> myBuilder(builder: T.() -> Unit)` is not yet supported.

2. It should provide public members or extensions that contain the corresponding type parameters in their signature. For example:

```
class ItemHolder<T> {
    private val items = mutableListOf<T>()

    fun addItem(x: T) {
        items.add(x)
    }

    fun getLastItem(): T? = items.lastOrNull()
}

fun <T> ItemHolder<T>.addAllItems(xs: List<T>) {
    xs.forEach { addItem(it) }
}

fun <T> itemHolderBuilder(builder: ItemHolder<T>.() -> Unit): ItemHolder<T> =
    ItemHolder<T>().apply(builder)

fun test(s: String) {
    val itemHolder1 = itemHolderBuilder { // Type of itemHolder1 is ItemHolder<String>
        addItem(s)
    }
    val itemHolder2 = itemHolderBuilder { // Type of itemHolder2 is ItemHolder<String>
        addAllItems(listOf(s))
    }
    val itemHolder3 = itemHolderBuilder { // Type of itemHolder3 is ItemHolder<String?>
        val lastItem: String? = getLastItem()
        // ...
    }
}
```

Supported features

Builder inference supports:

- Inferring several type arguments

```
fun <K, V> myBuilder(builder: MutableMap<K, V>.() -> Unit): Map<K, V> { ... }
```

- Inferring type arguments of several builder lambdas within one call including interdependent ones

```
fun <K, V> myBuilder(
    listBuilder: MutableList<V>.() -> Unit,
    mapBuilder: MutableMap<K, V>.() -> Unit
): Pair<List<V>, Map<K, V>> =
    mutableListOf<V>().apply(listBuilder) to mutableMapOf<K, V>().apply(mapBuilder)

fun main() {
    val result = myBuilder(
        { add(1) },
        { put("key", 2) }
    )
    // result has Pair<List<Int>, Map<String, Int>> type
}
```

- Inferring type arguments whose type parameters are lambda's parameter or return types

```
fun <K, V> myBuilder1(
    mapBuilder: MutableMap<K, V>.() -> K
): Map<K, V> = mutableMapOf<K, V>().apply { mapBuilder() }

fun <K, V> myBuilder2(
    mapBuilder: MutableMap<K, V>.(K) -> Unit
): Map<K, V> = mutableMapOf<K, V>().apply { mapBuilder(2 as K) }

fun main() {
    // result1 has the Map<Long, String> type inferred
    val result1 = myBuilder1 {
        put(1L, "value")
        2
    }
    val result2 = myBuilder2 {
        put(1, "value 1")
        // You can use `it` as "postponed type variable" type
        // See the details in the section below
        put(it, "value 2")
    }
}
```

How builder inference works

Postponed type variables

Builder inference works in terms of *postponed type variables*, which appear inside the builder lambda during builder inference analysis. A postponed type variable is a type argument's type, which is in the process of inferring. The compiler uses it to collect type information about the type argument.

Consider the example with `buildList()`:

```
val result = buildList {
    val x = get(0)
}
```

Here `x` has a type of postponed type variable: the `get()` call returns a value of type `E`, but `E` itself is not yet fixed. At this moment, a concrete type for `E` is unknown.

When a value of a postponed type variable gets associated with a concrete type, builder inference collects this information to infer the resulting type of the corresponding type argument at the end of the builder inference analysis. For example:

```
val result = buildList {
    val x = get(0)
    val y: String = x
} // result has the List<String> type inferred
```

After the postponed type variable gets assigned to a variable of the `String` type, builder inference gets the information that `x` is a subtype of `String`. This assignment is the last statement in the builder lambda, so the builder inference analysis ends with the result of inferring the type argument `E` into `String`.

Note that you can always call `equals()`, `hashCode()`, and `toString()` functions with a postponed type variable as a receiver.

Contributing to builder inference results

Builder inference can collect different varieties of type information that contribute to the analysis result. It considers:

- Calling methods on a lambda's receiver that use the type parameter's type

  ```
  val result = buildList {
      // Type argument is inferred into String based on the passed "value" argument
      add("value")
  } // result has the List<String> type inferred
  ```

- Specifying the expected type for calls that return the type parameter's type

  ```
  val result = buildList {
      // Type argument is inferred into Float based on the expected type
      val x: Float = get(0)
  } // result has the List<Float> type
  ```

  ```
  class Foo<T> {
      val items = mutableListOf<T>()
  }

  fun <K> myBuilder(builder: Foo<K>.() -> Unit): Foo<K> = Foo<K>().apply(builder)

  fun main() {
      val result = myBuilder {
          val x: List<CharSequence> = items
          // ...
      } // result has the Foo<CharSequence> type
  }
  ```

- Passing postponed type variables' types into methods that expect concrete types

```
fun takeMyLong(x: Long) { ... }

fun String.isMoreThan3() = length > 3

fun takeListOfStrings(x: List<String>) { ... }

fun main() {
    val result1 = buildList {
        val x = get(0)
        takeMyLong(x)
    } // result1 has the List<Long> type

    val result2 = buildList {
        val x = get(0)
        val isLong = x.isMoreThan3()
    // ...
    } // result2 has the List<String> type

    val result3 = buildList {
        takeListOfStrings(this)
    } // result3 has the List<String> type
}
```

- Taking a callable reference to the lambda receiver's member

```
fun main() {
    val result = buildList {
        val x: KFunction1<Int, Float> = ::get
    } // result has the List<Float> type
}
```

```
fun takeFunction(x: KFunction1<Int, Float>) { ... }

fun main() {
    val result = buildList {
        takeFunction(::get)
    } // result has the List<Float> type
}
```

At the end of the analysis, builder inference considers all collected type information and tries to merge it into the resulting type. See the example.

```
val result = buildList { // Inferring postponed type variable E
    // Considering E is Number or a subtype of Number
    val n: Number? = getOrNull(0)
    // Considering E is Int or a supertype of Int
    add(1)
    // E gets inferred into Int
} // result has the List<Int> type
```

The resulting type is the most specific type that corresponds to the type information collected during the analysis. If the given type information is contradictory and cannot be merged, the compiler reports an error.

Note that the Kotlin compiler uses builder inference only if regular type inference cannot infer a type argument. This means you can contribute type information outside a builder lambda, and then builder inference analysis is not required. Consider the example:

```
fun someMap() = mutableMapOf<CharSequence, String>()

fun <E> MutableMap<E, String>.f(x: MutableMap<E, String>) { ... }

fun main() {
    val x: Map<in String, String> = buildMap {
        put("", "")
        f(someMap()) // Type mismatch (required String, found CharSequence)
    }
}
```

Here a type mismatch appears because the expected type of the map is specified outside the builder lambda. The compiler analyzes all the statements inside with the fixed receiver type `Map<in String, String>`.

Context parameters

> Context parameters replace an older experimental feature called context receivers. You can find their main differences in the design document for context parameters. To migrate from context receivers to context parameters, you can use assisted support in IntelliJ IDEA, as described in the related blog post.

Context parameters allow functions and properties to declare dependencies that are implicitly available in the surrounding context.

With context parameters, you don't need to manually pass around values, such as services or dependencies, that are shared and rarely change across sets of function calls.

To declare context parameters for properties and functions, use the `context` keyword followed by a list of parameters, with each parameter declared as `name: Type`. Here is an example with a dependency on the `UserService` interface:

```
// UserService defines the dependency required in context
interface UserService {
    fun log(message: String)
    fun findUserById(id: Int): String
}

// Declares a function with a context parameter
context(users: UserService)
fun outputMessage(message: String) {
    // Uses log from the context
    users.log("Log: $message")
}

// Declares a property with a context parameter
context(users: UserService)
val firstUser: String
    // Uses findUserById from the context
    get() = users.findUserById(1)

fun main() {
    val users = object : UserService {
        override fun log(message: String) {
            println(message)
        }

        override fun findUserById(id: Int): String {
            return "User $id"
        }
    }

    context(users) {
        outputMessage("Looking up the first user")
        println(firstUser)
        // User 1
    }
}
```

You can use `_` as a context parameter name when you don't need to refer to the parameter directly. An anonymous context parameter can still satisfy the context parameters required by called functions, but you can't access it by name. To access its value explicitly, use `contextOf<T>()`:

```
// Uses "_" as context parameter name
context(_: UserService)
fun logWelcome() {
    // The anonymous parameter satisfies the UserService context parameter
    // required by outputMessage()
    outputMessage("Welcome!")

    // Retrieves the UserService value explicitly
    contextOf<UserService>().log("Hi!")
}
```

Context parameters resolution

Kotlin resolves context parameters at the call site by searching for matching context values in the current scope. Kotlin matches them by their type. If multiple compatible values exist at the same scope level, the compiler reports an ambiguity:

```
// UserService defines the dependency required in context
interface UserService {
    fun log(message: String)
}

// Declares a function with a context parameter
context(users: UserService)
fun outputMessage(message: String) {
    users.log("Log: $message")
}

fun main() {
    // Implements UserService
    val serviceA = object : UserService {
        override fun log(message: String) = println("A: $message")
    }

    // Implements UserService
    val serviceB = object : UserService {
        override fun log(message: String) = println("B: $message")
    }

    // Both serviceA and serviceB match the expected UserService type at the call site
    context(serviceA, serviceB) {
        // This results in an ambiguity error
        outputMessage("This will not compile")
    }
}
```

Experimental

Pass context arguments explicitly

When overloads differ only by context parameters, a call can become ambiguous if multiple matching context values are available.

To resolve the ambiguity, pass an explicit context argument at the call site:

```
class EmailSender
class SmsSender

context(emailSender: EmailSender)
fun sendNotification() {
    println("Sent email notification")
}

context(smsSender: SmsSender)
fun sendNotification() {
    println("Sent SMS notification")
}

context(defaultEmailSender: EmailSender, defaultSmsSender: SmsSender)
fun notifyUser() {
    // Selects the overload with the EmailSender context parameter
    sendNotification(emailSender = defaultEmailSender)

    // Selects the overload with the SmsSender context parameter
    sendNotification(smsSender = defaultSmsSender)
}
```

You can also use explicit context arguments to reduce nesting in some function calls:

- For a single call, use explicit context arguments to make the call easier to read.
- If multiple calls use the same context arguments, use the `context()` function.

This feature is Experimental. To opt in, add the following compiler option to your build file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xexplicit-context-arguments")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xexplicit-context-arguments</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

Restrictions

Context parameters are in continuous improvement, and some of the current restrictions include:

- Constructors can't declare context parameters.
- Properties with context parameters can't have backing fields or initializers.
- Properties with context parameters can't use delegation.

Despite these restrictions, context parameters simplify managing dependencies through simplified dependency injection, improved DSL design, and scoped operations.

Inline functions

Using higher-order functions imposes certain runtime penalties: each function is an object, and it captures a closure. A closure is a scope of variables that can be accessed in the body of the function. Memory allocations (both for function objects and classes) and virtual calls introduce runtime overhead.

But it appears that in many cases this kind of overhead can be eliminated by inlining the lambda expressions. The functions shown below are good examples of this situation. The `lock()` function could be easily inlined at call-sites. Consider the following case:

```
lock(l) { foo() }
```

Instead of creating a function object for the parameter and generating a call, the compiler could emit the following code:

```
l.lock()
try {
    foo()
} finally {
    l.unlock()
}
```

To make the compiler do this, mark the `lock()` function with the `inline` modifier:

```
inline fun <T> lock(lock: Lock, body: () -> T): T { ... }
```

The `inline` modifier affects both the function itself and the lambdas passed to it: all of those will be inlined into the call site.

Inlining may cause the generated code to grow. However, if you do it in a reasonable way (avoiding inlining large functions), it will pay off in performance, especially at "megamorphic" call-sites inside loops.

noinline

If you don't want all of the lambdas passed to an inline function to be inlined, mark some of your function parameters with the `noinline` modifier:

```
inline fun foo(inlined: () -> Unit, noinline notInlined: () -> Unit) { ... }
```

Inlinable lambdas can only be called inside inline functions or passed as inlinable arguments. `noinline` lambdas, however, can be manipulated in any way you like, including being stored in fields or passed around.

> If an inline function has no inlinable function parameters and no reified type parameters, the compiler will issue a warning, since inlining such functions is very unlikely to be beneficial (you can use the `@Suppress("NOTHING_TO_INLINE")` annotation to suppress the warning if you are sure the inlining is needed).

Non-local jump expressions

Returns

In Kotlin, you can only use a normal, unqualified `return` to exit a named function or an anonymous function. To exit a lambda, use a label. A bare `return` is forbidden inside a lambda because a lambda cannot make the enclosing function `return` :

```
fun ordinaryFunction(block: () -> Unit) {
    println("hi!")
}
fun foo() {
    ordinaryFunction {
        return // ERROR: cannot make `foo` return here
    }
}
fun main() {
    foo()
}
```

But if the function the lambda is passed to is inlined, the return can be inlined, as well. So it is allowed:

```
inline fun inlined(block: () -> Unit) {
    println("hi!")
}
fun foo() {
    inlined {
        return // OK: the lambda is inlined
    }
}
fun main() {
    foo()
}
```

Such returns (located in a lambda, but exiting the enclosing function) are called *non-local* returns. This sort of construct usually occurs in loops, which inline functions often enclose:

```
fun hasZeros(ints: List<Int>): Boolean {
    ints.forEach {
        if (it == 0) return true // returns from hasZeros
    }
    return false
}
```

Note that some inline functions may call the lambdas passed to them as parameters not directly from the function body, but from another execution context, such as a local object or a nested function. In such cases, non-local control flow is also not allowed in the lambdas. To indicate that the lambda parameter of the inline function cannot use non-local returns, mark the lambda parameter with the `crossinline` modifier:

```
inline fun f(crossinline body: () -> Unit) {
    val f = object: Runnable {
        override fun run() = body()
    }
    // ...
}
```

Break and continue

Similar to non-local `return`, you can apply `break` and `continue` jump expressions in lambdas passed as arguments to an inline function that encloses a loop:

```
fun processList(elements: List<Int>): Boolean {
    for (element in elements) {
        val variable = element.nullableMethod() ?: run {
            log.warning("Element is null or invalid, continuing...")
            continue
        }
        if (variable == 0) return true
    }
    return false
}
```

Reified type parameters

Sometimes you need to access a type passed as a parameter:

```
fun <T> TreeNode.findParentOfType(clazz: Class<T>): T? {
    var p = parent
    while (p ≠ null && !clazz.isInstance(p)) {
        p = p.parent
    }
    @Suppress("UNCHECKED_CAST")
    return p as T?
}
```

Here, you walk up a tree and use reflection to check whether a node has a certain type. It's all fine, but the call site is not very pretty:

```
treeNode.findParentOfType(MyTreeNode::class.java)
```

A better solution would be to simply pass a type to this function. You can call it as follows:

```
treeNode.findParentOfType<MyTreeNode>()
```

To enable this, inline functions support *reified type parameters*, so you can write something like this:

```
inline fun <reified T> TreeNode.findParentOfType(): T? {
    var p = parent
    while (p ≠ null && p !is T) {
        p = p.parent
    }
    return p as T?
}
```

The code above qualifies the type parameter with the `reified` modifier to make it accessible inside the function, almost as if it were a normal class. Since the function is inlined, no reflection is needed and normal operators like `!is` and `as` are now available for you to use. Also, you can call the function as shown above: `myTree.findParentOfType<MyTreeNodeType>()`.

Though reflection may not be needed in many cases, you can still use it with a reified type parameter:

```
inline fun <reified T> membersOf() = T::class.members

fun main(s: Array<String>) {
    println(membersOf<StringBuilder>().joinToString("\n"))
}
```

Normal functions (not marked as inline) cannot have reified parameters. A type that does not have a run-time representation (for example, a non-reified type parameter or a fictitious type like `Nothing`) cannot be used as an argument for a reified type parameter.

Inline properties

The `inline` modifier can be used on accessors of properties that don't have backing fields. You can annotate individual property accessors:

```
val foo: Foo
    inline get() = Foo()

var bar: Bar
    get() = ...
    inline set(v) { ... }
```

You can also annotate an entire property, which marks both of its accessors as `inline`:

```
inline var bar: Bar
    get() = ...
    set(v) { ... }
```

At the call site, inline accessors are inlined as regular inline functions.

Restrictions for public API inline functions

When an inline function is `public` or `protected` but is not a part of a `private` or `internal` declaration, it is considered a module's public API. It can be called in other modules and is inlined at such call sites as well.

This imposes certain risks of binary incompatibility caused by changes in the module that declares an inline function in case the calling module is not re-compiled after the change.

To eliminate the risk of such incompatibility being introduced by a change in a *non*-public API of a module, public API inline functions are not allowed to use non-public-API declarations, i.e. `private` and `internal` declarations and their parts, in their bodies.

An `internal` declaration can be annotated with `@PublishedApi`, which allows its use in public API inline functions. When an `internal` inline function is marked as `@PublishedApi`, its body is checked too, as if it were public.

Operator overloading

Kotlin allows you to provide custom implementations for the predefined set of operators on types. These operators have predefined symbolic representation (like `+` or `*`) and precedence. To implement an operator, provide a member function or an extension function with a specific name for the corresponding type. This type becomes the left-hand side type for binary operations and the argument type for the unary ones.

To overload an operator, mark the corresponding function with the `operator` modifier:

```
interface IndexedContainer {
    operator fun get(index: Int)
}
```

When overriding your operator overloads, you can omit `operator`:

```
class OrdersList: IndexedContainer {
    override fun get(index: Int) { /*...*/ }
}
```

Unary operations

Unary prefix operators

Expression	Translated to
`+a`	`a.unaryPlus()`
`-a`	`a.unaryMinus()`
`!a`	`a.not()`

This table says that when the compiler processes, for example, an expression `+a`, it performs the following steps:

- Determines the type of `a`, let it be `T`.
- Looks up a function `unaryPlus()` with the `operator` modifier and no parameters for the receiver `T`, that means a member function or an extension function.
- If the function is absent or ambiguous, it is a compilation error.
- If the function is present and its return type is `R`, the expression `+a` has type `R`.

These operations, as well as all the others, are optimized for basic types and do not introduce overhead of function calls for them.

As an example, here's how you can overload the unary minus operator:

```
data class Point(val x: Int, val y: Int)

operator fun Point.unaryMinus() = Point(-x, -y)

val point = Point(10, 20)

fun main() {
   println(-point)  // prints "Point(x=-10, y=-20)"
}
```

Increments and decrements

Expression	Translated to
`a++`	`a.inc()` + see below
`a--`	`a.dec()` + see below

The `inc()` and `dec()` functions must return a value, which will be assigned to the variable on which the `++` or `--` operation was used. They shouldn't mutate the object on which the `inc` or `dec` was invoked.

The compiler performs the following steps for resolution of an operator in the *postfix* form, for example `a++`:

- Determines the type of `a`, let it be `T`.
- Looks up a function `inc()` with the `operator` modifier and no parameters, applicable to the receiver of type `T`.
- Checks that the return type of the function is a subtype of `T`.

The effect of computing the expression is:

- Store the initial value of `a` to a temporary storage `a0`.
- Assign the result of `a0.inc()` to `a`.
- Return `a0` as the result of the expression.

For `a--` the steps are completely analogous.

For the *prefix* forms `++a` and `--a` resolution works the same way, and the effect is:

- Assign the result of `a.inc()` to `a`.
- Return the new value of `a` as a result of the expression.

Binary operations

Arithmetic operators

Expression	Translated to
`a + b`	`a.plus(b)`
`a - b`	`a.minus(b)`
`a * b`	`a.times(b)`
`a / b`	`a.div(b)`
`a % b`	`a.rem(b)`

Expression	Translated to
`a..b`	`a.rangeTo(b)`
`a..<b`	`a.rangeUntil(b)`

For the operations in this table, the compiler just resolves the expression in the *Translated to* column.

Below is an example `Counter` class that starts at a given value and can be incremented using the overloaded `+` operator:

```
data class Counter(val dayIndex: Int) {
    operator fun plus(increment: Int): Counter {
        return Counter(dayIndex + increment)
    }
}
```

in operator

Expression	Translated to
`a in b`	`b.contains(a)`
`a !in b`	`!b.contains(a)`

For `in` and `!in` the procedure is the same, but the order of arguments is reversed.

Indexed access operator

Expression	Translated to
`a[i]`	`a.get(i)`
`a[i, j]`	`a.get(i, j)`
`a[i_1, ..., i_n]`	`a.get(i_1, ..., i_n)`
`a[i] = b`	`a.set(i, b)`
`a[i, j] = b`	`a.set(i, j, b)`
`a[i_1, ..., i_n] = b`	`a.set(i_1, ..., i_n, b)`

Square brackets are translated to calls to `get` and `set` with appropriate numbers of arguments.

invoke operator

Expression	Translated to
`a()`	`a.invoke()`
`a(i)`	`a.invoke(i)`
`a(i, j)`	`a.invoke(i, j)`
`a(i_1, ..., i_n)`	`a.invoke(i_1, ..., i_n)`

Parentheses are translated to calls to `invoke` with appropriate number of arguments.

Augmented assignments

Expression	Translated to
`a += b`	`a.plusAssign(b)`
`a -= b`	`a.minusAssign(b)`
`a *= b`	`a.timesAssign(b)`
`a /= b`	`a.divAssign(b)`
`a %= b`	`a.remAssign(b)`

For the assignment operations, for example `a += b`, the compiler performs the following steps:

- If the function from the right column is available:
  - If the corresponding binary function (that means `plus()` for `plusAssign()`) is available too, `a` is a mutable variable, and the return type of `plus` is a subtype of the type of `a`, report an error (ambiguity).
  - Make sure its return type is `Unit`, and report an error otherwise.
  - Generate code for `a.plusAssign(b)`.
- Otherwise, try to generate code for `a = a + b` (this includes a type check: the type of `a + b` must be a subtype of `a`).

Assignments are *NOT* expressions in Kotlin.

Equality and inequality operators

Expression	Translated to
`a == b`	`a?.equals(b) ?: (b === null)`
`a != b`	`!(a?.equals(b) ?: (b === null))`

These operators only work with the function `equals(other: Any?): Boolean`, which you can override to provide a custom equality check implementation. Any other function with the same name (like `equals(other: Foo)`) is ignored.

Kotlin calls `.equals()` when neither operand compares directly to `null` in the `==` expression and the comparison isn't between two floating-point types. Otherwise, Kotlin uses `===` for direct `null` comparisons and compares non-null floating-point values by numeric value.

`===` and `!==` (identity checks) aren't overloadable, so no conventions exist for them.

Comparison operators

Expression	Translated to
`a > b`	`a.compareTo(b) > 0`
`a < b`	`a.compareTo(b) < 0`
`a >= b`	`a.compareTo(b) >= 0`
`a <= b`	`a.compareTo(b) <= 0`

All comparisons are translated into calls to `compareTo`, that is required to return `Int`.

Property delegation operators

`provideDelegate`, `getValue` and `setValue` operator functions are described in Delegated properties.

Infix calls for named functions

You can simulate custom infix operations by using infix function calls.

Experimental

Unused return value checker

This feature is planned to be stabilized and improved in future Kotlin releases. We would appreciate your feedback in our issue tracker YouTrack.

For more information, see the related KEEP proposal.

The unused return value checker allows you to detect *ignored results*. These are values returned from expressions that produce something other than `Unit`, `Nothing`, or `Nothing?` and aren't:

- Stored in a variable or property.
- Returned or thrown.
- Passed as an argument to another function.
- Used as a receiver in a call or safe call.
- Checked in a condition such as `if`, `when`, or `while`.
- Used as the last statement of a lambda.

The checker doesn't report ignored results for increment operations like `++` and `--`, or for boolean shortcuts where the right-hand side exits the current function, for example, `condition || return`.

You can use the unused return value checker to catch bugs where a function call produces a meaningful result, but the result is silently dropped. This helps prevent unexpected behavior and makes such issues easier to track down.

Here's an example where a string is created but never used, so the checker reports it as an ignored result:

```
fun formatGreeting(name: String): String {
    if (name.isBlank()) return "Hello, anonymous user!"
    if (!name.contains(' ')) {
        // The checker reports a warning that this result is ignored:
        // "Unused return value of 'plus'."
        "Hello, " + name.replaceFirstChar(Char::titlecase) + "!"
    }
    val (first, last) = name.split(' ')
    return "Hello, $first! Or should I call you Dr. $last?"
}
```

Configure the unused return value checker

You can control how the compiler reports ignored results with the `-Xreturn-value-checker` compiler option.

It has the following modes:

- `disable` disables the unused return value checker (default).
- `check` enables the checker, and reports warnings for ignored results from marked functions.
- `full` enables the checker, treats all functions in your project as marked, and reports warnings for ignored results.

All marked functions are propagated as such, and ignored results are reported if the checker is enabled in projects that use your code as a dependency.

To use the unused return value checker in your project, add the compiler option to your build configuration file:

Gradle

```
// build.gradle(.kts)
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xreturn-value-checker=check")
    }
}
```

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>org.jetbrains.kotlin</groupId>
    ..
    <configuration>
        <args>
            <arg>-Xreturn-value-checker=check</arg>
        </args>
    </configuration>
</plugin>
```

Mark functions to check ignored results

When you set the `-Xreturn-value-checker` compiler option to `check`, the checker reports ignored results only from expressions that are marked, like most functions in the Kotlin standard library.

To mark your own code, use the `@MustUseReturnValues` annotation. You can apply it to a file, class, or function depending on the scope you want the checker to cover.

For example, you can mark an entire file:

```
// Marks all functions and classes in this file so the checker reports unused return values
@file:MustUseReturnValues

package my.project

fun someFunction(): String
```

Or a specific class:

```
// Marks all functions in this class so the checker reports unused return values
@MustUseReturnValues
class Greeter {
    fun greet(name: String): String = "Hello, $name"
}

fun someFunction(): Int = ...
```

You can apply the checker to your entire project by setting the `-Xreturn-value-checker` compiler option to `full`. With this option, you don't have to annotate your code with `@MustUseReturnValues`.

Suppress reports for ignored results

You can suppress reports on specific functions by annotating them with `@IgnorableReturnValue`. Annotate functions where ignoring the result is common and expected, such as `MutableList.add`:

```
@IgnorableReturnValue
fun <T> MutableList<T>.addAndIgnoreResult(element: T): Boolean {
    return add(element)
}
```

You can suppress a warning without annotating the function itself. To do this, assign the result to a special unnamed variable with an underscore syntax (`_`):

```
// Non-ignorable function
fun computeValue(): Int = 42

fun main() {

    // Reports a warning: result is ignored
    computeValue()

    // Suppresses the warning only at this call site with a special unused variable
    val _ = computeValue()
}
```

Ignored results in function overrides

When you override a function, the override inherits the reporting rules defined by the annotations on the base declaration. This also applies when the base declaration is part of the Kotlin standard library or of other library dependencies, so the checker reports ignored results for overrides of functions like `Any.hashCode()`.

Additionally, you can't override a function marked with `@IgnorableReturnValue` with another function that requires its return value to be used. However, you can mark an override with `@IgnorableReturnValue` in a class or interface annotated with `@MustUseReturnValues` when its result can be safely ignored:

```
@MustUseReturnValues
interface Greeter {
    fun greet(name: String): String
}

object SilentGreeter : Greeter {
    @IgnorableReturnValue
    override fun greet(name: String): String = ""
}

fun check(g: Greeter) {
    // Reports a warning: unused return value
    g.greet("John")

    // No warning
    SilentGreeter.greet("John")
}
```

Check for unused results in higher-order functions

Some higher-order functions, such as the `let` scope function, return the result of a lambda. To check for unused lambda results of higher-order functions, add the Experimental `returnsResultOf()` contract to the function's contract.

> Kotlin contracts are Experimental. To opt in, add the `@OptIn(ExperimentalContracts::class)` annotation when declaring a function with a contract.

Here's an example:

```
import kotlin.contracts.ExperimentalContracts
import kotlin.contracts.contract

@OptIn(ExperimentalContracts::class)
inline fun <T, R> T.customLet(block: (T) -> R): R {
    contract {
        returnsResultOf(block)
    }
    return block(this)
}
```

You can then use a function with this contract, such as `.customLet()`, to check if the lambda result is used:

```
fun handleNullablePackageName(packageName: String?, builder: StringBuilder) {
    // The checker doesn't report a warning because the return value of append() can be ignored
    packageName?.customLet { builder.append(it) }

    // The checker reports a warning because the returned string is unused
    packageName?.customLet { "kotlin.$it" }
}
```

> The `returnsResultOf()` contract requires a separate compiler option to opt in. Be aware that using it produces pre-release binaries that Kotlin compiler versions earlier than 2.4.0 can't read.

To opt in for your project, add the following compiler option to your build file:

Gradle

```
// build.gradle(.kts)
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xallow-returns-result-of")
    }
}
```

Maven

```
<!-- pom.xml -->
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xallow-returns-result-of</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

Interoperability with Java annotations

Some Java libraries use similar mechanisms with different annotations. The unused return value checker treats the following annotations as equivalent to using `@MustUseReturnValues`:

- `com.google.errorprone.annotations.CheckReturnValue`
- `edu.umd.cs.findbugs.annotations.CheckReturnValue`
- `org.jetbrains.annotations.CheckReturnValue`
- `org.springframework.lang.CheckReturnValue`
- `org.jooq.CheckReturnValue`

It also treats `com.google.errorprone.annotations.CanIgnoreReturnValue` as equivalent to using `@IgnorableReturnValue`.

Classes

> Before creating classes, consider using a data class if the purpose is to store data. Alternatively, think about extending an existing class with an extension, rather than creating a new one from scratch.

Like other object-oriented languages, Kotlin uses *classes* to encapsulate data (properties) and behavior (functions) for reusable, structured code.

Classes are blueprints or templates for objects, which you create via constructors. When you create an instance of a class, you are creating a concrete object based on that blueprint.

Kotlin offers concise syntax for declaring classes. To declare a class, use the `class` keyword followed by the class name:

```
class Person { /*...*/ }
```

The class declaration consists of:

- **Class header**, including but not limited to:

- `class` keyword
- Class name
- Type parameters (if any)
- Primary constructor (optional)

- **Class body** (optional), surrounded by curly braces `{}`, and including **class members** such as:
  - Secondary constructors
  - Initializer blocks
  - Functions
  - Properties
  - Nested and inner classes
  - Object declarations

You can keep both the class header and body to a bare minimum. If the class doesn't have a body, you can omit the curly braces `{}`:

```
// Class with primary constructor, but without a body
class Person(val name: String, var age: Int)
```

Here's an example that declares a class with a header and body, then creates an instance from it:

```
// Person class with a primary constructor
// that initializes the name property
class Person(val name: String) {
    // Class body with age property
    var age: Int = 0
}

fun main() {
    // Creates an instance of the Person class by calling the constructor
    val person = Person("Alice")

    // Accesses the instance's properties
    println(person.name)
    // Alice
    println(person.age)
    // 0
}
```

Creating instances

An instance is created when you use the class as a blueprint to build a real object to work with in your program.

To create an instance of a class, use the class name followed by parentheses `()`, similar to calling a function:

```
// Creates an instance of the Person class
val anonymousUser = Person()
```

In Kotlin, you can create instances:

- **Without arguments** (`Person()`): creates an instance using the default values, if they are declared in the class.

- **With arguments** (`Person(value)`): creates an instance by passing specific values.

You can assign the created instance to a mutable (`var`) or read-only (`val`) variable:

```
// Creates an instance using the default value
// and assigns it to a mutable variable
var anonymousUser = Person()

// Creates an instance by passing a specific value
// and assigns it to a read-only variable
val namedUser = Person("Joe")
```

It's possible to create instances wherever you need them, inside the `main()` function, within other functions, or inside another class. Additionally, you can create instances inside another function and call that function from `main()` .

The following code declares a `Person` class with a property for storing a name. It also demonstrates how to create an instance with both the default constructor's value and a specific value:

```
// Class header with a primary constructor
// that initializes name with a default value
class Person(val name: String = "Sebastian")

fun main() {
    // Creates an instance using the default constructor's value
    val anonymousUser = Person()

    // Creates an instance by passing a specific value
    val namedUser = Person("Joe")

    // Accesses the instances' name property
    println(anonymousUser.name)
    // Sebastian
    println(namedUser.name)
    // Joe
}
```

In Kotlin, unlike other object-oriented programming languages, there is no need for the `new` keyword when creating class instances.

For information about creating instances of nested, inner, and anonymous inner classes, see the Nested classes section.

Constructors and initializer blocks

When you create a class instance, you call one of its constructors. A class in Kotlin can have a *primary constructor* and one or more *secondary constructors*.

The primary constructor is the main way to initialize a class. You declare it in the class header. A secondary constructor provides additional initialization logic. You declare it in the class body.

Both primary and secondary constructors are optional, but a class must have at least one constructor.

Primary constructor

The primary constructor sets up the initial state of an instance when it's created.

To declare a primary constructor, place it in the class header after the class name:

```
class Person constructor(name: String) { /*...*/ }
```

If the primary constructor doesn't have any annotations or visibility modifiers, you can omit the `constructor` keyword:

```
class Person(name: String) { /*...*/ }
```

The primary constructor can declare parameters as properties. Use the `val` keyword before the argument name to declare a read-only property and the `var` keyword for a mutable property:

```
class Person(val name: String, var age: Int) { /*...*/ }
```

These constructor parameter properties are stored as part of the instance and are accessible from outside the class.

It's also possible to declare primary constructor parameters that are not properties. These parameters don't have `val` or `var` in front of them, so they are not stored in the instance and are available only within the class body:

```
// Primary constructor parameter that is also a property
class PersonWithProperty(val name: String) {
    fun greet() {
        println("Hello, $name")
    }
}

// Primary constructor parameter only (not stored as a property)
class PersonWithAssignment(name: String) {
    // Must be assigned to a property to be usable later
    val displayName: String = name

    fun greet() {
        println("Hello, $displayName")
    }
}
```

Properties declared in the primary constructor are accessible by member functions of the class:

```
// Class with a primary constructor declaring properties
class Person(val name: String, var age: Int) {
    // Member function accessing class properties
    fun introduce(): String {
        return "Hi, I'm $name and I'm $age years old."
    }
}
```

You can also assign default values to properties in the primary constructor:

```
class Person(val name: String = "John", var age: Int = 30) { /*...*/ }
```

If no value is passed to the constructor during instance creation, properties use their default value:

```
// Class with a primary constructor
// including default values for name and age
class Person(val name: String = "John", var age: Int = 30)

fun main() {
    // Creates an instance using default values
    val person = Person()
    println("Name: ${person.name}, Age: ${person.age}")
    // Name: John, Age: 30
}
```

You can use the primary constructor parameters to initialize additional class properties directly in the class body:

```
// Class with a primary constructor
// including default values for name and age
class Person(
    val name: String = "John",
    var age: Int = 30
) {
    // Initializes the description property
    // from the primary constructor parameters
    val description: String = "Name: $name, Age: $age"
}

fun main() {
    // Creates an instance of the Person class
    val person = Person()
    // Accesses the description property
    println(person.description)
    // Name: John, Age: 30
}
```

As with functions, you can use trailing commas in constructor declarations:

```
class Person(
    val name: String,
    val lastName: String,
    var age: Int,
) { /*...*/ }
```

Initializer blocks

The primary constructor initializes the class and sets its properties. In most cases, you can handle this with simple code.

If you need to perform more complex operations during instance creation, place that logic in *initializer blocks* inside the class body. These blocks run when the primary constructor executes.

Declare initializer blocks with the `init` keyword followed by curly braces `{}`. Write within the curly braces any code that you want to run during initialization:

```
// Class with a primary constructor that initializes name and age
class Person(val name: String, var age: Int) {
    init {
        // Initializer block runs when an instance is created
        println("Person created: $name, age $age.")
    }
}

fun main() {
    // Creates an instance of the Person class
    Person("John", 30)
    // Person created: John, age 30.
}
```

Add as many initializer blocks (`init {}`) as you need. They run in the order in which they appear in the class body, along with property initializers:

```
// Class with a primary constructor that initializes name and age
class Person(val name: String, var age: Int) {
    // First initializer block
    init {
        // Runs first when an instance is created
        println("Person created: $name, age $age.")
    }

    // Second initializer block
    init {
        // Runs after the first initializer block
        if (age < 18) {
            println("$name is a minor.")
        } else {
            println("$name is an adult.")
        }
    }
}

fun main() {
    // Creates an instance of the Person class
    Person("John", 30)
    // Person created: John, age 30.
    // John is an adult.
}
```

You can use primary constructor parameters in initializer blocks. For example, in the code above, the first and second initializers use the `name` and `age` parameters from the primary constructor.

A common use case for `init` blocks is data validation. For example, by calling the `require` function:

```
class Person(val age: Int) {
    init {
        require(age > 0) { "age must be positive" }
    }
}
```

Secondary constructors

In Kotlin, secondary constructors are additional constructors that a class can have beyond its primary constructor. Secondary constructors are useful when you need multiple ways to initialize a class or for Java interoperability.

To declare a secondary constructor, use the `constructor` keyword inside the class body with the constructor parameters within parentheses `()`. Add the constructor logic within curly braces `{}`:

```
// Class header with a primary constructor that initializes name and age
class Person(val name: String, var age: Int) {

    // Secondary constructor that takes age as a
    // String and converts it to an Int
    constructor(name: String, age: String) : this(name, age.toIntOrNull() ?: 0) {
        println("$name created with converted age: ${this.age}")
    }
}

fun main() {
    // Uses the secondary constructor with age as a String
    Person("Bob", "8")
    // Bob created with converted age: 8
}
```

The expression `age.toIntOrNull() ?: 0` uses the Elvis operator. For more information, see Null safety.

In the code above, the secondary constructor delegates to the primary constructor via the `this` keyword, passing `name` and the `age` value converted to an integer.

In Kotlin, secondary constructors must delegate to the primary constructor. This delegation ensures that all primary constructor initialization logic is executed before any secondary constructor logic runs.

Constructor delegation can be:

- **Direct**, where the secondary constructor calls the primary constructor immediately.
- **Indirect**, where one secondary constructor calls another, which in turn delegates to the primary constructor.

Here's an example demonstrating how direct and indirect delegation works:

```
// Class header with a primary constructor that initializes name and age
class Person(
    val name: String,
    var age: Int
) {
    // Secondary constructor with direct delegation
    // to the primary constructor
    constructor(name: String) : this(name, 0) {
        println("Person created with default age: $age and name: $name.")
    }

    // Secondary constructor with indirect delegation:
    // this("Bob") → constructor(name: String) → primary constructor
    constructor() : this("Bob") {
        println("New person created with default age: $age and name: $name.")
    }
}

fun main() {
    // Creates an instance based on the direct delegation
    Person("Alice")
    // Person created with default age: 0 and name: Alice.

    // Creates an instance based on the indirect delegation
    Person()
    // Person created with default age: 0 and name: Bob.
    // New person created with default age: 0 and name: Bob.
}
```

In classes with initializer blocks (`init {}`), the code within these blocks becomes part of the primary constructor. Given that secondary constructors delegate to the primary constructor first, all initializer blocks and property initializers run before the body of the secondary constructor. Even if the class has no primary constructor, the delegation still happens implicitly:

```
// Class header with no primary constructor
class Person {
    // Initializer block runs when an instance is created
    init {
        // Runs before the secondary constructor
        println("1. First initializer block runs")
    }

    // Secondary constructor that takes an integer parameter
    constructor(i: Int) {
        // Runs after the initializer block
        println("2. Person $i is created")
    }
}

fun main() {
    // Creates an instance of the Person class
    Person(1)
    // 1. First initializer block runs
    // 2. Person 1 created
}
```

Classes without constructors

Classes that don't declare any constructors (primary or secondary) have an implicit primary constructor with no parameters:

```
// Class with no explicit constructors
class Person {
    // No primary or secondary constructors declared
}

fun main() {
    // Creates an instance of the Person class
    // using the implicit primary constructor
    val person = Person()
}
```

The visibility of this implicit primary constructor is public, meaning it can be accessed from anywhere. If you don't want your class to have a public constructor, declare an empty primary constructor with non-default visibility:

```
class Person private constructor() { /*...*/ }
```

On the JVM, if all primary constructor parameters have default values, the compiler implicitly provides a parameterless constructor that uses those default values.

This makes it easier to use Kotlin with libraries such as Jackson or Spring Data JPA, which create class instances through parameterless constructors.

In the following example, Kotlin implicitly provides a parameterless constructor `Person()` that uses the default value `""`:

```
class Person(val personName: String = "")
```

Inheritance

Class inheritance in Kotlin allows you to create a new class (derived class) from an existing class (base class), inheriting its properties and functions while adding or modifying behavior.

For detailed information about inheritance hierarchies and how to use the `open` keyword, see the Inheritance section.

Abstract classes

In Kotlin, abstract classes are classes that can't be instantiated directly. They are designed to be inherited by other classes which define their actual behavior. This behavior is called an *implementation*.

An abstract class can declare abstract properties and functions, which must be implemented by subclasses.

Abstract classes can also have constructors. These constructors initialize class properties and enforce required parameters for subclasses. Declare an abstract class using the `abstract` keyword:

```
abstract class Person(val name: String, val age: Int)
```

An abstract class can have both abstract and non-abstract members (properties and functions). To declare a member as abstract, you must use the `abstract` keyword explicitly.

You don't need to annotate abstract classes or functions with the `open` keyword because they are implicitly inheritable by default. For more details about the `open` keyword, see Inheritance.

Abstract members don't have an implementation in the abstract class. You define the implementation in a subclass or inheriting class with an `override` function or property:

```
// Abstract class with a primary constructor that declares name and age
abstract class Person(
    val name: String,
    val age: Int
) {
    // Abstract member
    // Doesn't provide implementation,
    // and it must be implemented by subclasses
    abstract fun introduce()

    // Non-abstract member (has an implementation)
    fun greet() {
        println("Hello, my name is $name.")
    }
}

// Subclass that provides an implementation for the abstract member
class Student(
    name: String,
    age: Int,
    val school: String
) : Person(name, age) {
    override fun introduce() {
        println("I am $name, $age years old, and I study at $school.")
    }
}

fun main() {
    // Creates an instance of the Student class
    val student = Student("Alice", 20, "Engineering University")

    // Calls the non-abstract member
    student.greet()
    // Hello, my name is Alice.

    // Calls the overridden abstract member
    student.introduce()
    // I am Alice, 20 years old, and I study at Engineering University.
}
```

Companion objects

In Kotlin, each class can have a companion object. Companion objects are a type of object declaration that allows you to access its members using the class name without creating a class instance.

Suppose you need to write a function that can be called without creating an instance of a class, but it is still logically connected to the class (such as a factory function). In that case, you can declare it inside a companion object declaration within the class:

```
// Class with a primary constructor that declares the name property
class Person(
    val name: String
) {
    // Class body with a companion object
    companion object {
        fun createAnonymous() = Person("Anonymous")
    }
}

fun main() {
    // Calls the function without creating an instance of the class
    val anonymous = Person.createAnonymous()
    println(anonymous.name)
    // Anonymous
}
```

If you declare a companion object inside your class, you can access its members using only the class name as a qualifier.

For more information, see Companion objects.

Data classes

Data classes in Kotlin are primarily used to hold data. For each data class, the compiler automatically generates additional member functions that allow you to print an instance to readable output, compare instances, copy instances, and more. Data classes are marked with `data`:

```
data class User(val name: String, val age: Int)
```

The compiler automatically derives the following members from all properties declared in the primary constructor:

- `equals()` / `hashCode()` pair.
- `toString()` of the form `"User(name=John, age=42)"`.
- `componentN()` functions corresponding to the properties in their order of declaration.
- `copy()` function.

To ensure consistency and meaningful behavior of the generated code, data classes have to fulfill the following requirements:

- The primary constructor must have at least one parameter.
- All primary constructor parameters must be marked as `val` or `var`.
- Data classes can't be abstract, open, sealed, or inner.

Additionally, the generation of data class members follows these rules with regard to the members' inheritance:

- If there are explicit implementations of `equals()`, `hashCode()`, or `toString()` in the data class body or `final` implementations in a superclass, then these functions are not generated, and the existing implementations are used.
- If a supertype has `componentN()` functions that are `open` and return compatible types, the corresponding functions are generated for the data class and override those of the supertype. If the functions of the supertype cannot be overridden due to incompatible signatures or due to their being final, an error is reported.

- Providing explicit implementations for the `componentN()` and `copy()` functions is not allowed.

Data classes may extend other classes (see Sealed classes for examples).

> On the JVM, if the generated class needs to have a parameterless constructor, default values for the properties have to be specified (see Constructors):
>
> ```
> data class User(val name: String = "", val age: Int = 0)
> ```

Properties declared in the class body

The compiler only uses the properties defined inside the primary constructor for the automatically generated functions. To exclude a property from the generated implementations, declare it inside the class body:

```
data class Person(val name: String) {
    var age: Int = 0
}
```

In the example below, only the `name` property is used by default inside the `toString()`, `equals()`, `hashCode()`, and `copy()` implementations, and there is only one component function, `component1()`. The `age` property is declared inside the class body and is excluded. Therefore, two `Person` objects with the same `name` but different `age` values are considered equal since `equals()` only evaluates properties from the primary constructor:

```
data class Person(val name: String) {
    var age: Int = 0
}
fun main() {
    val person1 = Person("John")
    val person2 = Person("John")
    person1.age = 10
    person2.age = 20

    println("person1 == person2: ${person1 == person2}")
    // person1 == person2: true

    println("person1 with age ${person1.age}: ${person1}")
    // person1 with age 10: Person(name=John)

    println("person2 with age ${person2.age}: ${person2}")
    // person2 with age 20: Person(name=John)
}
```

Copying

Use the `copy()` function to copy an object, allowing you to alter *some* of its properties while keeping the rest unchanged. The implementation of this function for the `User` class above would be as follows:

```
fun copy(name: String = this.name, age: Int = this.age) = User(name, age)
```

You can then write the following:

```
val jack = User(name = "Jack", age = 1)
val olderJack = jack.copy(age = 2)
```

The `copy()` function creates a *shallow* copy of the instance. In other words, it doesn't copy components recursively. As a result, references to other objects are shared.

For example, if a property holds a mutable list, changes made through the "original" value are also visible through the copy, and changes made through the copy are visible through the original:

```
data class Employee(val name: String, val roles: MutableList<String>)

fun main() {
    val original = Employee("Jamie", mutableListOf("developer"))
    val duplicate = original.copy()

    duplicate.roles.add("team lead")

    println(original)
    // Employee(name=Jamie, roles=[developer, team lead])
    println(duplicate)
    // Employee(name=Jamie, roles=[developer, team lead])
}
```

As you can see, modifying the `duplicate.roles` property also changes the `original.roles` property because both properties share the same list reference.

Data classes and destructuring declarations

Component functions generated for data classes make it possible to use them in destructuring declarations:

```
val jane = User("Jane", 35)
val (name, age) = jane
println("$name, $age years of age")
// Jane, 35 years of age
```

Standard data classes

The standard library provides the `Pair` and `Triple` classes. In most cases, though, named data classes are a better design choice because they make the code easier to read by providing meaningful names for the properties.

Extensions

Kotlin *extensions* let you extend a class or an interface with new functionality without using inheritance or design patterns like *Decorator*. They are useful when working with third-party libraries you can't modify directly. Once created, you call these extensions as if they were members of the original class or interface.

The most common forms of extensions are *extension functions* and *extension properties*.

Importantly, extensions don't modify the classes or interfaces they extend. When you define an extension, you don't add new members. You make new functions callable or new properties accessible using the same syntax.

Receivers

Extensions are always called on a receiver. The receiver has to have the same type as the class or interface being extended. To use an extension, prefix it with the receiver followed by a `.` and the function or property name.

For example, the `.appendLine()` extension function from the standard library extends the `StringBuilder` class. So in this case, the receiver is a `StringBuilder` instance, and the *receiver type* is `StringBuilder`:

```
fun main() {
    // builder is an instance of StringBuilder
    val builder = StringBuilder()
        // Calls .appendLine() extension function on builder
        .appendLine("Hello")
        .appendLine()
        .appendLine("World")
    println(builder.toString())
    // Hello
    //
    // World
}
```

Extension functions

Before creating your own extension functions, see if what you are looking for is already available in the Kotlin standard library. The standard library provides many useful extension functions for:

- Operating on collections: `.map()`, `.filter()`, `.reduce()`, `.fold()`, `.groupBy()`.
- Converting to strings: `.joinToString()`.
- Working with null values: `.filterNotNull()`.

To create your own extension function, prefix its name with a receiver type followed by a `.`. In this example, the `.truncate()` function extends the `String` class, so the receiver type is `String`:

```
fun String.truncate(maxLength: Int): String {
    return if (this.length ≤ maxLength) this else take(maxLength - 3) + "..."
}

fun main() {
    val shortUsername = "KotlinFan42"
    val longUsername = "JetBrainsLoverForever"

    println("Short username: ${shortUsername.truncate(15)}")
    // KotlinFan42
    println("Long username:  ${longUsername.truncate(15)}")
    // JetBrainsLov...
}
```

The `.truncate()` function truncates any string that it's called on by the number in the `maxLength` argument and adds an ellipsis `...`. If the string is shorter than `maxLength`, the function returns the original string.

In this example, the `.displayInfo()` function extends the `User` interface:

```
interface User {
    val name: String
    val email: String
}

fun User.displayInfo(): String = "User(name=$name, email=$email)"

// Inherits from and implements the properties of the User interface
class RegularUser(override val name: String, override val email: String) : User

fun main() {
    val user = RegularUser("Alice", "alice@example.com")
    println(user.displayInfo())
    // User(name=Alice, email=alice@example.com)
}
```

The `.displayInfo()` function returns a string containing the `name` and `email` of a `RegularUser` instance. Defining an extension on an interface like this is useful when you want to add functionality to all types that implement an interface only once.

In this example, the `.mostVoted()` function extends the `Map<String, Int>` class:

```
fun Map<String, Int>.mostVoted(): String? {
    return maxByOrNull { (key, value) -> value }?.key
}

fun main() {
    val poll = mapOf(
        "Cats" to 37,
        "Dogs" to 58,
        "Birds" to 22
    )

    println("Top choice: ${poll.mostVoted()}")
    // Dogs
}
```

The `.mostVoted()` function iterates through the key-value pairs of the map it's called on and uses the `maxByOrNull()` function to return the key of the pair containing the highest value. If the map is empty, the `maxByOrNull()` function returns `null`. The `mostVoted()` function uses a safe call `?.` to only access the `key` property when the `maxByOrNull()` function returns a non-null value.

Generic extension functions

To create generic extension functions, declare the generic type parameter before the function name to make it available in the receiver type expression. In this example, the `.endpoints()` function extends `List<T>` where `T` can be any type:

```
fun <T> List<T>.endpoints(): Pair<T, T> {
    return first() to last()
}

fun main() {
    val cities = listOf("Paris", "London", "Berlin", "Prague")
    val temperatures = listOf(21.0, 19.5, 22.3)

    val cityEndpoints = cities.endpoints()
    val tempEndpoints = temperatures.endpoints()

    println("First and last cities: $cityEndpoints")
    // (Paris, Prague)
    println("First and last temperatures: $tempEndpoints")
    // (21.0, 22.3)
}
```

The `.endpoints()` function returns a pair containing the first and last elements of the list that it's called on. Inside the function body, it calls the `first()` and `last()` functions and combines their returned values into a `Pair` using the `to` infix function.

For more information about generics, see generic functions.

Nullable receivers

You can define extension functions with a nullable receiver type, which allows you to call them on a variable even if its value is null. When the receiver is `null`, `this` is also `null`. Make sure to handle nullability correctly within your functions. For example, use `this == null` checks inside function bodies, safe calls `?.`, or the Elvis operator `?:`.

In this example, you can call the `.toString()` function without checking for `null` because the check already happens inside the extension function:

```
fun main() {
        // Extension function on nullable Any
    fun Any?.toString(): String {
        if (this == null) return "null"
        // After null check, `this` is smart-cast to non-nullable Any
        // So this call resolves to the regular toString() function
        return toString()
    }

    val number: Int? = 42
    val nothing: Any? = null

    println(number.toString())
    // 42
    println(nothing.toString())
    // null
    //sampleEnd
}
```

Extension or member functions?

Since extension and member function calls have the same notation, how does the compiler know which one to use? Extension functions are dispatched *statically*, meaning the compiler determines which function to call based on the receiver type at compile time. For example:

```
fun main() {
    open class Shape
    class Rectangle: Shape()

    fun Shape.getName() = "Shape"
    fun Rectangle.getName() = "Rectangle"

    fun printClassName(shape: Shape) {
        println(shape.getName())
    }

    printClassName(Rectangle())
    // Shape
}
```

In this example, the compiler calls the `Shape.getName()` extension function because the parameter `shape` is declared as type `Shape`. Because extension functions are resolved statically, the compiler chooses the function based on the declared type, not the actual instance.

So even though the example passes a `Rectangle` instance, the `.getName()` function resolves to `Shape.getName()` since the variable is declared as type `Shape`.

If a class has a member function and there's an extension function with the same receiver type, the same name, and compatible arguments, the member function takes precedence. For example:

```
fun main() {
    class Example {
        fun printFunctionType() { println("Member function") }
    }

    fun Example.printFunctionType() { println("Extension function") }

    Example().printFunctionType()
    // Member function
}
```

However, extension functions can overload member functions that have the same name but a *different* signature:

```
fun main() {
    class Example {
        fun printFunctionType() { println("Member function") }
    }

    // Same name but different signature
    fun Example.printFunctionType(index: Int) { println("Extension function #$index") }

    Example().printFunctionType(1)
    // Extension function #1
}
```

In this example, since an `Int` is passed to the `.printFunctionType()` function, the compiler chooses the extension function because it matches the signature. The compiler ignores the member function, which takes no arguments.

Anonymous extension functions

You can define extension functions without giving them a name. This is useful when you want to avoid cluttering the global namespace or when you need to pass some extension behavior as a parameter.

For example, suppose you want to extend a data class with a one-time function to calculate shipping, without giving it a name:

```
fun main() {
        data class Order(val weight: Double)
    val calculateShipping = fun Order.(rate: Double): Double = this.weight * rate

    val order = Order(2.5)
    val cost = order.calculateShipping(3.0)
    println("Shipping cost: $cost")
    // Shipping cost: 7.5
}
```

To pass extension behavior as a parameter, use a lambda expression with a type annotation. For example, let's say you want to check if a number is within a range without defining a named function:

```
fun main() {
    val isInRange: Int.(min: Int, max: Int) -> Boolean = { min, max -> this in min..max }

    println(5.isInRange(1, 10))
    // true
    println(20.isInRange(1, 10))
    // false
}
```

In this example, the `isInRange` variable holds a function of type `Int.(min: Int, max: Int) -> Boolean`. The type is an extension function on the `Int` class that takes `min` and `max` parameters and returns a `Boolean`.

The lambda body `{ min, max -> this in min..max }` checks whether the `Int` value the function is called on falls within the range between `min` and `max` parameters. If the check is successful, the lambda returns `true`.

For more information, see Lambda expressions and anonymous functions.

Extension properties

Kotlin supports extension properties, which are useful for performing data transformations or creating UI display helpers without cluttering the class you're working with.

To create an extension property, write the name of the class that you want to extend, followed by a `.` and the name of your property.

For example, suppose you have a data class that represents a user with a first and last name, and you want to create a property that returns an email-style username when accessed. Your code might look like this:

```
data class User(val firstName: String, val lastName: String)

// An extension property to get a username-style email handle
val User.emailUsername: String
    get() = "${firstName.lowercase()}.${lastName.lowercase()}"

fun main() {
    val user = User("Mickey", "Mouse")
    // Calls extension property
    println("Generated email username: ${user.emailUsername}")
    // Generated email username: mickey.mouse
}
```

Since extensions don't actually add members to classes, there's no efficient way for an extension property to have a backing field. That's why initializers are not allowed for extension properties. You can define their behavior only by explicitly providing getters and setters. For example:

```
data class House(val streetName: String)

// Doesn't compile because there is no getter and setter
// var House.number = 1
// Error: Initializers are not allowed for extension properties

// Compiles successfully
val houseNumbers = mutableMapOf<House, Int>()
var House.number: Int
    get() = houseNumbers[this] ?: 1
    set(value) {
        println("Setting house number for ${this.streetName} to $value")
        houseNumbers[this] = value
    }

fun main() {
    val house = House("Maple Street")

    // Shows the default
    println("Default number: ${house.number} ${house.streetName}")
    // Default number: 1 Maple Street

    house.number = 99
    // Setting house number for Maple Street to 99

    // Shows the updated number
    println("Updated number: ${house.number} ${house.streetName}")
    // Updated number: 99 Maple Street
}
```

In this example, the getter uses the Elvis operator to return the house number if it exists in the `houseNumbers` map or `1`. To learn more about how to write getters and setters, see Custom getters and setters.

Companion object extensions

If a class defines a companion object, you can also define extension functions and properties for the companion object. Just like regular members of the companion object, you can call them using only the class name as the qualifier. The compiler names the companion object `Companion` by default:

```
class Logger {
    companion object { }
}

fun Logger.Companion.logStartupMessage() {
    println("Application started.")
}

fun main() {
    Logger.logStartupMessage()
    // Application started.
}
```

Declaring extensions as members

You can declare extensions for one class inside another. Extensions like this have multiple *implicit receivers*. An implicit receiver is an object whose members you can access without qualifying them with `this`:

- The class where you declare the extension is the *dispatch receiver*.
- The extension function's receiver type is the *extension receiver*.

Consider this example where the `Connection` class has an extension function for the `Host` class called `printConnectionString()`:

```
class Host(val hostname: String) {
    fun printHostname() { print(hostname) }
}

class Connection(val host: Host, val port: Int) {
    fun printPort() { print(port) }

    // Host is the extension receiver
    fun Host.printConnectionString() {
        // Calls Host.printHostname()
        printHostname()
        print(":")
        // Calls Connection.printPort()
        // Connection is the dispatch receiver
        printPort()
    }

    fun connect() {
        /*...*/
        // Calls the extension function
        host.printConnectionString()
    }
}

fun main() {
    Connection(Host("kotl.in"), 443).connect()
    // kotl.in:443

    // Triggers an error because the extension function isn't available outside Connection
    // Host("kotl.in").printConnectionString()
    // Unresolved reference 'printConnectionString'.
}
```

This example declares the `printConnectionString()` function inside the `Connection` class, so the `Connection` class is the dispatch receiver. The extension function's receiver type is the `Host` class, so the `Host` class is the extension receiver.

If the dispatch receiver and the extension receiver have members with the same name, the extension receiver's member takes precedence. To access the dispatch receiver explicitly, use the qualified `this` syntax:

```
class Connection {
    fun Host.getConnectionString() {
        // Calls Host.toString()
        toString()
        // Calls Connection.toString()
        this@Connection.toString()
    }
}
```

Overriding member extensions

You can declare member extensions as `open` and override them in subclasses, which is useful when you want to customize the extension's behavior for each subclass. The compiler handles each receiver type differently:

Receiver type	Resolution time	Dispatch type
Dispatch receiver	Runtime	Virtual
Extension receiver	Compile time	Static

Consider this example, where the `User` class is `open` and the `Admin` class inherits from it. The `NotificationSender` class defines `sendNotification()` extension functions for both `User` and `Admin` classes, and the `SpecialNotificationSender` class overrides them:

```
open class User

class Admin : User()

open class NotificationSender {
    open fun User.sendNotification() {
        println("Sending user notification from normal sender")
    }

    open fun Admin.sendNotification() {
        println("Sending admin notification from normal sender")
    }

    fun notify(user: User) {
        user.sendNotification()
    }
}

class SpecialNotificationSender : NotificationSender() {
    override fun User.sendNotification() {
        println("Sending user notification from special sender")
    }

    override fun Admin.sendNotification() {
        println("Sending admin notification from special sender")
    }
}

fun main() {
    // Dispatch receiver is NotificationSender
    // Extension receiver is User
    // Resolves to User.sendNotification() in NotificationSender
    NotificationSender().notify(User())
    // Sending user notification from normal sender

    // Dispatch receiver is SpecialNotificationSender
    // Extension receiver is User
    // Resolves to User.sendNotification() in SpecialNotificationSender
    SpecialNotificationSender().notify(User())
    // Sending user notification from special sender

    // Dispatch receiver is SpecialNotificationSender
    // Extension receiver is User NOT Admin
    // The notify() function declares user as type User
    // Statically resolves to User.sendNotification() in SpecialNotificationSender
    SpecialNotificationSender().notify(Admin())
    // Sending user notification from special sender
}
```

The dispatch receiver is resolved at runtime using virtual dispatch, which makes the behavior in the `main()` function easier to follow. What may surprise you is that when you call the `notify()` function on an `Admin` instance, the compiler chooses the extension based on the declared type: `user: User`, because it resolves the extension receiver statically.

Extensions and visibility modifiers

Extensions use the same visibility modifiers as regular functions declared in the same scope, including extensions declared as members of other classes.

For example, an extension declared at the top level of a file can access other `private` top-level declarations in the same file:

```
// File: StringUtils.kt

private fun removeWhitespace(input: String): String {
    return input.replace("\\s".toRegex(), "")
}

fun String.cleaned(): String {
    return removeWhitespace(this)
}

fun main() {
    val rawEmail = "  user @example. com  "
    val cleaned = rawEmail.cleaned()
    println("Raw:     '$rawEmail'")
    // Raw:     '  user @example. com  '
    println("Cleaned: '$cleaned'")
    // Cleaned: 'user@example.com'
    println("Looks like an email: ${cleaned.contains("@") && cleaned.contains(".")}")
    // Looks like an email: true
}
```

And if an extension is declared outside its receiver type, it can't access the receiver's `private` or `protected` members:

```
class User(private val password: String) {
    fun isLoggedIn(): Boolean = true
    fun passwordLength(): Int = password.length
}

// Extension declared outside the class
fun User.isSecure(): Boolean {
    // Can't access password because it's private:
    // return password.length >= 8

    // Instead, we rely on public members:
    return passwordLength() >= 8 && isLoggedIn()
}

fun main() {
    val user = User("supersecret")
    println("Is user secure: ${user.isSecure()}")
    // Is user secure: true
}
```

If an extension is marked as `internal`, it's only accessible within its module:

```
// Networking module
// JsonParser.kt
internal fun String.parseJson(): Map<String, Any> {
    return mapOf("fakeKey" to "fakeValue")
}
```

Scope of extensions

In most cases, you define extensions on the top level, directly under packages:

```
package org.example.declarations

fun List<String>.getLongestString() { /*...*/}
```

To use an extension outside its declaring package, import it at the call site:

```
package org.example.usage

import org.example.declarations.getLongestString

fun main() {
    val list = listOf("red", "green", "blue")
    list.getLongestString()
}
```

For more information, see Imports.

Interfaces

Interfaces in Kotlin can contain declarations of abstract methods, as well as method implementations. What makes them different from abstract classes is that interfaces cannot store state. They can have properties, but these need to be abstract or provide accessor implementations.

An interface is defined using the keyword `interface`:

```
interface MyInterface {
    fun bar()
    fun foo() {
      // optional body
    }
}
```

Implementing interfaces

A class or object can implement one or more interfaces:

```
class Child : MyInterface {
    override fun bar() {
        // body
    }
}
```

Properties in interfaces

You can declare properties in interfaces. A property declared in an interface can either be abstract or provide implementations for accessors. Properties declared in interfaces can't have backing fields, and therefore accessors declared in interfaces can't reference them:

```
interface MyInterface {
    val prop: Int // abstract

    val propertyWithImplementation: String
        get() = "foo"

    fun foo() {
        print(prop)
    }
}

class Child : MyInterface {
    override val prop: Int = 29
}
```

Interfaces Inheritance

An interface can derive from other interfaces, meaning it can both provide implementations for their members and declare new functions and properties. Quite naturally, classes implementing such an interface are only required to define the missing implementations:

```
interface Named {
    val name: String
}

interface Person : Named {
    val firstName: String
    val lastName: String

    override val name: String get() = "$firstName $lastName"
}

data class Employee(
    // implementing 'name' is not required
    override val firstName: String,
    override val lastName: String,
    val position: Position
) : Person
```

Resolving overriding conflicts

When you declare many types in your supertype list, you may inherit more than one implementation of the same method:

```
interface A {
    fun foo() { print("A") }
    fun bar()
}

interface B {
    fun foo() { print("B") }
    fun bar() { print("bar") }
}

class C : A {
    override fun bar() { print("bar") }
}

class D : A, B {
    override fun foo() {
        super<A>.foo()
        super<B>.foo()
    }

    override fun bar() {
        super<B>.bar()
    }
}
```

Interfaces *A* and *B* both declare functions *foo()* and *bar()*. Both of them implement *foo()*, but only *B* implements *bar()* (*bar()* is not marked as abstract in *A*, because this is the default for interfaces if the function has no body). Now, if you derive a concrete class *C* from *A*, you have to override *bar()* and provide an implementation.

However, if you derive *D* from *A* and *B*, you need to implement all the methods that you have inherited from multiple interfaces, and you need to specify how exactly *D* should implement them. This rule applies both to methods for which you've inherited a single implementation (*bar()*) and to those for which you've inherited multiple implementations (*foo()*).

JVM default method generation for interface functions

On the JVM, functions declared in interfaces are compiled to default methods. You can control this behavior using the `-jvm-default` compiler option with the following values:

- `enable` (default): generates default implementations in interfaces and includes bridge functions in subclasses and `DefaultImpls` classes. Use this mode to maintain binary compatibility with older Kotlin versions.
- `no-compatibility` : generates only default implementations in interfaces. This mode skips compatibility bridges and `DefaultImpls` classes, making it suitable for new Kotlin code.
- `disable` : skips default methods and generates only compatibility bridges and `DefaultImpls` classes.

To configure the `-jvm-default` compiler option, set the `jvmDefault` property in your Gradle Kotlin DSL:

```
kotlin {
    compilerOptions {
        jvmDefault = JvmDefaultMode.NO_COMPATIBILITY
    }
}
```

Delegation

The Delegation pattern has proven to be a good alternative to implementation inheritance, and Kotlin supports it natively requiring zero boilerplate code.

A class `Derived` can implement an interface `Base` by delegating all of its public members to a specified object:

```
interface Base {
    fun print()
}

class BaseImpl(val x: Int) : Base {
    override fun print() { print(x) }
}

class Derived(b: Base) : Base by b

fun main() {
    val base = BaseImpl(10)
    Derived(base).print()
}
```

The `by` -clause in the supertype list for `Derived` indicates that `b` will be stored internally in objects of `Derived` and the compiler will generate all the methods of `Base` that forward to `b`.

Overriding a member of an interface implemented by delegation

Overrides work as you expect: the compiler will use your `override` implementations instead of those in the delegate object. If you want to add `override fun printMessage() { print("abc") }` to `Derived`, the program would print *abc* instead of *10* when `printMessage` is called:

```
interface Base {
    fun printMessage()
    fun printMessageLine()
}

class BaseImpl(val x: Int) : Base {
    override fun printMessage() { print(x) }
    override fun printMessageLine() { println(x) }
}

class Derived(b: Base) : Base by b {
    override fun printMessage() { print("abc") }
}

fun main() {
    val base = BaseImpl(10)
    Derived(base).printMessage()
    Derived(base).printMessageLine()
}
```

Note, however, that members overridden in this way do not get called from the members of the delegate object, which can only access its own implementations of the interface members:

```
interface Base {
    val message: String
    fun print()
}

class BaseImpl(x: Int) : Base {
    override val message = "BaseImpl: x = $x"
    override fun print() { println(message) }
}

class Derived(b: Base) : Base by b {
    // This property is not accessed from b's implementation of `print`
    override val message = "Message of Derived"
}

fun main() {
    val b = BaseImpl(10)
    val derived = Derived(b)
    derived.print()
    println(derived.message)
}
```

Learn more about delegated properties.

Inheritance

> Before creating an inheritance hierarchy with classes, consider using abstract classes or interfaces. You can inherit from abstract classes and interfaces by default. They are designed so that other classes can inherit their members and implement them.

All classes in Kotlin have a common superclass, `Any`, which is the default superclass for a class with no supertypes declared:

```
class Example // Implicitly inherits from Any
```

`Any` has three methods: `equals()`, `hashCode()`, and `toString()`. Thus, these methods are defined for all Kotlin classes.

By default, Kotlin classes are final – they can't be inherited. To make a class inheritable, mark it with the `open` keyword:

```
open class Base // Class is open for inheritance
```

For more information, see Open keyword.

To declare an explicit supertype, place the type after a colon in the class header:

```
open class Base(p: Int)

class Derived(p: Int) : Base(p)
```

If the derived class has a primary constructor, the base class can (and must) be initialized in that primary constructor according to its parameters.

If the derived class has no primary constructor, then each secondary constructor has to initialize the base type using the `super` keyword or it has to delegate to another constructor which does. Note that in this case, different secondary constructors can call different constructors of the base type:

```
class MyView : View {
    constructor(ctx: Context) : super(ctx)

    constructor(ctx: Context, attrs: AttributeSet) : super(ctx, attrs)
}
```

Open keyword

In Kotlin, the `open` keyword indicates that a class or a member (function or property) can be overridden in subclasses. By default, Kotlin classes and their members are *final*, meaning they cannot be inherited from (for classes) or overridden (for members) unless you explicitly mark them as `open`:

```
// Base class with the open keyword to allow inheritance
open class Person(
    val name: String
) {
    // Open function that can be overridden in a subclass
    open fun introduce() {
        println("Hello, my name is $name.")
    }
}

// Subclass inheriting from Person and overriding the introduce() function
class Student(
    name: String,
    val school: String
) : Person(name) {
    override fun introduce() {
        println("Hi, I'm $name, and I study at $school.")
    }
}
```

If you override a member of a base class, the overriding member is also open by default. If you want to change this and forbid the subclasses of your class from overriding your implementation, you can explicitly mark the overriding member as `final`:

```
// Base class with the open keyword to allow inheritance
open class Person(val name: String) {
    // Open function that can be overridden in a subclass
    open fun introduce() {
        println("Hello, my name is $name.")
    }
}

//  A subclass that inherits from Person and overrides the introduce() function
class Student(name: String, val school: String) : Person(name) {
    // The final keyword prevents further overrides in subclasses
    final override fun introduce() {
        println("Hi, I'm $name, and I study at $school.")
    }
}
```

Overriding methods

Kotlin requires explicit modifiers for overridable members and overrides:

```
open class Shape {
    open fun draw() { /*...*/ }
    fun fill() { /*...*/ }
}

class Circle() : Shape() {
    override fun draw() { /*...*/ }
}
```

The `override` modifier is required for `Circle.draw()`. If it's missing, the compiler will complain. If there is no `open` modifier on a function, like `Shape.fill()`, declaring a method with the same signature in a subclass is not allowed, either with `override` or without it. The `open` modifier has no effect when added to members of a final class – a class without an `open` modifier.

A member marked `override` is itself open, so it may be overridden in subclasses. If you want to prohibit re-overriding, use `final`:

```
open class Rectangle() : Shape() {
    final override fun draw() { /*...*/ }
}
```

Overriding properties

The overriding mechanism works on properties in the same way that it does on methods. Properties declared on a superclass that are then redeclared on a derived class must be prefaced with `override`, and they must have a compatible type. Each declared property can be overridden by a property with an initializer or by a property with a `get` method:

```
open class Shape {
    open val vertexCount: Int = 0
}

class Rectangle : Shape() {
    override val vertexCount = 4
}
```

You can also override a `val` property with a `var` property, but not vice versa. This is allowed because a `val` property essentially declares a `get` method, and overriding it as a `var` additionally declares a `set` method in the derived class.

Note that you can use the `override` keyword as part of the property declaration in a primary constructor:

```
interface Shape {
    val vertexCount: Int
}

class Rectangle(override val vertexCount: Int = 4) : Shape // Always has 4 vertices

class Polygon : Shape {
    override var vertexCount: Int = 0  // Can be set to any number later
}
```

Derived class initialization order

During the construction of a new instance of a derived class, the base class initialization is done as the first step (preceded only by evaluation of the arguments for the base class constructor), which means that it happens before the initialization logic of the derived class is run.

```
open class Base(val name: String) {

    init { println("Initializing a base class") }

    open val size: Int =
        name.length.also { println("Initializing size in the base class: $it") }
}

class Derived(
    name: String,
    val lastName: String,
) : Base(name.replaceFirstChar { it.uppercase() }.also { println("Argument for the base class: $it")
}) {

    init { println("Initializing a derived class") }

    override val size: Int =
        (super.size + lastName.length).also { println("Initializing size in the derived class: $it") }
}

fun main() {
    println("Constructing the derived class(\"hello\", \"world\")")
    Derived("hello", "world")
}
```

This means that when the base class constructor is executed, the properties declared or overridden in the derived class have not yet been initialized. Using any of those properties in the base class initialization logic (either directly or indirectly through another overridden `open` member implementation) may lead to incorrect behavior or a runtime failure. When designing a base class, you should therefore avoid using `open` members in the constructors, property initializers, or `init` blocks.

Calling the superclass implementation

Code in a derived class can call its superclass functions and property accessor implementations using the `super` keyword:

```
open class Rectangle {
    open fun draw() { println("Drawing a rectangle") }
    val borderColor: String get() = "black"
}

class FilledRectangle : Rectangle() {
    override fun draw() {
        super.draw()
        println("Filling the rectangle")
    }

    val fillColor: String get() = super.borderColor
}
```

Inside an inner class, accessing the superclass of the outer class is done using the `super` keyword qualified with the outer class name: `super@Outer`:

```
open class Rectangle {
    open fun draw() { println("Drawing a rectangle") }
    val borderColor: String get() = "black"
}

class FilledRectangle: Rectangle() {
    override fun draw() {
        val filler = Filler()
        filler.drawAndFill()
    }

    inner class Filler {
        fun fill() { println("Filling") }
        fun drawAndFill() {
            super@FilledRectangle.draw() // Calls Rectangle's implementation of draw()
            fill()
            println("Drawn a filled rectangle with color ${super@FilledRectangle.borderColor}") //
Uses Rectangle's implementation of borderColor's get()
        }
    }
}

fun main() {
    val fr = FilledRectangle()
        fr.draw()
}
```

Overriding rules

In Kotlin, implementation inheritance is regulated by the following rule: if a class inherits multiple implementations of the same member from its immediate superclasses, it must override this member and provide its own implementation (perhaps, using one of the inherited ones).

To denote the supertype from which the inherited implementation is taken, use `super` qualified by the supertype name in angle brackets, such as `super<Base>`:

```
open class Rectangle {
    open fun draw() { /* ... */ }
}

interface Polygon {
    fun draw() { /* ... */ } // interface members are 'open' by default
}

class Square() : Rectangle(), Polygon {
    // The compiler requires draw() to be overridden:
    override fun draw() {
        super<Rectangle>.draw() // call to Rectangle.draw()
        super<Polygon>.draw() // call to Polygon.draw()
    }
}
```

It's fine to inherit from both `Rectangle` and `Polygon`, but both of them have their implementations of `draw()`, so you need to override `draw()` in `Square` and provide a separate implementation for it to eliminate the ambiguity.

Object declarations and expressions

In Kotlin, objects allow you to define a class and create an instance of it in a single step. This is useful when you need either a reusable singleton instance or a one-time object. To handle these scenarios, Kotlin provides two key approaches: *object declarations* for creating singletons and *object expressions* for creating anonymous, one-time objects.

> A singleton ensures that a class has only one instance and provides a global point of access to it.

Object declarations and object expressions are best used for scenarios when:

- **Using singletons for shared resources:** You need to ensure that only one instance of a class exists throughout the application. For example, managing a database connection pool.
- **Creating factory methods:** You need a convenient way to create instances efficiently. Companion objects allow you to define class-level functions and properties tied to a class, simplifying the creation and management of these instances.
- **Modifying existing class behavior temporarily:** You want to modify the behavior of an existing class without the need to create a new subclass. For example, adding temporary functionality to an object for a specific operation.
- **Type-safe design is required:** You require one-time implementations of interfaces or abstract classes using object expressions. This can be useful for scenarios like a button click handler.

Object declarations

You can create single instances of objects in Kotlin using object declarations, which always have a name following the `object` keyword. This allows you to define a class and create an instance of it in a single step, which is useful for implementing singletons:

```
// Declares a Singleton object to manage data providers
object DataProviderManager {
    private val providers = mutableListOf<DataProvider>()

    // Registers a new data provider
    fun registerDataProvider(provider: DataProvider) {
        providers.add(provider)
    }

    // Retrieves all registered data providers
    val allDataProviders: Collection<DataProvider>
        get() = providers
}

// Example data provider interface
interface DataProvider {
    fun provideData(): String
}

// Example data provider implementation
class ExampleDataProvider : DataProvider {
    override fun provideData(): String {
        return "Example data"
    }
}

fun main() {
    // Creates an instance of ExampleDataProvider
    val exampleProvider = ExampleDataProvider()

    // To refer to the object, use its name directly
    DataProviderManager.registerDataProvider(exampleProvider)

    // Retrieves and prints all data providers
    println(DataProviderManager.allDataProviders.map { it.provideData() })
    // [Example data]
}
```

The initialization of an object declaration is thread-safe and done on first access.

To refer to the `object`, use its name directly:

```
DataProviderManager.registerDataProvider(exampleProvider)
```

Object declarations can also have supertypes, similar to how anonymous objects can inherit from existing classes or implement interfaces:

```
object DefaultListener : MouseAdapter() {
    override fun mouseClicked(e: MouseEvent) { ... }

    override fun mouseEntered(e: MouseEvent) { ... }
}
```

Like variable declarations, object declarations are not expressions, so they cannot be used on the right-hand side of an assignment statement:

```
// Syntax error: An object expression cannot bind a name.
val myObject = object MySingleton {
    val name = "Singleton"
}
```

Object declarations cannot be local, which means they cannot be nested directly inside a function. However, they can be nested within other object declarations or non-inner classes.

Data objects

When printing a plain object declaration in Kotlin, the string representation contains both its name and the hash of the `object`:

```
object MyObject

fun main() {
    println(MyObject)
    // MyObject@hashcode
}
```

However, by marking an object declaration with the `data` modifier, you can instruct the compiler to return the actual name of the object when calling `toString()`, the same way it works for data classes:

```
data object MyDataObject {
    val number: Int = 3
}

fun main() {
    println(MyDataObject)
    // MyDataObject
}
```

Additionally, the compiler generates several functions for your `data object`:

- `toString()` returns the name of the data object
- `equals()` / `hashCode()` enables equality checks and hash-based collections

> You can't provide a custom `equals` or `hashCode` implementation for a `data object`.

The `equals()` function for a `data object` ensures that all objects that have the type of your `data object` are considered equal. In most cases, you will only have a single instance of your `data object` at runtime, since a `data object` declares a singleton. However, in the edge case where another object of the same type is generated at runtime (for example, by using platform reflection with `java.lang.reflect` or a JVM serialization library that uses this API under the hood), this ensures that the objects are treated as being equal.

> Make sure that you only compare `data objects` structurally (using the `==` operator) and never by reference (using the `===` operator). This helps you to avoid pitfalls when more than one instance of a data object exists at runtime.

```
import java.lang.reflect.Constructor

data object MySingleton

fun main() {
    val evilTwin = createInstanceViaReflection()

    println(MySingleton)
    // MySingleton

    println(evilTwin)
    // MySingleton

    // Even when a library forcefully creates a second instance of MySingleton,
    // its equals() function returns true:
    println(MySingleton == evilTwin)
    // true

    // Don't compare data objects using ===
    println(MySingleton === evilTwin)
    // false
}

fun createInstanceViaReflection(): MySingleton {
    // Kotlin reflection does not permit the instantiation of data objects.
    // This creates a new MySingleton instance "by force" (using Java platform reflection)
    // Don't do this yourself!
    return (MySingleton.javaClass.declaredConstructors[0].apply { isAccessible = true } as
Constructor<MySingleton>).newInstance()
}
```

The generated `hashCode()` function has a behavior that is consistent with the `equals()` function, so that all runtime instances of a `data object` have the same hash code.

Differences between data objects and data classes

While `data object` and `data class` declarations are often used together and have some similarities, there are some functions that are not generated for a `data object`:

- No `copy()` function. Because a `data object` declaration is intended to be used as singletons, no `copy()` function is generated. Singletons restrict the instantiation of a class to a single instance, which would be violated by allowing copies of the instance to be created.
- No `componentN()` function. Unlike a `data class`, a `data object` does not have any data properties. Since attempting to destructure such an object without data properties wouldn't make sense, no `componentN()` functions are generated.

Use data objects with sealed hierarchies

Data object declarations are particularly useful for sealed hierarchies like sealed classes or sealed interfaces. They allow you to maintain symmetry with any data classes you may have defined alongside the object.

In this example, declaring `EndOfFile` as a `data object` instead of a plain `object` means that it will get the `toString()` function without the need to override it manually:

```
sealed interface ReadResult
data class Number(val number: Int) : ReadResult
data class Text(val text: String) : ReadResult
data object EndOfFile : ReadResult

fun main() {
    println(Number(7))
    // Number(number=7)
    println(EndOfFile)
    // EndOfFile
}
```

Companion objects

Companion objects allow you to define class-level functions and properties. This makes it easy to create factory methods, hold constants, and access shared utilities.

An object declaration inside a class can be marked with the `companion` keyword:

```
class MyClass {
    companion object Factory {
        fun create(): MyClass = MyClass()
    }
}
```

Members of the `companion object` can be called simply by using the class name as the qualifier:

```
class User(val name: String) {
    // Defines a companion object that acts as a factory for creating User instances
    companion object Factory {
        fun create(name: String): User = User(name)
    }
}

fun main(){
    // Calls the companion object's factory method using the class name as the qualifier.
    // Creates a new User instance
    val userInstance = User.create("John Doe")
    println(userInstance.name)
    // John Doe
}
```

The name of the `companion object` can be omitted, in which case the name `Companion` is used:

```
class User(val name: String) {
    // Defines a companion object without a name
    companion object { }
}

// Accesses the companion object
val companionUser = User.Companion
```

Class members can access `private` members of their corresponding `companion object`:

```
class User(val name: String) {
    companion object {
        private val defaultGreeting = "Hello"
    }

    fun sayHi() {
        println(defaultGreeting)
    }
}
User("Nick").sayHi()
// Hello
```

When a class name is used by itself, it acts as a reference to the companion object of the class, regardless of whether the companion object is named or not:

```
class User1 {
    // Defines a named companion object
    companion object Named {
        fun show(): String = "User1's Named Companion Object"
    }
}

// References the companion object of User1 using the class name
val reference1 = User1

class User2 {
    // Defines an unnamed companion object
    companion object {
        fun show(): String = "User2's Companion Object"
    }
}

// References the companion object of User2 using the class name
val reference2 = User2

fun main() {
    // Calls the show() function from the companion object of User1
    println(reference1.show())
    // User1's Named Companion Object

    // Calls the show() function from the companion object of User2
    println(reference2.show())
    // User2's Companion Object
}
```

Although members of companion objects in Kotlin look like static members from other languages, they are actually instance members of the companion object, meaning they belong to the object itself. This allows companion objects to implement interfaces:

```
interface Factory<T> {
    fun create(name: String): T
}

class User(val name: String) {
    // Defines a companion object that implements the Factory interface
    companion object : Factory<User> {
        override fun create(name: String): User = User(name)
    }
}

fun main() {
    // Uses the companion object as a Factory
    val userFactory: Factory<User> = User
    val newUser = userFactory.create("Example User")
    println(newUser.name)
    // Example User
}
```

However, on the JVM, you can have members of companion objects generated as real static methods and fields if you use the `@JvmStatic` annotation. See the Java interoperability section for more detail.

Object expressions

Object expressions declare a class and create an instance of that class, but without naming either of them. These classes are useful for one-time use. They can either be created from scratch, inherit from existing classes, or implement interfaces. Instances of these classes are also called *anonymous objects* because they are defined by an expression, not a name.

Create anonymous objects from scratch

Object expressions start with the `object` keyword.

If the object doesn't extend any classes or implement interfaces, you can define an object's members directly inside curly braces after the `object` keyword:

```
fun main() {
    val helloWorld = object {
        val hello = "Hello"
        val world = "World"
        // Object expressions extend the Any class, which already has a toString() function,
        // so it must be overridden
        override fun toString() = "$hello $world"
    }

    print(helloWorld)
    // Hello World
}
```

Inherit anonymous objects from supertypes

To create an anonymous object that inherits from some type (or types), specify this type after `object` and a colon `:`. Then implement or override the members of this class as if you were inheriting from it:

```
window.addMouseListener(object : MouseAdapter() {
    override fun mouseClicked(e: MouseEvent) { /*...*/ }

    override fun mouseEntered(e: MouseEvent) { /*...*/ }
})
```

If a supertype has a constructor, pass the appropriate constructor parameters to it. Multiple supertypes can be specified, separated by commas, after the colon:

```
// Creates an open class BankAccount with a balance property
open class BankAccount(initialBalance: Int) {
    open val balance: Int = initialBalance
}

// Defines an interface Transaction with an execute() function
interface Transaction {
    fun execute()
}

// A function to perform a special transaction on a BankAccount
fun specialTransaction(account: BankAccount) {
    // Creates an anonymous object that inherits from the BankAccount class and implements the
Transaction interface
    // The balance of the provided account is passed to the BankAccount superclass constructor
    val temporaryAccount = object : BankAccount(account.balance), Transaction {

        override val balance = account.balance + 500  // Temporary bonus

        // Implements the execute() function from the Transaction interface
        override fun execute() {
            println("Executing special transaction. New balance is $balance.")
        }
    }
    // Executes the transaction
    temporaryAccount.execute()
}
fun main() {
    // Creates a BankAccount with an initial balance of 1000
    val myAccount = BankAccount(1000)
    // Performs a special transaction on the created account
    specialTransaction(myAccount)
    // Executing special transaction. New balance is 1500.
}
```

Use anonymous objects as return and value types

When you return an anonymous object from a local or `private` function or property, all the members of that anonymous object are accessible through that function or property:

```
class UserPreferences {
    private fun getPreferences() = object {
        val theme: String = "Dark"
        val fontSize: Int = 14
    }

    fun printPreferences() {
        val preferences = getPreferences()
        println("Theme: ${preferences.theme}, Font Size: ${preferences.fontSize}")
    }
}

fun main() {
    val userPreferences = UserPreferences()
    userPreferences.printPreferences()
    // Theme: Dark, Font Size: 14
}
```

This allows you to return an anonymous object with specific properties, offering a simple way to encapsulate data or behavior without creating a separate class.

If a function or property that returns an anonymous object has `public`, `protected`, or `internal` visibility, its actual type is:

- `Any` if the anonymous object doesn't have a declared supertype.
- The declared supertype of the anonymous object, if there is exactly one such type.
- The explicitly declared type if there is more than one declared supertype.

In all these cases, members added in the anonymous object are not accessible. Overridden members are accessible if they are declared in the actual type of the function or property. For example:

```
interface Notification {
    // Declares notifyUser() in the Notification interface
    fun notifyUser()
}

interface DetailedNotification

class NotificationManager {
    // The return type is Any. The message property is not accessible.
    // When the return type is Any, only members of the Any class are accessible.
    fun getNotification() = object {
        val message: String = "General notification"
    }

    // The return type is Notification because the anonymous object implements only one interface
    // The notifyUser() function is accessible because it is part of the Notification interface
    // The message property is not accessible because it is not declared in the Notification interface
    fun getEmailNotification() = object : Notification {
        override fun notifyUser() {
            println("Sending email notification")
        }
        val message: String = "You've got mail!"
    }

    // The return type is DetailedNotification. The notifyUser() function and the message property are
not accessible
    // Only members declared in the DetailedNotification interface are accessible
    fun getDetailedNotification(): DetailedNotification = object : Notification, DetailedNotification
{
        override fun notifyUser() {
            println("Sending detailed notification")
        }
        val message: String = "Detailed message content"
    }
}
fun main() {
    // This produces no output
    val notificationManager = NotificationManager()

    // The message property is not accessible here because the return type is Any
    // This produces no output
    val notification = notificationManager.getNotification()

    // The notifyUser() function is accessible
    // The message property is not accessible here because the return type is Notification
    val emailNotification = notificationManager.getEmailNotification()
    emailNotification.notifyUser()
    // Sending email notification

    // The notifyUser() function and message property are not accessible here because the return type
is DetailedNotification
    // This produces no output
    val detailedNotification = notificationManager.getDetailedNotification()
}
```

Access variables from anonymous objects

Code within the body of object expressions can access variables from the enclosing scope:

```
import java.awt.event.MouseAdapter
import java.awt.event.MouseEvent

fun countClicks(window: JComponent) {
    var clickCount = 0
    var enterCount = 0

    // MouseAdapter provides default implementations for mouse event functions
    // Simulates MouseAdapter handling mouse events
    window.addMouseListener(object : MouseAdapter() {
        override fun mouseClicked(e: MouseEvent) {
            clickCount++
        }

        override fun mouseEntered(e: MouseEvent) {
            enterCount++
        }
    })
    // The clickCount and enterCount variables are accessible within the object expression
}
```

Behavior difference between object declarations and expressions

There are differences in the initialization behavior between object declarations and object expressions:

- Object expressions are executed (and initialized) *immediately*, where they are used.
- Object declarations are initialized *lazily*, when accessed for the first time.
- A companion object is initialized when the corresponding class is loaded (resolved) that matches the semantics of a Java static initializer.

This expressions

The `this` expression refers to the current receiver (the object with which the function works). How you use `this` depends on the context:

- In a member of a class, `this` refers to the current object of that class.

  For example, in the following code, `this.name` means the `name` property of the current `Language` object:

  ```
  class Language(val name: String) {
      fun printName() {
          println(this.name)
      }
  }

  fun main() {
      val language = Language("Kotlin")
      language.printName()
      // Kotlin
  }
  ```

- In an extension function or a function literal with receiver, `this` refers to the receiver.

In the following example, `lastCharacter()` is called on the string `"Kotlin"`. Therefore, `"Kotlin"` is the receiver. Inside the extension function, `this` refers to `"Kotlin"`. This means that `this.length` is the length of `"Kotlin"`:

```
fun String.lastCharacter(): Char {
    println(this.length)
    // 6
    return this[this.length - 1]
}

fun main() {
    println("Kotlin".lastCharacter())
    // n
}
```

In simple cases, you don't need to write `this` explicitly. Kotlin resolves it from the current scope. Learn more about Implicit this.

Qualified `this`

Your code can have several receivers available at the same time when receiver scopes are nested. Kotlin can use any available receiver to access its members implicitly, but receivers from inner scopes have higher priority. To explicitly refer to a particular receiver, use a qualified `this`. It is especially useful when multiple receivers have members with the same name, and you need to access a member of an outer receiver.

To use a qualified `this`, add a label qualifier:

```
this@label
```

The label tells the compiler which receiver to access. You can use the name of an enclosing class or extension function. For example, `this@foo` refers to the receiver of an enclosing extension function named `foo`.

Access an outer class from an inner class

In an inner class, unqualified `this` refers to the inner class instance. To access the outer class object, use qualified `this`:

```
class User(val name: String) {
    inner class Age(val value: Int) {
        fun printInfo() {

            // Refers to the value property of the current Age object
            println(this.value)
            // 22

            // Refers to the name property of the outer User object
            println(this@User.name)
            // Jane Doe
        }
    }
}

fun main() {
    val user = User("Jane Doe")
    val age = user.Age(22)
    age.printInfo()
}
```

Only inner classes hold a reference to an outer class instance. Regular nested classes don't have access to `this` from the outer class.

Access a class from an extension function

If you declare an extension function inside a class, two receivers are available:

- The extension receiver: the value on which you call the extension function.
- The dispatch receiver: the current object of the class where you declare the extension function.

Use qualified `this` to specify which receiver you need:

```
class User(val name: String) {
    val prefix = "Name"

    fun String.formatName(): String {
        return "${this@User.prefix}: ${this.uppercase()}"
    }

    fun printName() {
        println(name.formatName())
    }
}

fun main() {
    val user = User("Jane Doe")
    user.printName()
    // Name: JANE DOE
}
```

Here:

- `this` refers to the extension receiver (`String`), so `this.uppercase()` converts the string to uppercase.
- `this@User` refers to the current `User` object.
- `this@User.prefix` accesses the `prefix` property of the current `User` object.

Access from a lambda

Unlike a regular lambda, a lambda with receiver introduces a receiver into its scope. As a result, `this` inside the lambda refers to the lambda's receiver, not to one from an enclosing scope. If a lambda with receiver is nested inside another receiver scope, add a label to the lambda and use a qualified `this` to refer explicitly to the lambda's receiver or to a receiver from an enclosing scope:

```
class User(val name: String) {
    fun printWithPrefix() {
        val printString: String.() -> Unit = stringLabel@ {
            println("${this@stringLabel}: ${this@User.name}")
        }

        printString("User")
    }
}

fun main() {
    val user = User("Jane Doe")
    user.printWithPrefix()
    // User: Jane Doe
}
```

Here:

- `stringLabel@` labels the lambda.
- `this@stringLabel` refers to the string receiver of the lambda.
- `this@User` refers to the current `User` object.

The label doesn't call anything or change how the lambda works. It only helps you refer to the lambda's receiver.

Access an anonymous object or its outer class

An anonymous object has its own receiver scope. Inside the object body, unqualified `this` refers to the anonymous object itself. However, since anonymous objects don't have class names, you can't use them as `this` qualifiers. Therefore, you can refer to the anonymous object only with unqualified `this`:

```
interface UserPrinter {
    fun print()
}

fun main() {
    val printer = object : UserPrinter {
        val prefix = "User"

        override fun print() {
            // `this` refers to the anonymous object
            // `this.prefix` accesses its `prefix` property
            println(this.prefix)
        }
    }
    printer.print()
    // User
}
```

If you declare an anonymous object inside another class, you can use qualified `this` to access the enclosing object:

```
interface UserPrinter {
    fun print()
}

class User(val name: String) {
    fun createPrinter(): UserPrinter {
        return object : UserPrinter {
            override fun print() {
                // `this@User` refers to the enclosing `User` object
                // `this@User.name` accesses its `name` property
                println(this@User.name)
            }
        }
    }
}

fun main() {
    val printer = User("Jane Doe").createPrinter()
    printer.print()
    // Jane Doe
}
```

Implicit `this`

When you call a member function on `this`, you can omit the `this.` qualifier. However, if another callable with the same name is available in a closer lexical scope, Kotlin resolves the unqualified call to that callable instead of the member function. To explicitly call the member function, use the `this.` qualifier:

```
fun main() {
    class A {
        fun printLine() {
            println("Member function")
        }

        fun invokePrintLine() {
            fun printLine() {
                println("Local function")
            }

            printLine()
            // Local function

            this.printLine()
            // Member function
        }
    }

    A().invokePrintLine()
}
```

Sealed classes and interfaces

Sealed classes and interfaces provide controlled inheritance of your class hierarchies. All direct subclasses of a sealed class are known at compile time. No other subclasses may appear outside the module and package within which the sealed class is defined. The same logic applies to sealed interfaces and their implementations: once a module with a sealed interface is compiled, no new implementations can be created.

Direct subclasses are classes that immediately inherit from their superclass.

Indirect subclasses are classes that inherit from more than one level down from their superclass.

When you combine sealed classes and interfaces with the `when` expression, you can cover the behavior of all possible subclasses and ensure that no new subclasses are created to affect your code adversely.

Sealed classes are best used for scenarios when:

- **Limited class inheritance is desired:** You have a predefined, finite set of subclasses that extend a class, all of which are known at compile time.
- **Type-safe design is required:** Safety and pattern matching are crucial in your project. Particularly for state management or handling complex conditional logic. For an example, check out Use sealed classes with when expressions.
- **Working with closed APIs:** You want robust and maintainable public APIs for libraries that ensure that third-party clients use the APIs as intended.

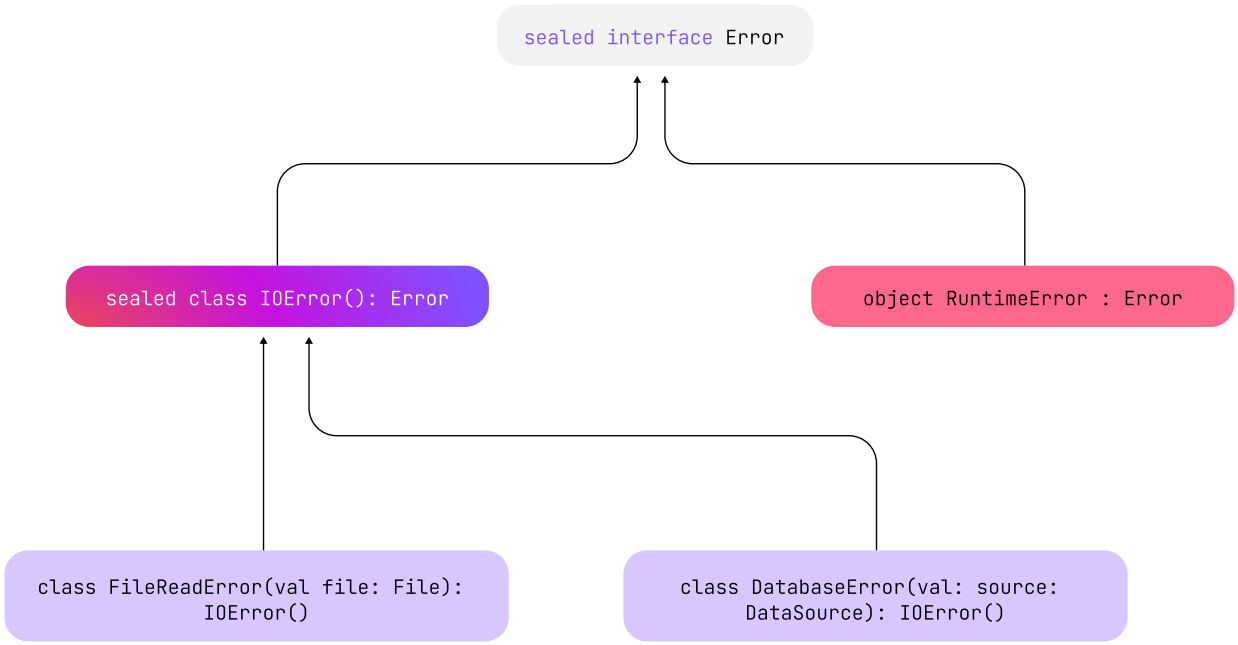
For more detailed practical applications, see Use case scenarios.

Java 15 introduced a similar concept, where sealed classes use the `sealed` keyword along with the `permits` clause to define restricted hierarchies.

Declare a sealed class or interface

To declare a sealed class or interface, use the `sealed` modifier:

```
// Create a sealed interface
sealed interface Error



// Create a sealed class that implements sealed interface Error
sealed class IOError(): Error

// Define subclasses that extend sealed class 'IOError'
class FileReadError(val file: File): IOError()
class DatabaseError(val source: DataSource): IOError()

// Create a singleton object implementing the 'Error' sealed interface
object RuntimeError : Error
```

This example could represent a library's API that contains error classes to let library users handle errors that it can throw. If the hierarchy of such error classes includes interfaces or abstract classes visible in the public API, then nothing prevents other developers from implementing or extending them in the client code. Since the library doesn't know about errors declared outside of it, it can't treat them consistently with its own classes. However, with a **sealed** hierarchy of error classes, library authors can be sure that they know all the possible error types and that other error types can't appear later.

The hierarchy of the example looks like this:

Hierarchy illustration of sealed classes and interfaces

Constructors

A sealed class itself is always an abstract class, and as a result, can't be instantiated directly. However, it may contain or inherit constructors. These constructors aren't for creating instances of the sealed class itself but for its subclasses. Consider the following example with a sealed class called `Error` and its several subclasses, which we instantiate:

```
sealed class Error(val message: String) {
    class NetworkError : Error("Network failure")
    class DatabaseError : Error("Database cannot be reached")
    class UnknownError : Error("An unknown error has occurred")
}

fun main() {
    val errors = listOf(Error.NetworkError(), Error.DatabaseError(), Error.UnknownError())
    errors.forEach { println(it.message) }
}
// Network failure
// Database cannot be reached
// An unknown error has occurred
```

You can use `enum` classes within your sealed classes to use enum constants to represent states and provide additional detail. Each enum constant exists only as a **single** instance, while subclasses of a sealed class may have **multiple** instances. In the example, the `sealed class Error` along with its several subclasses, employs an `enum` to denote error severity. Each subclass constructor initializes the `severity` and can alter its state:

```
enum class ErrorSeverity { MINOR, MAJOR, CRITICAL }

sealed class Error(val severity: ErrorSeverity) {
    class FileReadError(val file: File): Error(ErrorSeverity.MAJOR)
    class DatabaseError(val source: DataSource): Error(ErrorSeverity.CRITICAL)
    object RuntimeError : Error(ErrorSeverity.CRITICAL)
    // Additional error types can be added here
}
```

Constructors of sealed classes can have one of two visibilities: `protected` (by default) or `private`:

```
sealed class IOError {
    // A sealed class constructor has protected visibility by default. It's visible inside this class
and its subclasses
    constructor() { /*...*/ }

    // Private constructor, visible inside this class only.
    // Using a private constructor in a sealed class allows for even stricter control over
instantiation, enabling specific initialization procedures within the class.
    private constructor(description: String): this() { /*...*/ }

    // This will raise an error because public and internal constructors are not allowed in sealed
classes
    // public constructor(code: Int): this() {}
}
```

Inheritance

Direct subclasses of sealed classes and interfaces must be declared in the same package. They may be top-level or nested inside any number of other named classes, named interfaces, or named objects. Subclasses can have any visibility as long as they are compatible with normal inheritance rules in Kotlin, including those for overriding properties.

Subclasses of sealed classes must have a properly qualified name. They can't be local or anonymous objects.

`enum` classes can't extend a sealed class, or any other class. However, they can implement sealed interfaces:

```
sealed interface Error

// enum class extending the sealed interface Error
enum class ErrorType : Error {
    FILE_ERROR, DATABASE_ERROR
}
```

These restrictions don't apply to indirect subclasses. If a direct subclass of a sealed class is not marked as sealed, it can be extended in any way that its modifiers allow:

```
// Sealed interface 'Error' has implementations only in the same package and module
sealed interface Error

// Sealed class 'IOError' extends 'Error' and is extendable only within the same package
sealed class IOError(): Error

// Open class 'CustomError' extends 'Error' and can be extended anywhere it's visible
open class CustomError(): Error
```

Inheritance in multiplatform projects

There is one more inheritance restriction in multiplatform projects: direct subclasses of sealed classes must reside in the same source set. It applies to sealed classes without the expected and actual modifiers.

If a sealed class is declared as `expect` in a common source set and have `actual` implementations in platform source sets, both `expect` and `actual` versions can have subclasses in their source sets. Moreover, if you use a hierarchical structure, you can create subclasses in any source set between the `expect` and `actual` declarations.

Learn more about the hierarchical structure of multiplatform projects.

Use sealed classes with when expression

The key benefit of using sealed classes comes into play when you use them in a `when` expression. The `when` expression, used with a sealed class, allows the Kotlin compiler to check exhaustively that all possible cases are covered. In such cases, you don't need to add an `else` clause:

```
// Sealed class and its subclasses
sealed class Error {
    class FileReadError(val file: String): Error()
    class DatabaseError(val source: String): Error()
    object RuntimeError : Error()
}

// Function to log errors
fun log(e: Error) = when(e) {
    is Error.FileReadError -> println("Error while reading file ${e.file}")
    is Error.DatabaseError -> println("Error while reading from database ${e.source}")
    Error.RuntimeError -> println("Runtime error")
    // No `else` clause is required because all the cases are covered
}

// List all errors
fun main() {
    val errors = listOf(
        Error.FileReadError("example.txt"),
        Error.DatabaseError("usersDatabase"),
        Error.RuntimeError
    )

    errors.forEach { log(it) }
}
```

To reduce repetition in `when` expressions, try out context-sensitive resolution (currently in preview). This feature allows you to omit the type name when matching sealed class members if the expected type is known.

For more information, see Preview of context-sensitive resolution or the related KEEP proposal.

When using sealed classes with `when` expressions, you can also add guard conditions to include additional checks in a single branch. For more information, see Guard conditions in when expressions.

In multiplatform projects, if you have a sealed class with a `when` expression as an expected declaration in your common code, you still need an `else` branch. This is because subclasses of `actual` platform implementations may extend sealed classes that aren't known in the common code.

Use case scenarios

Let's explore some practical scenarios where sealed classes and interfaces can be particularly useful.

State management in UI applications

You can use sealed classes to represent different UI states in an application. This approach allows for structured and safe handling of UI changes. This example demonstrates how to manage various UI states:

```
sealed class UIState {
    data object Loading : UIState()
    data class Success(val data: String) : UIState()
    data class Error(val exception: Exception) : UIState()
}

fun updateUI(state: UIState) {
    when (state) {
        is UIState.Loading -> showLoadingIndicator()
        is UIState.Success -> showData(state.data)
        is UIState.Error -> showError(state.exception)
    }
}
```

Payment method handling

In practical business applications, handling various payment methods efficiently is a common requirement. You can use sealed classes with `when` expressions to implement such business logic. By representing different payment methods as subclasses of a sealed class, it establishes a clear and manageable structure for processing transactions:

```
sealed class Payment {
    data class CreditCard(val number: String, val expiryDate: String) : Payment()
    data class PayPal(val email: String) : Payment()
    data object Cash : Payment()
}

fun processPayment(payment: Payment) {
    when (payment) {
        is Payment.CreditCard → processCreditCardPayment(payment.number, payment.expiryDate)
        is Payment.PayPal → processPayPalPayment(payment.email)
        is Payment.Cash → processCashPayment()
    }
}
```

`Payment` is a sealed class that represents different payment methods in an e-commerce system: `CreditCard`, `PayPal`, and `Cash`. Each subclass can have its specific properties, like `number` and `expiryDate` for `CreditCard`, and `email` for `PayPal`.

The `processPayment()` function demonstrates how to handle different payment methods. This approach ensures that all possible payment types are considered, and the system remains flexible for new payment methods to be added in the future.

API request-response handling

You can use sealed classes and sealed interfaces to implement a user authentication system that handles API requests and responses. The user authentication system has login and logout functionalities. The `ApiRequest` sealed interface defines specific request types: `LoginRequest` for login, and `LogoutRequest` for logout operations. The sealed class, `ApiResponse`, encapsulates different response scenarios: `UserSuccess` with user data, `UserNotFound` for absent users, and `Error` for any failures. The `handleRequest` function processes these requests in a type-safe manner using a `when` expression, while `getUserById` simulates user retrieval:

```kotlin
// Import necessary modules
import io.ktor.server.application.*
import io.ktor.server.resources.*

import kotlinx.serialization.*

// Define the sealed interface for API requests using Ktor resources
@Resource("api")
sealed interface ApiRequest

@Serializable
@Resource("login")
data class LoginRequest(val username: String, val password: String) : ApiRequest

@Serializable
@Resource("logout")
object LogoutRequest : ApiRequest

// Define the ApiResponse sealed class with detailed response types
sealed class ApiResponse {
    data class UserSuccess(val user: UserData) : ApiResponse()
    data object UserNotFound : ApiResponse()
    data class Error(val message: String) : ApiResponse()
}

// User data class to be used in the success response
data class UserData(val userId: String, val name: String, val email: String)

// Function to validate user credentials (for demonstration purposes)
fun isValidUser(username: String, password: String): Boolean {
    // Some validation logic (this is just a placeholder)
    return username == "validUser" && password == "validPass"
}

// Function to handle API requests with detailed responses
fun handleRequest(request: ApiRequest): ApiResponse {
    return when (request) {
        is LoginRequest -> {
            if (isValidUser(request.username, request.password)) {
                ApiResponse.UserSuccess(UserData("userId", "userName", "userEmail"))
            } else {
                ApiResponse.Error("Invalid username or password")
            }
        }
        is LogoutRequest -> {
            // Assuming logout operation always succeeds for this example
            ApiResponse.UserSuccess(UserData("userId", "userName", "userEmail")) // For demonstration
        }
    }
}

// Function to simulate a getUserById call
fun getUserById(userId: String): ApiResponse {
    return if (userId == "validUserId") {
        ApiResponse.UserSuccess(UserData("validUserId", "John Doe", "john@example.com"))
    } else {
        ApiResponse.UserNotFound
    }
    // Error handling would also result in an Error response.
}

// Main function to demonstrate the usage
```

```
fun main() {
    val loginResponse = handleRequest(LoginRequest("user", "pass"))
    println(loginResponse)

    val logoutResponse = handleRequest(LogoutRequest)
    println(logoutResponse)

    val userResponse = getUserById("validUserId")
    println(userResponse)

    val userNotFoundResponse = getUserById("invalidId")
    println(userNotFoundResponse)
}
```

What's next

Learn more about inheritance in Kotlin.

Enum classes

The most basic use case for enum classes is the implementation of type-safe enums:

```
enum class Direction {
    NORTH, SOUTH, WEST, EAST
}
```

Each enum constant is an object. Enum constants are separated by commas.

Since each enum is an instance of the enum class, it can be initialized as:

```
enum class Color(val rgb: Int) {
    RED(0xFF0000),
    GREEN(0x00FF00),
    BLUE(0x0000FF)
}
```

Anonymous classes

Enum constants can declare their own anonymous classes with their corresponding methods, as well as with overriding base methods.

```
enum class ProtocolState {
    WAITING {
        override fun signal() = TALKING
    },

    TALKING {
        override fun signal() = WAITING
    };

    abstract fun signal(): ProtocolState
}
```

If the enum class defines any members, separate the constant definitions from the member definitions with a semicolon.

Implementing interfaces in enum classes

An enum class can implement an interface (but it cannot derive from a class), providing either a common implementation of interface members for all the entries, or separate implementations for each entry within its anonymous class. This is done by adding the interfaces you want to implement to the enum class declaration as follows:

```
import java.util.function.BinaryOperator
import java.util.function.IntBinaryOperator

enum class IntArithmetics : BinaryOperator<Int>, IntBinaryOperator {
    PLUS {
        override fun apply(t: Int, u: Int): Int = t + u
    },
    TIMES {
        override fun apply(t: Int, u: Int): Int = t * u
    };

    override fun applyAsInt(t: Int, u: Int) = apply(t, u)
}

fun main() {
    val a = 13
    val b = 31
    for (f in IntArithmetics.entries) {
        println("$f($a, $b) = ${f.apply(a, b)}")
    }
}
```

All enum classes implement the Comparable interface by default. Constants in the enum class are defined in the natural order. For more information, see Ordering.

Working with enum constants

Enum classes in Kotlin have synthetic properties and methods for listing the defined enum constants and getting an enum constant by its name. The signatures of these methods are as follows (assuming the name of the enum class is `EnumClass`):

```
EnumClass.valueOf(value: String): EnumClass
EnumClass.entries: EnumEntries<EnumClass> // specialized List<EnumClass>
```

Below is an example of them in action:

```
enum class RGB { RED, GREEN, BLUE }

fun main() {
    for (color in RGB.entries) println(color.toString()) // prints RED, GREEN, BLUE
    println("The first color is: ${RGB.valueOf("RED")}") // prints "The first color is: RED"
}
```

The `valueOf()` method throws an `IllegalArgumentException` if the specified name does not match any of the enum constants defined in the class.

Prior to the introduction of `entries` in Kotlin 1.9.0, the `values()` function was used to retrieve an array of enum constants.

Every enum constant also has properties: `name` and `ordinal`, for obtaining its name and position (starting from 0) in the enum class declaration:

```
enum class RGB { RED, GREEN, BLUE }

fun main() {
        println(RGB.RED.name)    // prints RED
    println(RGB.RED.ordinal) // prints 0
    //sampleEnd
}
```

> To reduce repetition when working with enum entries, try out context-sensitive resolution (currently in preview). This feature allows you to omit the enum class name when the expected type is known, such as in `when` expressions or when assigning to a typed variable.
>
> For more information, see Preview of context-sensitive resolution or the related KEEP proposal.

You can access the constants in an enum class in a generic way using the `enumValues<T>()` and `enumValueOf<T>()` functions. In Kotlin 2.0.0, the `enumEntries<T>()` function is introduced as a replacement for the `enumValues<T>()` function. The `enumEntries<T>()` function returns a list of all enum entries for the given enum type `T`.

The `enumValues<T>()` function is still supported, but we recommend that you use the `enumEntries<T>()` function instead because it has less performance impact. Every time you call `enumValues<T>()` a new array is created, whereas whenever you call `enumEntries<T>()` the same list is returned each time, which is far more efficient.

For example:

```
enum class RGB { RED, GREEN, BLUE }

inline fun <reified T : Enum<T>> printAllValues() {
    println(enumEntries<T>().joinToString { it.name })
}

printAllValues<RGB>()
// RED, GREEN, BLUE
```

> For more information about inline functions and reified type parameters, see Inline functions.

Inline value classes

Sometimes it is useful to wrap a value in a class to create a more domain-specific type. However, it introduces runtime overhead due to additional heap allocations. Moreover, if the wrapped type is primitive, the performance hit is significant, because primitive types are usually heavily optimized by the runtime, while their wrappers don't get any special treatment.

To solve such issues, Kotlin introduces a special kind of class called an *inline class*. Inline classes are a subset of value-based classes. They don't have an identity and can only hold values.

To declare an inline class, use the `value` modifier before the name of the class:

```
value class Password(private val s: String)
```

To declare an inline class for the JVM backend, use the `value` modifier along with the `@JvmInline` annotation before the class declaration:

```
// For JVM backends
@JvmInline
value class Password(private val s: String)
```

An inline class must have a single property initialized in the primary constructor. At runtime, instances of the inline class will be represented using this single property (see details about runtime representation below):

```
// No actual instantiation of class 'Password' happens
// At runtime 'securePassword' contains just 'String'
val securePassword = Password("Don't try this in production")
```

This is the main feature of inline classes, which inspired the name *inline*: data of the class is *inlined* into its usages (similar to how the content of inline functions is inlined to call sites).

Members

Inline classes support some functionality of regular classes. In particular, they are allowed to declare properties and functions, have an `init` block and secondary constructors:

```
@JvmInline
value class Person(private val fullName: String) {
    init {
        require(fullName.isNotEmpty()) {
            "Full name shouldn't be empty"
        }
    }

    constructor(firstName: String, lastName: String) : this("$firstName $lastName") {
        require(lastName.isNotBlank()) {
            "Last name shouldn't be empty"
        }
    }

    val length: Int
        get() = fullName.length

    fun greet() {
        println("Hello, $fullName")
    }
}

fun main() {
    val name1 = Person("Kotlin", "Mascot")
    val name2 = Person("Kodee")
    name1.greet() // the `greet()` function is called as a static method
    println(name2.length) // property getter is called as a static method
}
```

Inline class properties cannot have backing fields. They can only have simple computable properties (no `lateinit` /delegated properties).

Inheritance

Inline classes are allowed to inherit from interfaces:

```
interface Printable {
    fun prettyPrint(): String
}

@JvmInline
value class Name(val s: String) : Printable {
    override fun prettyPrint(): String = "Let's $s!"
}

fun main() {
    val name = Name("Kotlin")
    println(name.prettyPrint()) // Still called as a static method
}
```

It is forbidden for inline classes to participate in a class hierarchy. This means that inline classes cannot extend other classes and are always `final`.

Representation

In generated code, the Kotlin compiler keeps a *wrapper* for each inline class. Inline class instances can be represented at runtime either as wrappers or as the underlying type. This is similar to how `Int` can be represented either as a primitive `int` or as the wrapper `Integer`.

The Kotlin compiler will prefer using underlying types instead of wrappers to produce the most performant and optimized code. However, sometimes it is necessary to keep wrappers around. As a rule of thumb, inline classes are boxed whenever they are used as another type.

```
interface I

@JvmInline
value class Foo(val i: Int) : I

fun asInline(f: Foo) {}
fun <T> asGeneric(x: T) {}
fun asInterface(i: I) {}
fun asNullable(i: Foo?) {}

fun <T> id(x: T): T = x

fun main() {
    val f = Foo(42)

    asInline(f)    // unboxed: used as Foo itself
    asGeneric(f)   // boxed: used as generic type T
    asInterface(f) // boxed: used as type I
    asNullable(f)  // boxed: used as Foo?, which is different from Foo

    // below, 'f' first is boxed (while being passed to 'id') and then unboxed (when returned from
'id')
    // In the end, 'c' contains unboxed representation (just '42'), as 'f'
    val c = id(f)
}
```

Because inline classes may be represented both as the underlying value and as a wrapper, referential equality is pointless for them and is therefore prohibited.

Inline classes can also have a generic type parameter as the underlying type. In this case, the compiler maps it to `Any?` or, generally, to the upper bound of the type parameter.

```
@JvmInline
value class UserId<T>(val value: T)

fun compute(s: UserId<String>) {} // compiler generates fun compute-<hashcode>(s: Any?)
```

Mangling

Since inline classes are compiled to their underlying type, it may lead to various obscure errors, for example, unexpected platform signature clashes:

```
@JvmInline
value class UInt(val x: Int)

// Represented as 'public final void compute(int x)' on the JVM
fun compute(x: Int) { }

// Also represented as 'public final void compute(int x)' on the JVM!
fun compute(x: UInt) { }
```

To mitigate such issues, functions using inline classes are *mangled* by adding some stable hashcode to the function name. Therefore, `fun compute(x: UInt)` will be represented as `public final void compute-<hashcode>(int x)`, which solves the clash problem.

Calling from Java code

You can call functions that accept inline classes from Java code. To do so, you should manually disable mangling: add the `@JvmName` annotation before the function declaration:

```
@JvmInline
value class UInt(val x: Int)

fun compute(x: Int) { }

@JvmName("computeUInt")
fun compute(x: UInt) { }
```

By default, Kotlin compiles inline classes using **unboxed representations**, which makes them difficult to access from Java. To learn how to compile inline classes into **boxed representations** that are accessible from Java, see the guide to Calling Kotlin from Java.

Inline classes vs type aliases

At first sight, inline classes seem very similar to type aliases. Indeed, both seem to introduce a new type and both will be represented as the underlying type at runtime.

However, the crucial difference is that type aliases are *assignment-compatible* with their underlying type (and with other type aliases with the same underlying type), while inline classes are not.

In other words, inline classes introduce a truly *new* type, contrary to type aliases which only introduce an alternative name (alias) for an existing type:

```
typealias NameTypeAlias = String

@JvmInline
value class NameInlineClass(val s: String)

fun acceptString(s: String) {}
fun acceptNameTypeAlias(n: NameTypeAlias) {}
fun acceptNameInlineClass(p: NameInlineClass) {}

fun main() {
    val nameAlias: NameTypeAlias = ""
    val nameInlineClass: NameInlineClass = NameInlineClass("")
    val string: String = ""

    acceptString(nameAlias) // OK: pass alias instead of underlying type
    acceptString(nameInlineClass) // Not OK: can't pass inline class instead of underlying type

    // And vice versa:
    acceptNameTypeAlias(string) // OK: pass underlying type instead of alias
    acceptNameInlineClass(string) // Not OK: can't pass underlying type instead of inline class
}
```

Inline classes and delegation

Implementation by delegation to inlined value of inlined class is allowed with interfaces:

```
interface MyInterface {
    fun bar()
    fun foo() = "foo"
}

@JvmInline
value class MyInterfaceWrapper(val myInterface: MyInterface) : MyInterface by myInterface

fun main() {
    val my = MyInterfaceWrapper(object : MyInterface {
        override fun bar() {
            // body
        }
    })
    println(my.foo()) // prints "foo"
}
```

Nested and inner classes

Classes can be nested in other classes:

```
class Outer {
    private val bar: Int = 1
    class Nested {
        fun foo() = 2
    }
}

val demo = Outer.Nested().foo() // == 2
```

You can also use interfaces with nesting. All combinations of classes and interfaces are possible: You can nest interfaces in classes, classes in interfaces, and interfaces in interfaces.

```
interface OuterInterface {
    class InnerClass
    interface InnerInterface
}

class OuterClass {
    class InnerClass
    interface InnerInterface
}
```

Inner classes

A nested class marked as `inner` can access the members of its outer class. Inner classes carry a reference to an object of an outer class:

```
class Outer {
    private val bar: Int = 1
    inner class Inner {
        fun foo() = bar
    }
}

val demo = Outer().Inner().foo() // == 1
```

See Qualified `this` expressions to learn about disambiguation of `this` in inner classes.

Anonymous inner classes

Anonymous inner class instances are created using an object expression:

```
window.addMouseListener(object : MouseAdapter() {

    override fun mouseClicked(e: MouseEvent) { ... }

    override fun mouseEntered(e: MouseEvent) { ... }
})
```

On the JVM, if the object is an instance of a functional Java interface (that means a Java interface with a single abstract method), you can create it using a lambda expression prefixed with the type of the interface:

```
val listener = ActionListener { println("clicked") }
```

Functional (SAM) interfaces

An interface with only one abstract member function is called a *functional interface*, or a *Single Abstract Method (SAM) interface*. The functional interface can have several non-abstract member functions but only one abstract member function.

To declare a functional interface in Kotlin, use the `fun` modifier.

```
fun interface KRunnable {
    fun invoke()
}
```

SAM conversions

For functional interfaces, you can use SAM conversions that help make your code more concise and readable by using lambda expressions.

Instead of creating a class that implements a functional interface manually, you can use a lambda expression. With a SAM conversion, Kotlin can convert any lambda expression whose signature matches the signature of the interface's single method into the code, which dynamically instantiates the interface implementation.

For example, consider the following Kotlin functional interface:

```
fun interface IntPredicate {
    fun accept(i: Int): Boolean
}
```

If you don't use a SAM conversion, you will need to write code like this:

```
// Creating an instance of a class
val isEven = object : IntPredicate {
    override fun accept(i: Int): Boolean {
        return i % 2 == 0
    }
}
```

By leveraging Kotlin's SAM conversion, you can write the following equivalent code instead:

```
// Creating an instance using lambda
val isEven = IntPredicate { it % 2 == 0 }
```

A short lambda expression replaces all the unnecessary code.

```
fun interface IntPredicate {
    fun accept(i: Int): Boolean
}

val isEven = IntPredicate { it % 2 == 0 }

fun main() {
    println("Is 7 even? - ${isEven.accept(7)}")
}
```

You can also use SAM conversions for Java interfaces.

Migration from an interface with constructor function to a functional interface

Starting from 1.6.20, Kotlin supports callable references to functional interface constructors, which adds a source-compatible way to migrate from an interface with a constructor function to a functional interface. Consider the following code:

```
interface Printer {
    fun print()
}

fun Printer(block: () -> Unit): Printer = object : Printer {
    override fun print() = block()
}
```

With callable references to functional interface constructors enabled, this code can be replaced with just a functional interface declaration:

```
fun interface Printer {
    fun print()
}
```

Its constructor will be created implicitly, and any code using the `::Printer` function reference will compile. For example:

```
documentsStorage.addPrinter(::Printer)
```

Preserve the binary compatibility by marking the legacy function `Printer` with the `@Deprecated` annotation with `DeprecationLevel.HIDDEN`:

```
@Deprecated(message = "Your message about the deprecation", level = DeprecationLevel.HIDDEN)
fun Printer(...) {...}
```

Functional interfaces vs. type aliases

You can also simply rewrite the above using a type alias for a functional type:

```
typealias IntPredicate = (i: Int) -> Boolean

val isEven: IntPredicate = { it % 2 == 0 }

fun main() {
    println("Is 7 even? - ${isEven(7)}")
}
```

However, functional interfaces and type aliases serve different purposes. Type aliases are just names for existing types – they don't create a new type, while functional interfaces do. You can provide extensions that are specific to a particular functional interface to be inapplicable for plain functions or their type aliases.

Type aliases can have only one member, while functional interfaces can have multiple non-abstract member functions and one abstract member function. Functional interfaces can also implement and extend other interfaces.

Functional interfaces are more flexible and provide more capabilities than type aliases, but they can be more costly both syntactically and at runtime because they can require conversions to a specific interface. When you choose which one to use in your code, consider your needs:

- If your API needs to accept a function (any function) with some specific parameter and return types – use a simple functional type or define a type alias to give a shorter name to the corresponding functional type.
- If your API accepts a more complex entity than a function – for example, it has non-trivial contracts and/or operations on it that can't be expressed in a functional type's signature – declare a separate functional interface for it.

Properties

In Kotlin, properties let you store and manage data without writing functions to access or change the data. You can use properties in classes, interfaces, objects, companion objects, and even outside these structures as top-level properties.

Every property has a name, a type, and an automatically generated `get()` function called a getter. You can use the getter to read the property's value. If the property is mutable, it also has a `set()` function called a setter, which allows you to change the property's value.

Getters and setters are called *accessors*.

Declaring properties

Properties can be mutable (`var`) or read-only (`val`). You can declare them as a top-level property in a `.kt` file. Think of a top-level property as a global variable that belongs to a package:

```
// File: Constants.kt
package my.app

val pi = 3.14159
var counter = 0
```

You can also declare properties inside a class, interface, or object:

```
// Class with properties
class Address {
    var name: String = "Holmes, Sherlock"
    var street: String = "Baker"
    var city: String = "London"
}

// Interface with a property
interface ContactInfo {
    val email: String
}

// Object with properties
object Company {
    var name: String = "Detective Inc."
    val country: String = "UK"
}

// Class implementing the interface
class PersonContact : ContactInfo {
    override val email: String = "sherlock@example.com"
}
```

To use a property, refer to it by its name:

```
class Address {
    var name: String = "Holmes, Sherlock"
    var street: String = "Baker"
    var city: String = "London"
}

interface ContactInfo {
    val email: String
}

object Company {
    var name: String = "Detective Inc."
    val country: String = "UK"
}

class PersonContact : ContactInfo {
    override val email: String = "sherlock@example.com"
}

fun copyAddress(address: Address): Address {
    val result = Address()
    // Accesses properties in the result instance
    result.name = address.name
    result.street = address.street
    result.city = address.city
    return result
}

fun main() {
    val sherlockAddress = Address()
    val copy = copyAddress(sherlockAddress)
    // Accesses properties in the copy instance
    println("Copied address: ${copy.name}, ${copy.street}, ${copy.city}")
    // Copied address: Holmes, Sherlock, Baker, London

    // Accesses properties in the Company object
    println("Company: ${Company.name} in ${Company.country}")
    // Company: Detective Inc. in UK

    val contact = PersonContact()
    // Access properties in the contact instance
    println("Email: ${contact.email}")
    // Email: sherlock@email.com
}
```

In Kotlin, we recommend initializing properties when you declare them to keep your code safe and easy to read. However, you can initialize them later in special cases.

Declaring the property type is optional if the compiler can infer it from the initializer or the getter's return type:

```
var initialized = 1 // The inferred type is Int
var allByDefault    // ERROR: Property must be initialized.
```

Custom getters and setters

By default, Kotlin automatically generates getters and setters. You can define your own custom accessors when you need extra logic, such as validation, formatting, or calculations based on other properties.

A custom getter runs every time the property is accessed:

```
class Rectangle(val width: Int, val height: Int) {
    val area: Int
        get() = this.width * this.height
}
fun main() {
    val rectangle = Rectangle(3, 4)
    println("Width=${rectangle.width}, height=${rectangle.height}, area=${rectangle.area}")
}
```

You can omit the type if the compiler can infer it from the getter:

```
val area get() = this.width * this.height
```

A custom setter runs every time you assign a value to the property, except during initialization. By convention, the name of the setter parameter is `value`, but you can choose a different name:

```
class Point(var x: Int, var y: Int) {
    var coordinates: String
        get() = "$x,$y"
        set(value) {
            val parts = value.split(",")
            x = parts[0].toInt()
            y = parts[1].toInt()
        }
}

fun main() {
    val location = Point(1, 2)
    println(location.coordinates)
    // 1,2

    location.coordinates = "10,20"
    println("${location.x}, ${location.y}")
    // 10, 20
}
```

Changing visibility or adding annotations

In Kotlin, you can change accessor visibility or add annotations without replacing the default implementation. You don't have to make these changes within a body `{}`.

To change the visibility of an accessor, use the modifier before the `get` or `set` keyword:

```
class BankAccount(initialBalance: Int) {
    var balance: Int = initialBalance
        // Only the class can modify the balance
        private set

    fun deposit(amount: Int) {
        if (amount > 0) balance += amount
    }

    fun withdraw(amount: Int) {
        if (amount > 0 && amount ⩽ balance) balance -= amount
    }
}

fun main() {
    val account = BankAccount(100)
    println("Initial balance: ${account.balance}")
    // 100

    account.deposit(50)
    println("After deposit: ${account.balance}")
    // 150

    account.withdraw(70)
    println("After withdrawal: ${account.balance}")
    // 80

    // account.balance = 1000
    // Error: cannot assign because setter is private
}
```

To annotate an accessor, use the annotation before the `get` or `set` keyword:

```
// Defines an annotation that can be applied to a getter
@Target(AnnotationTarget.PROPERTY_GETTER)
annotation class Inject

class Service {
    var dependency: String = "Default Service"
        // Annotates the getter
        @Inject get
}

fun main() {
    val service = Service()
    println(service.dependency)
    // Default service
    println(service::dependency.getter.annotations)
    // [@Inject()]
    println(service::dependency.setter.annotations)
    // []
}
```

This example uses reflection to show which annotations are present on the getter and setter.

Backing fields

The compiler automatically generates backing fields for properties when a value needs to be stored in memory.

For example, the compiler creates a backing field when you use the default `get()` and `set()` functions because they read and write the stored value:

```
var count = 0
```

You can access backing fields by using the `field` keyword in a custom `get()` or `set()` function. For example, you can add extra logic to a getter or setter, or trigger an additional action when a property changes.

In this example, the `score` property uses the backing field inside the `set()` function so that updating the value also triggers a log event:

```
class Scoreboard {
    var score: Int = 0
        set(value) {
            field = value
            // Adds logging when updating the value
            println("Score updated to $field")
        }
}

fun main() {
    val board = Scoreboard()
    board.score = 10
    // Score updated to 10
    board.score = 20
    // Score updated to 20
}
```

Backing fields aren't created by default for all properties because they might not need them. For example, the `isEmpty` property doesn't have a backing field because the value is calculated from the `size` property each time you access it:

```
val isEmpty: Boolean
    get() = this.size == 0
```

Explicit backing fields

Sometimes you might need more flexibility. For example, if you have an API where you want to be able to modify the property internally but not externally. In such cases, you can use an *explicit backing field*.

In the following example, the `ShoppingCart` class has an `items` property that represents everything in the shopping cart. The class exposes the `items` property as a read-only list of strings, but internally it stores the data in a mutable list with an explicit backing field:

```
class ShoppingCart {
    // Public read-only view with explicit backing field
    val items: List<String>
        field = mutableListOf()

    fun addItem(item: String) {
        items.add(item)
    }

    fun removeItem(item: String) {
        items.remove(item)
    }
}

fun main() {
    val cart = ShoppingCart()
    cart.addItem("Apple")
    cart.addItem("Banana")

    println(cart.items)
    // [Apple, Banana]

    cart.removeItem("Apple")
    println(cart.items)
    // [Banana]
}
```

In this example, the compiler infers the type of the backing field from the `mutableListOf()` call: `MutableList<String>`. You can also declare the type of the backing field explicitly:

```
val items: List<String>
    // Explicit backing field with explicit type
    field: MutableList<String> = mutableListOf()
```

In the example of the `ShoppingCart` class, the compiler smart casts the `items` property to the `MutableList<String>` type, so the class can add and remove items from the cart through the `add()` and `remove()` functions. Outside the class, the compiler uses the public property type `List<String>`, so API users can only read what's in the `items` list.

Limitations

To use explicit backing fields, their properties and the backing fields themselves must follow certain rules. Properties can have explicit backing fields only if they:

- Don't have a custom getter.
- Are read-only (`val`).
- Aren't `open` .
- Aren't a delegated property.
- Aren't compile-time constants.

In addition, the backing field type must be a subtype of the property's type and have `private` visibility.

You can work around these restrictions by using backing properties instead.

Backing properties

If explicit backing fields don't fit your use case, you can try using a coding pattern called a *backing property*.

For example, if your property needs a custom getter:

```
class UserDirectory {
    private val _users = mutableListOf(
        "sarah",
        "mike",
        "emma"
    )

    val users: List<String>
        get() = _users.sorted()

    fun addUser(username: String) {
        _users.add(username)
    }
}

fun main() {
    val directory = UserDirectory()

    directory.addUser("alex")
    println(directory.users)
    // [alex, emma, mike, sarah]
}
```

Use a leading underscore when naming backing properties to follow Kotlin coding conventions.

In this example, the `UserDirectory` class has a read-only `users` property that lists every user in the directory. The `_users` variable is the private backing property containing the real list. The getter for the public `users` property sorts the entries before returning them.

Compile-time constants

If the value of a read-only property is known at compile time, mark it as a *compile-time constant* using the `const` modifier. Compile-time constants are inlined at compile time, so each reference is replaced with its actual value. They are accessed more efficiently because no getter is called:

```
// File: AppConfig.kt
package com.example

// Compile-time constant
const val MAX_LOGIN_ATTEMPTS = 3
```

Compile-time constants must meet the following requirements:

- They must be either a top-level property, or a member of an `object` declaration or a companion object.
- They must be initialized with a value of type `String` or a primitive type.
- They can't have a custom getter.

Compile-time constants still have a backing field, so you can interact with them using reflection.

You can also use these properties in annotations:

```
const val SUBSYSTEM_DEPRECATED: String = "This subsystem is deprecated"

@Deprecated(SUBSYSTEM_DEPRECATED) fun processLegacyOrders() { ... }
```

Late-initialized properties and variables

Normally, you must initialize properties in the constructor. However, this isn't always convenient. For example, you might initialize properties through dependency injection or inside the setup method of a unit test.

To handle these situations, mark the property with the `lateinit` modifier:

```
public class OrderServiceTest {
    lateinit var orderService: OrderService

    @SetUp fun setup() {
        orderService = OrderService()
    }

    @Test fun processesOrderSuccessfully() {
        // Calls orderService directly without checking for null
        // or initialization
        orderService.processOrder()
    }
}
```

You can use the `lateinit` modifier on `var` properties declared as:

- Top-level properties.
- Local variables.
- Properties inside the body of a class.

For class properties:

- You can't declare them in the primary constructor.
- They must not have a custom getter or setter.

In all cases, the property or variable must be non-nullable and must not be a primitive type.

If you access a `lateinit` property before initializing it, Kotlin throws a specific exception that identifies the uninitialized property being accessed:

```
class ReportGenerator {
    lateinit var report: String

    fun printReport() {
        // Throws an exception as it's accessed before
        // initialization
        println(report)
    }
}

fun main() {
    val generator = ReportGenerator()
    generator.printReport()
    // Exception in thread "main" kotlin.UninitializedPropertyAccessException: lateinit property
report has not been initialized
}
```

To check whether a `lateinit var` has already been initialized, use the `isInitialized` property on the reference to that property:

```
class WeatherStation {
    lateinit var latestReading: String

    fun printReading() {
        // Checks whether the property is initialized
        if (this::latestReading.isInitialized) {
            println("Latest reading: $latestReading")
        } else {
            println("No reading available")
        }
    }
}

fun main() {
    val station = WeatherStation()

    station.printReading()
    // No reading available
    station.latestReading = "22°C, sunny"
    station.printReading()
    // Latest reading: 22°C, sunny
}
```

You can only use `isInitialized` on a property if you can already access that property in your code. The property must be declared in the same class, in an outer class, or as a top-level property in the same file.

Overriding properties

See Overriding properties.

Delegated properties

To reuse logic and reduce code duplication, you can delegate the responsibility of getting and setting a property to a separate object.

Delegating accessor behavior keeps the property's accessor logic centralized, making it easier to reuse. This approach is useful when implementing behaviors like:

- Computing a value lazily.
- Reading from a map by a given key.
- Accessing a database.
- Notifying a listener when a property is accessed.

You can implement these common behaviors in libraries yourself or use existing delegates provided by external libraries. For more information, see delegated properties.

Delegated properties

With some common kinds of properties, even though you can implement them manually every time you need them, it is more helpful to implement them once, add them to a library, and reuse them later. For example:

- *Lazy* properties: the value is computed only on first access.
- *Observable* properties: listeners are notified about changes to this property.
- Storing properties in a *map* instead of a separate field for each property.

To cover these (and other) cases, Kotlin supports *delegated properties*:

```
class Example {
    var p: String by Delegate()
}
```

The syntax is: `val/var <property name>: <Type> by <expression>`. The expression after `by` is a *delegate*, because the `get()` (and `set()`) that correspond to the property will be delegated to its `getValue()` and `setValue()` methods. Property delegates don't have to implement an interface, but they have to provide a `getValue()` function (and `setValue()` for `var`s).

For example:

```
import kotlin.reflect.KProperty

class Delegate {
    operator fun getValue(thisRef: Any?, property: KProperty<*>): String {
        return "$thisRef, thank you for delegating '${property.name}' to me!"
    }

    operator fun setValue(thisRef: Any?, property: KProperty<*>, value: String) {
        println("$value has been assigned to '${property.name}' in $thisRef.")
    }
}
```

When you read from `p`, which delegates to an instance of `Delegate`, the `getValue()` function from `Delegate` is called. Its first parameter is the object you read `p` from, and the second parameter holds a description of `p` itself (for example, you can take its name).

```
val e = Example()
println(e.p)
```

This prints:

```
Example@33a17727, thank you for delegating 'p' to me!
```

Similarly, when you assign to `p`, the `setValue()` function is called. The first two parameters are the same, and the third holds the value being assigned:

```
e.p = "NEW"
```

This prints:

```
NEW has been assigned to 'p' in Example@33a17727.
```

The specification of the requirements for the delegated object can be found below.

You can declare a delegated property inside a function or code block; it doesn't have to be a member of a class. Below you can find an example.

Standard delegates

The Kotlin standard library provides factory methods for several useful kinds of delegates.

Lazy properties

`lazy()` is a function that takes a lambda and returns an instance of `Lazy<T>`, which can serve as a delegate for implementing a lazy property. The first call to `get()` executes the lambda passed to `lazy()` and remembers the result. Subsequent calls to `get()` simply return the remembered result.

```
val lazyValue: String by lazy {
    println("computed!")
    "Hello"
}

fun main() {
    println(lazyValue)
    println(lazyValue)
}
```

By default, the evaluation of lazy properties is *synchronized*: the value is computed only in one thread, but all threads will see the same value. If the synchronization of the initialization delegate is not required to allow multiple threads to execute it simultaneously, pass `LazyThreadSafetyMode.PUBLICATION` as a parameter to `lazy()`.

If you're sure that the initialization will always happen in the same thread as the one where you use the property, you can use `LazyThreadSafetyMode.NONE`. It doesn't incur any thread-safety guarantees and related overhead.

Observable properties

`Delegates.observable()` takes two arguments: the initial value and a handler for modifications.

The handler is called every time you assign to the property (*after* the assignment has been performed). It has three parameters: the property being assigned to, the old value, and the new value:

```
import kotlin.properties.Delegates

class User {
    var name: String by Delegates.observable("<no name>") {
        prop, old, new →
        println("$old → $new")
    }
}

fun main() {
    val user = User()
    user.name = "first"
    user.name = "second"
}
```

If you want to intercept assignments and *veto* them, use `vetoable()` instead of `observable()`. The handler passed to `vetoable` will be called *before* the assignment of a new property value.

Delegating to another property

A property can delegate its getter and setter to another property. Such delegation is available for both top-level and class properties (member and extension). The delegate property can be:

- A top-level property
- A member or an extension property of the same class
- A member or an extension property of another class

To delegate a property to another property, use the `::` qualifier in the delegate name, for example, `this::delegate` or `MyClass::delegate`.

```
var topLevelInt: Int = 0
class ClassWithDelegate(val anotherClassInt: Int)

class MyClass(var memberInt: Int, val anotherClassInstance: ClassWithDelegate) {
    var delegatedToMember: Int by this::memberInt
    var delegatedToTopLevel: Int by ::topLevelInt

    val delegatedToAnotherClass: Int by anotherClassInstance::anotherClassInt
}
var MyClass.extDelegated: Int by ::topLevelInt
```

This may be useful, for example, when you want to rename a property in a backward-compatible way: introduce a new property, annotate the old one with the `@Deprecated` annotation, and delegate its implementation.

```
class MyClass {
   var newName: Int = 0
   @Deprecated("Use 'newName' instead", ReplaceWith("newName"))
   var oldName: Int by this::newName
}
fun main() {
   val myClass = MyClass()
   // Notification: 'oldName: Int' is deprecated.
   // Use 'newName' instead
   myClass.oldName = 42
   println(myClass.newName) // 42
}
```

Storing properties in a map

One common use case is storing the values of properties in a map. This comes up often in applications for things like parsing JSON or performing other dynamic tasks. In this case, you can use the map instance itself as the delegate for a delegated property.

```
class User(val map: Map<String, Any?>) {
    val name: String by map
    val age: Int     by map
}
```

In this example, the constructor takes a map:

```
val user = User(mapOf(
    "name" to "John Doe",
    "age"  to 25
))
```

Delegated properties take values from this map through string keys, which are associated with the names of properties:

```
class User(val map: Map<String, Any?>) {
    val name: String by map
    val age: Int     by map
}

fun main() {
    val user = User(mapOf(
        "name" to "John Doe",
        "age"  to 25
    ))
    println(user.name) // Prints "John Doe"
    println(user.age)  // Prints 25
}
```

This also works for `var`'s properties if you use a `MutableMap` instead of a read-only `Map`:

```
class MutableUser(val map: MutableMap<String, Any?>) {
    var name: String by map
    var age: Int     by map
}
```

Local delegated properties

You can declare local variables as delegated properties. For example, you can make a local variable lazy:

```
fun example(computeFoo: () -> Foo) {
    val memoizedFoo by lazy(computeFoo)

    if (someCondition && memoizedFoo.isValid()) {
        memoizedFoo.doSomething()
    }
}
```

The `memoizedFoo` variable will be computed on first access only. If `someCondition` fails, the variable won't be computed at all.

Property delegate requirements

For a *read-only* property (`val`), a delegate should provide an operator function `getValue()` with the following parameters:

- `thisRef` must be the same type as, or a supertype of, the *property owner* (for extension properties, it should be the type being extended).
- `property` must be of type `KProperty<*>` or its supertype.

`getValue()` must return the same type as the property (or its subtype).

```
class Resource

class Owner {
    val valResource: Resource by ResourceDelegate()
}

class ResourceDelegate {
    operator fun getValue(thisRef: Owner, property: KProperty<*>): Resource {
        return Resource()
    }
}
```

For a *mutable* property (`var`), a delegate has to additionally provide an operator function `setValue()` with the following parameters:

- `thisRef` must be the same type as, or a supertype of, the *property owner* (for extension properties, it should be the type being extended).
- `property` must be of type `KProperty<*>` or its supertype.
- `value` must be of the same type as the property (or its supertype).

```
class Resource

class Owner {
    var varResource: Resource by ResourceDelegate()
}

class ResourceDelegate(private var resource: Resource = Resource()) {
    operator fun getValue(thisRef: Owner, property: KProperty<*>): Resource {
        return resource
    }
    operator fun setValue(thisRef: Owner, property: KProperty<*>, value: Any?) {
        if (value is Resource) {
            resource = value
        }
    }
}
```

`getValue()` and/or `setValue()` functions can be provided either as member functions of the delegate class or as extension functions. The latter is handy when you need to delegate a property to an object that doesn't originally provide these functions. Both of the functions need to be marked with the `operator` keyword.

You can create delegates as anonymous objects without creating new classes, by using the interfaces `ReadOnlyProperty` and `ReadWriteProperty` from the Kotlin standard library. They provide the required methods: `getValue()` is declared in `ReadOnlyProperty` ; `ReadWriteProperty` extends it and adds `setValue()` . This means you can pass a `ReadWriteProperty` whenever a `ReadOnlyProperty` is expected.

```
fun resourceDelegate(resource: Resource = Resource()): ReadWriteProperty<Any?, Resource> =
    object : ReadWriteProperty<Any?, Resource> {
        var curValue = resource
        override fun getValue(thisRef: Any?, property: KProperty<*>): Resource = curValue
        override fun setValue(thisRef: Any?, property: KProperty<*>, value: Resource) {
            curValue = value
        }
    }

val readOnlyResource: Resource by resourceDelegate()  // ReadWriteProperty as val
var readWriteResource: Resource by resourceDelegate()
```

Translation rules for delegated properties

Under the hood, the Kotlin compiler generates auxiliary properties for some kinds of delegated properties and then delegates to them.

> For optimization purposes, the compiler *does not* generate auxiliary properties in several cases. Learn about the optimization on the example of delegating to another property.

For example, for the property `prop` it generates the hidden property `prop$delegate`, and the code of the accessors simply delegates to this additional property:

```
class C {
    var prop: Type by MyDelegate()
}

// this code is generated by the compiler instead:
class C {
    private val prop$delegate = MyDelegate()
    var prop: Type
        get() = prop$delegate.getValue(this, this::prop)
        set(value: Type) = prop$delegate.setValue(this, this::prop, value)
}
```

The Kotlin compiler provides all the necessary information about `prop` in the arguments: the first argument `this` refers to an instance of the outer class `C`, and `this::prop` is a reflection object of the `KProperty` type describing `prop` itself.

Optimized cases for delegated properties

The `$delegate` field will be omitted if a delegate is:

- A referenced property:

```
class C<Type> {
    private var impl: Type = ...
    var prop: Type by ::impl
}
```

- A named object:

```
object NamedObject {
    operator fun getValue(thisRef: Any?, property: KProperty<*>): String = ...
}

val s: String by NamedObject
```

- A final `val` property with a backing field and a default getter in the same module:

```
val impl: ReadOnlyProperty<Any?, String> = ...

class A {
    val s: String by impl
}
```

- A constant expression, enum entry, `this`, `null`. The example of `this`:

```
class A {
    operator fun getValue(thisRef: Any?, property: KProperty<*>) ...

    val s by this
}
```

Translation rules when delegating to another property

When delegating to another property, the Kotlin compiler generates immediate access to the referenced property. This means that the compiler doesn't generate the field `prop$delegate`. This optimization helps save memory.

Take the following code, for example:

```
class C<Type> {
    private var impl: Type = ...
    var prop: Type by ::impl
}
```

Property accessors of the `prop` variable invoke the `impl` variable directly, skipping the delegated property's `getValue` and `setValue` operators, and thus the `KProperty` reference object is not needed.

For the code above, the compiler generates the following code:

```
class C<Type> {
    private var impl: Type = ...

    var prop: Type
        get() = impl
        set(value) {
            impl = value
        }

    fun getProp$delegate(): Type = impl // This method is needed only for reflection
}
```

Providing a delegate

By defining the `provideDelegate` operator, you can extend the logic for creating the object to which the property implementation is delegated. If the object used on the right-hand side of `by` defines `provideDelegate` as a member or extension function, that function will be called to create the property delegate instance.

One of the possible use cases of `provideDelegate` is to check the consistency of the property upon its initialization.

For example, to check the property name before binding, you can write something like this:

```
class ResourceDelegate<T> : ReadOnlyProperty<MyUI, T> {
    override fun getValue(thisRef: MyUI, property: KProperty<*>): T { ... }
}

class ResourceLoader<T>(id: ResourceID<T>) {
    operator fun provideDelegate(
            thisRef: MyUI,
            prop: KProperty<*>
    ): ReadOnlyProperty<MyUI, T> {
        checkProperty(thisRef, prop.name)
        // create delegate
        return ResourceDelegate()
    }

    private fun checkProperty(thisRef: MyUI, name: String) { ... }
}

class MyUI {
    fun <T> bindResource(id: ResourceID<T>): ResourceLoader<T> { ... }

    val image by bindResource(ResourceID.image_id)
    val text by bindResource(ResourceID.text_id)
}
```

The parameters of `provideDelegate` are the same as those of `getValue`:

- `thisRef` must be the same type as, or a supertype of, the *property owner* (for extension properties, it should be the type being extended);
- `property` must be of type `KProperty<*>` or its supertype.

The `provideDelegate` method is called for each property during the creation of the `MyUI` instance, and it performs the necessary validation right away.

Without this ability to intercept the binding between the property and its delegate, to achieve the same functionality you'd have to pass the property name explicitly, which isn't very convenient:

```
// Checking the property name without "provideDelegate" functionality
class MyUI {
    val image by bindResource(ResourceID.image_id, "image")
    val text by bindResource(ResourceID.text_id, "text")
}

fun <T> MyUI.bindResource(
        id: ResourceID<T>,
        propertyName: String
): ReadOnlyProperty<MyUI, T> {
    checkProperty(this, propertyName)
    // create delegate
}
```

In the generated code, the `provideDelegate` method is called to initialize the auxiliary `prop$delegate` property. Compare the generated code for the property declaration `val prop: Type by MyDelegate()` with the generated code above (when the `provideDelegate` method is not present):

```
class C {
    var prop: Type by MyDelegate()
}

// this code is generated by the compiler
// when the 'provideDelegate' function is available:
class C {
    // calling "provideDelegate" to create the additional "delegate" property
    private val prop$delegate = MyDelegate().provideDelegate(this, this::prop)
    var prop: Type
        get() = prop$delegate.getValue(this, this::prop)
        set(value: Type) = prop$delegate.setValue(this, this::prop, value)
}
```

Note that the `provideDelegate` method affects only the creation of the auxiliary property and doesn't affect the code generated for the getter or the setter.

With the `PropertyDelegateProvider` interface from the standard library, you can create delegate providers without creating new classes.

```
val provider = PropertyDelegateProvider { thisRef: Any?, property ->
    ReadOnlyProperty<Any?, Int> {_, property -> 42 }
}
val delegate: Int by provider
```

Null safety

Null safety is a Kotlin feature designed to significantly reduce the risk of null references, also known as The Billion-Dollar Mistake.

One of the most common pitfalls in many programming languages, including Java, is that accessing a member of a null reference results in a null reference exception. In Java, this would be the equivalent of a `NullPointerException`, or an *NPE* for short.

Kotlin explicitly supports nullability as part of its type system, meaning you can explicitly declare which variables or properties are allowed to be `null`. Also, when you declare non-null variables, the compiler enforces that these variables cannot hold a `null` value, preventing an NPE.

Kotlin's null safety ensures safer code by catching potential null-related issues at compile time rather than runtime. This feature improves code robustness, readability, and maintainability by explicitly expressing `null` values, making the code easier to understand and manage.

The only possible causes of an NPE in Kotlin are:

- An explicit call to `throw NullPointerException()`.
- Usage of the not-null assertion operator `!!`.
- Data inconsistency during initialization, such as when:
  - An uninitialized `this` available in a constructor is used somewhere else (a "leaking `this`").
  - A superclass constructor calling an open member whose implementation in the derived class uses an uninitialized state.
- Java interoperation:
  - Attempts to access a member of a `null` reference of a platform type.

- Nullability issues with generic types. For example, a piece of Java code adding `null` into a Kotlin `MutableList<String>`, which would require `MutableList<String?>` to handle it properly.
- Other issues caused by external Java code.

> Besides NPE, another exception related to null safety is `UninitializedPropertyAccessException`. Kotlin throws this exception when you try to access a property that has not been initialized, ensuring that non-nullable properties are not used until they are ready. This typically happens with `lateinit` properties.

Nullable types and non-nullable types

In Kotlin, the type system distinguishes between types that can hold `null` (nullable types) and those that cannot (non-nullable types). For example, a regular variable of type `String` cannot hold `null`:

```
fun main() {
    // Assigns a non-null string to a variable
    var a: String = "abc"
    // Attempts to re-assign null to the non-nullable variable
    a = null
    print(a)
    // Null can not be a value of a non-null type String
}
```

You can safely call a method or access a property on `a`. It's guaranteed not to cause an NPE because `a` is a non-nullable variable. The compiler ensures that `a` always holds a valid `String` value, so there's no risk of accessing its properties or methods when it's `null`:

```
fun main() {
    // Assigns a non-null string to a variable
    val a: String = "abc"
    // Returns the length of a non-nullable variable
    val l = a.length
    print(l)
    // 3
}
```

To allow `null` values, declare a variable with a `?` sign right after the variable type. For example, you can declare a nullable string by writing `String?`. This expression makes `String` a type that can accept `null`:

```
fun main() {
    // Assigns a nullable string to a variable
    var b: String? = "abc"
    // Successfully re-assigns null to the nullable variable
    b = null
    print(b)
    // null
}
```

If you try accessing `length` directly on `b`, the compiler reports an error. This is because `b` is declared as a nullable variable and can hold `null` values. Attempting to access properties on nullables directly leads to an NPE:

```
fun main() {
    // Assigns a nullable string to a variable
    var b: String? = "abc"
    // Re-assigns null to the nullable variable
    b = null
    // Tries to directly return the length of a nullable variable
    val l = b.length
    print(l)
    // Only safe (?.) or non-null asserted (!!.) calls are allowed on a nullable receiver of type
String?
}
```

In the example above, the compiler requires you to use safe calls to check for nullability before accessing properties or performing operations. There are several ways to handle nullables:

- Check for `null` with the `if` conditional
- Safe call operator `?.`
- Elvis operator `?:`
- Not-null assertion operator `!!`
- Nullable receiver
- `let` function
- Safe casts `as?`
- Collections of a nullable type

Read the next sections for details and examples of `null` handling tools and techniques.

Check for null with the if conditional

When working with nullable types, you need to handle nullability safely to avoid an NPE. One way to handle this is checking for nullability explicitly with the `if` conditional expression.

For example, check whether `b` is `null` and then access `b.length`:

```
fun main() {
    // Assigns null to a nullable variable
    val b: String? = null
    // Checks for nullability first and then accesses length
    val l = if (b ≠ null) b.length else -1
    print(l)
    // -1
}
```

In the example above, the compiler performs a smart cast to change the type from nullable `String?` to non-nullable `String`. It also tracks the information about the check you performed and allows the call to `length` inside the `if` conditional.

More complex conditions are supported as well:

```
fun main() {
    // Assigns a nullable string to a variable
    val b: String? = "Kotlin"

    // Checks for nullability first and then accesses length
    if (b ≠ null && b.length > 0) {
        print("String of length ${b.length}")
        // String of length 6
    } else {
        // Provides alternative if the condition is not met
        print("Empty string")
    }
}
```

Note that the example above only works when the compiler can guarantee that `b` doesn't change between the check and its usage, same as the smart cast prerequisites.

Safe call operator

The safe call operator `?.` allows you to handle nullability safely in a shorter form. Instead of throwing an NPE, if the object is `null`, the `?.` operator simply returns `null`:

```
fun main() {
    // Assigns a nullable string to a variable
    val a: String? = "Kotlin"
    // Assigns null to a nullable variable
    val b: String? = null

    // Checks for nullability and returns length or null
    println(a?.length)
    // 6
    println(b?.length)
    // null
}
```

The `b?.length` expression checks for nullability and returns `b.length` if `b` is non-null, or `null` otherwise. The type of this expression is `Int?`.

You can use the `?.` operator with both `var` and `val` variables in Kotlin:

- A nullable `var` can hold a `null` (for example, `var nullableValue: String? = null`) or a non-null value (for example, `var nullableValue: String? = "Kotlin"`). If it's a non-null value, you can change it to `null` at any point.
- A nullable `val` can hold a `null` (for example, `val nullableValue: String? = null`) or a non-null value (for example, `val nullableValue: String? = "Kotlin"`). If it's a non-null value, you cannot change it to `null` subsequently.

Safe calls are useful in chains. For example, Bob is an employee who may be assigned to a department (or not). That department may, in turn, have another employee as a department head. To obtain the name of Bob's department head (if there is one), you write the following:

```
bob?.department?.head?.name
```

This chain returns `null` if any of its properties are `null`.

You can also place a safe call on the left side of an assignment:

```
person?.department?.head = managersPool.getManager()
```

In the example above, if one of the receivers in the safe call chain is `null`, the assignment is skipped, and the expression on the right is not evaluated at all. For example, if either `person` or `person.department` is `null`, the function is not called. Here's the equivalent of the same safe call but with the `if` conditional:

```
if (person ≠ null && person.department ≠ null) {
    person.department.head = managersPool.getManager()
}
```

Elvis operator

When working with nullable types, you can check for `null` and provide an alternative value. For example, if `b` is not `null`, access `b.length`. Otherwise, return an alternative value:

```
fun main() {
    // Assigns null to a nullable variable
    val b: String? = null
    // Checks for nullability. If not null, returns length. If null, returns 0
    val l: Int = if (b ≠ null) b.length else 0
    println(l)
    // 0
}
```

Instead of writing the complete `if` expression, you can handle this in a more concise way with the Elvis operator `?:`:

```
fun main() {
    // Assigns null to a nullable variable
    val b: String? = null
    // Checks for nullability. If not null, returns length. If null, returns a non-null value
    val l = b?.length ?: 0
    println(l)
    // 0
}
```

If the expression to the left of `?:` is not `null`, the Elvis operator returns it. Otherwise, the Elvis operator returns the expression to the right. The expression on the right-hand side is evaluated only if the left-hand side is `null`.

Since `throw` and `return` are expressions in Kotlin, you can also use them on the right-hand side of the Elvis operator. This can be handy, for example, when checking function arguments:

```
fun foo(node: Node): String? {
    // Checks for getParent(). If not null, it's assigned to parent. If null, returns null
    val parent = node.getParent() ?: return null
    // Checks for getName(). If not null, it's assigned to name. If null, throws exception
    val name = node.getName() ?: throw IllegalArgumentException("name expected")
    // ...
}
```

Not-null assertion operator

The not-null assertion operator `!!` converts any value to a non-nullable type.

When you apply the `!!` operator to a variable whose value is not `null`, it's safely handled as a non-nullable type, and the code executes normally. However, if the value is `null`, the `!!` operator forces it to be treated as non-nullable, which results in an NPE.

When `b` is not `null` and the `!!` operator makes it return its non-null value (which is a `String` in this example), it accesses `length` correctly:

```
fun main() {
    // Assigns a nullable string to a variable
    val b: String? = "Kotlin"
    // Treats b as non-null and accesses its length
    val l = b!!.length
    println(l)
    // 6
}
```

When `b` is `null` and the `!!` operator makes it return its non-null value, and an NPE occurs:

```
fun main() {
    // Assigns null to a nullable variable
    val b: String? = null
    // Treats b as non-null and tries to access its length
    val l = b!!.length
    println(l)
    // Exception in thread "main" java.lang.NullPointerException
}
```

The `!!` operator is particularly useful when you are confident that a value is not `null` and there's no chance of getting an NPE, but the compiler cannot guarantee this due to certain rules. In such cases, you can use the `!!` operator to explicitly tell the compiler that the value is not `null`.

Nullable receiver

You can use extension functions with a nullable receiver type, allowing these functions to be called on variables that might be `null`.

By defining an extension function on a nullable receiver type, you can handle `null` values within the function itself instead of checking for `null` at every place where you call the function.

For example, the `.toString()` extension function can be called on a nullable receiver. When invoked on a `null` value, it safely returns the string `"null"` without throwing an exception:

```
fun main() {
    // Assigns null to a nullable Person object stored in the person variable
    val person: Person? = null

    // Applies .toString to the nullable person variable and prints a string
    println(person.toString())
    // null
}

// Defines a simple Person class
data class Person(val name: String)
```

In the example above, even though `person` is `null`, the `.toString()` function safely returns the string `"null"`. This can be helpful for debugging and logging.

If you expect the `.toString()` function to return a nullable string (either a string representation or `null`), use the safe-call operator `?.`. The `?.` operator calls `.toString()` only if the object is not `null`, otherwise it returns `null`:

```
fun main() {
    // Assigns a nullable Person object to a variable
    val person1: Person? = null
    val person2: Person? = Person("Alice")

    // Prints "null" if person is null; otherwise prints the result of person.toString()
    println(person1?.toString())
    // null
    println(person2?.toString())
    // Person(name=Alice)
}

// Defines a Person class
data class Person(val name: String)
```

The `?.` operator allows you to safely handle potential `null` values while still accessing properties or functions of objects that might be `null`.

Let function

To handle `null` values and perform operations only on non-null types, you can use the safe call operator `?.` together with the `let` function.

This combination is useful for evaluating an expression, check the result for `null`, and execute code only if it's not `null`, avoiding manual null checks:

```
fun main() {
    // Declares a list of nullable strings
    val listWithNulls: List<String?> = listOf("Kotlin", null)

    // Iterates over each item in the list
    for (item in listWithNulls) {
        // Checks if the item is null and only prints non-null values
        item?.let { println(it) }
        //Kotlin
    }
}
```

Safe casts

The regular Kotlin operator for type casts is the `as` operator. However, regular casts can result in an exception if the object is not of the target type.

You can use the `as?` operator for safe casts. It tries to cast a value to the specified type and returns `null` if the value is not of that type:

```
fun main() {
    // Declares a variable of type Any, which can hold any type of value
    val a: Any = "Hello, Kotlin!"

    // Safe casts to Int using the 'as?' operator
    val aInt: Int? = a as? Int
    // Safe casts to String using the 'as?' operator
    val aString: String? = a as? String

    println(aInt)
    // null
    println(aString)
    // "Hello, Kotlin!"
}
```

The code above prints `null` because `a` is not an `Int`, so the cast fails safely. It also prints `"Hello, Kotlin!"` because it matches the `String?` type, so the safe cast succeeds.

Collections of a nullable type

If you have a collection of nullable elements and want to keep only the non-null ones, use the `filterNotNull()` function:

```
fun main() {
    // Declares a list containing some null and non-null integer values
    val nullableList: List<Int?> = listOf(1, 2, null, 4)

    // Filters out null values, resulting in a list of non-null integers
    val intList: List<Int> = nullableList.filterNotNull()

    println(intList)
    // [1, 2, 4]
}
```

What's next?

- Learn how to handle nullability in Java and Kotlin.
- Learn about generic types that are definitely non-nullable.

Equality

In Kotlin, there are two types of equality:

- *Structural* equality (`==`) - a check for the `equals()` function
- *Referential* equality (`===`) - a check for two references pointing to the same object

Structural equality

Structural equality verifies if two objects have the same content or structure. Structural equality is checked by the `==` operation and its negated counterpart `!=`. By convention, an expression like `a == b` is translated to:

```
a?.equals(b) ?: (b === null)
```

If `a` is not `null`, it calls the `equals(Any?)` function. Otherwise (`a` is `null`), it checks that `b` is referentially equal to `null`:

```
fun main() {
    var a = "hello"
    var b = "hello"
    var c = null
    var d = null
    var e = d

    println(a == b)
    // true
    println(a == c)
    // false
    println(c == e)
    // true
}
```

Note that there's no point in optimizing your code when comparing to `null` explicitly: `a == null` will be automatically translated to `a === null`.

In Kotlin, the `equals()` function is inherited by all classes from the `Any` class. By default, the `equals()` function implements referential equality. However, classes in Kotlin can override the `equals()` function to provide a custom equality logic and, in this way, implement structural equality.

Value classes and data classes are two specific Kotlin types that automatically override the `equals()` function. That's why they implement structural equality by default.

However, in the case of data classes, if the `equals()` function is marked as `final` in the parent class, its behavior remains unchanged.

Distinctly, non-data classes (those not declared with the `data` modifier) do not override the `equals()` function by default. Instead, non-data classes implement referential equality behavior inherited from the `Any` class. To implement structural equality, non-data classes require a custom equality logic to override the `equals()` function.

To provide a custom equals check implementation, override the `equals(other: Any?): Boolean` function:

```
class Point(val x: Int, val y: Int) {
    override fun equals(other: Any?): Boolean {
        if (this === other) return true
        if (other !is Point) return false

        // Compares properties for structural equality
        return this.x == other.x && this.y == other.y
    }
}
```

When overriding the equals() function, you should also override the hashCode() function to keep consistency between equality and hashing and ensure the proper behavior of these functions.

Functions with the same name and other signatures (like `equals(other: Foo)`) don't affect equality checks with the operators `==` and `!=`.

Structural equality has nothing to do with comparison defined by the `Comparable<...>` interface, so only a custom `equals(Any?)` implementation may affect the behavior of the operator.

Referential equality

Referential equality verifies the memory addresses of two objects to determine if they are the same instance.

Referential equality is checked by the `===` operation and its negated counterpart `!==`. `a === b` evaluates to true if and only if `a` and `b` point to the same object:

```
fun main() {
    var a = "Hello"
    var b = a
    var c = "world"
    var d = "world"

    println(a === b)
    // true
    println(a === c)
    // false
    println(c === d)
    // true

}
```

For values represented by primitive types at runtime (for example, `Int`), the `===` equality check is equivalent to the `==` check.

> The referential equality is implemented differently in Kotlin/JS. For more information about equality, see the Kotlin/JS documentation.

Floating-point numbers equality

When the operands of an equality check are statically known to be `Float` or `Double` (nullable or not), the check follows the IEEE 754 Standard for Floating-Point Arithmetic.

The behavior is different for operands that are not statically typed as floating-point numbers. In these cases, structural equality is implemented. As a result, checks with operands not statically typed as floating-point numbers differ from the IEEE standard. In this scenario:

- `NaN` is equal to itself
- `NaN` is greater than any other element (including `POSITIVE_INFINITY`)
- `-0.0` is not equal to `0.0`

For more information, see Floating-point numbers comparison.

Array equality

To compare whether two arrays have the same elements in the same order, use `contentEquals()`.

For more information, see Compare arrays.

Generics: in, out, where

Classes in Kotlin can have type parameters, just like in Java:

```
class Box<T>(t: T) {
    var value = t
}
```

To create an instance of such a class, simply provide the type arguments:

```
val box: Box<Int> = Box<Int>(1)
```

If the compiler can infer the type arguments, for example, from the constructor arguments, you don't need to specify them explicitly:

```
val box = Box(1) // 1 has type Int, so the compiler figures out that it is Box<Int>
```

Variance

One of the trickiest aspects of Java's type system is the wildcard types (see Java Generics FAQ). Kotlin doesn't have these. Instead, Kotlin has declaration-site variance and type projections.

Variance and wildcards in Java

Let's think about why Java needs these mysterious wildcards. First, generic types in Java are *invariant*, meaning that `List<String>` is *not* a subtype of `List<Object>`. If `List` were not *invariant*, it would have been no better than Java's arrays, as the following code would have compiled but caused an exception at runtime:

```
// Java
List<String> strs = new ArrayList<String>();

// Java reports a type mismatch here at compile-time.
List<Object> objs = strs;

// What if it didn't?
// We would be able to put an Integer into a list of Strings.
objs.add(1);

// And then at runtime, Java would throw
// a ClassCastException: Integer cannot be cast to String
String s = strs.get(0);
```

Java prohibits such things to guarantee runtime safety. But this has implications. For example, consider the `addAll()` method from the `Collection` interface. What's the signature of this method? Intuitively, you'd write it this way:

```
// Java
interface Collection<E> ... {
    void addAll(Collection<E> items);
}
```

But then, you would not be able to do the following (which is perfectly safe):

```java
// Java

// The following would not compile with the naive declaration of addAll:
// Collection<String> is not a subtype of Collection<Object>
void copyAll(Collection<Object> to, Collection<String> from) {
    to.addAll(from);
}
```

That's why the actual signature of `addAll()` is the following:

```java
// Java
interface Collection<E> ... {
    void addAll(Collection<? extends E> items);
}
```

The *wildcard type argument* `? extends E` indicates that this method accepts a collection of objects of `E` *or a subtype of* `E`, not just `E` itself. This means that you can safely *read* `E`'s from items (elements of this collection are instances of a subclass of E), but *cannot write* to it as you don't know what objects comply with that unknown subtype of `E`. In return for this limitation, you get the desired behavior: `Collection<String>` *is* a subtype of `Collection<? extends Object>`. In other words, the wildcard with an *extends*-bound (*upper* bound) makes the type *covariant*.

The key to understanding why this works is rather simple: if you can only *take* items from a collection, then using a collection of `String`s and reading `Object`s from it is fine. Conversely, if you can only *put* items into the collection, it's okay to take a collection of `Object`s and put `String`s into it: in Java there is `List<? super String>`, which accepts `String`s or any of its supertypes.

The latter is called *contravariance*, and you can only call methods that take `String` as an argument on `List<? super String>` (for example, you can call `add(String)` or `set(int, String)`). If you call something that returns `T` in `List<T>`, you don't get a `String`, but rather an `Object`.

Joshua Bloch, in his book Effective Java, 3rd Edition, explains the problem well (Item 31: "Use bounded wildcards to increase API flexibility"). He gives the name *Producers* to objects you only *read from* and *Consumers* to those you only *write to*. He recommends:

> "For maximum flexibility, use wildcard types on input parameters that represent producers or consumers."

He then proposes the following mnemonic: *PECS* stands for *Producer-Extends, Consumer-Super.*

If you use a producer-object, say, `List<? extends Foo>`, you are not allowed to call `add()` or `set()` on this object, but this does not mean that it is *immutable*: for example, nothing prevents you from calling `clear()` to remove all the items from the list, since `clear()` does not take any parameters at all.

The only thing guaranteed by wildcards (or other types of variance) is *type safety*. Immutability is a completely different story.

Declaration-site variance

Let's suppose that there is a generic interface `Source<T>` that does not have any methods that take `T` as a parameter, only methods that return `T`:

```java
// Java
interface Source<T> {
    T nextT();
}
```

Then, it would be perfectly safe to store a reference to an instance of `Source<String>` in a variable of type `Source<Object>` - there are no consumer-methods to call. But Java does not know this, and still prohibits it:

```java
// Java
void demo(Source<String> strs) {
    Source<Object> objects = strs; // !!! Not allowed in Java
    // ...
}
```

To fix this, you should declare objects of type `Source<? extends Object>`. Doing so is meaningless, because you can call all the same methods on such a variable as before, so there's no value added by the more complex type. But the compiler does not know that.

In Kotlin, there is a way to explain this sort of thing to the compiler. This is called *declaration-site variance*: you can annotate the *type parameter* `T` of `Source` to make sure that it is only *returned* (produced) from members of `Source<T>`, and never consumed. To do this, use the `out` modifier:

```
interface Source<out T> {
    fun nextT(): T
}

fun demo(strs: Source<String>) {
    val objects: Source<Any> = strs // This is OK, since T is an out-parameter
    // ...
}
```

The general rule is this: when a type parameter `T` of a class `C` is declared `out`, it may occur only in the *out*-position in the members of `C`, but in return `C<Base>` can safely be a supertype of `C<Derived>`.

In other words, you can say that the class `C` is *covariant* in the parameter `T`, or that `T` is a *covariant* type parameter. You can think of `C` as being a *producer* of `T`'s, and NOT a *consumer* of `T`'s.

The `out` modifier is called a *variance annotation*, and since it is provided at the type parameter declaration site, it provides *declaration-site variance*. This is in contrast with Java's *use-site variance* where wildcards in the type usages make the types covariant.

In addition to `out`, Kotlin provides a complementary variance annotation: `in`. It makes a type parameter *contravariant*, meaning it can only be consumed and never produced. A good example of a contravariant type is `Comparable`:

```
interface Comparable<in T> {
    operator fun compareTo(other: T): Int
}

fun demo(x: Comparable<Number>) {
    x.compareTo(1.0) // 1.0 has type Double, which is a subtype of Number
    // Thus, you can assign x to a variable of type Comparable<Double>
    val y: Comparable<Double> = x // OK!
}
```

The words *in* and *out* seem to be self-explanatory (as they've already been used successfully in C# for quite some time), and so the mnemonic mentioned above is not really needed. It can in fact be rephrased at a higher level of abstraction:

The Existential **Transformation: Consumer in, Producer out!**:-)

Type projections

Use-site variance: type projections

It is very easy to declare a type parameter `T` as `out` and avoid trouble with subtyping on the use site, but some classes *can't* actually be restricted to only return `T`'s! A good example of this is `Array`:

```
class Array<T>(val size: Int) {
    operator fun get(index: Int): T { ... }
    operator fun set(index: Int, value: T) { ... }
}
```

This class can be neither co- nor contravariant in `T`. And this imposes certain inflexibilities. Consider the following function:

```
fun copy(from: Array<Any>, to: Array<Any>) {
    assert(from.size == to.size)
    for (i in from.indices)
        to[i] = from[i]
}
```

This function is supposed to copy items from one array to another. Let's try to apply it in practice:

```
val ints: Array<Int> = arrayOf(1, 2, 3)
val any = Array<Any>(3) { "" }
copy(ints, any)
//   ^ type is Array<Int> but Array<Any> was expected
```

Here you run into the same familiar problem: `Array<T>` is *invariant* in `T`, and so neither `Array<Int>` nor `Array<Any>` is a subtype of the other. Why not? Again, this is because `copy` could have an unexpected behavior, for example, it may attempt to write a `String` to `from`, and if you actually pass an array of `Int` there, a `ClassCastException` will be thrown later.

To prohibit the `copy` function from *writing* to `from`, you can do the following:

```
fun copy(from: Array<out Any>, to: Array<Any>) { ... }
```

This is *type projection*, which means that `from` is not a simple array, but is rather a restricted (*projected*) one. You can only call methods that return the type parameter `T`, which in this case means that you can only call `get()`. This is our approach to *use-site variance*, and it corresponds to Java's `Array<? extends Object>` while being slightly simpler.

You can project a type with `in` as well:

```
fun fill(dest: Array<in String>, value: String) { ... }
```

`Array<in String>` corresponds to Java's `Array<? super String>`. This means that you can pass an array of `String`, `CharSequence`, or `Object` to the `fill()` function.

Star-projections

Sometimes you want to say that you know nothing about the type argument, but you still want to use it in a safe way. The safe way here is to define such a projection of the generic type, that every concrete instantiation of that generic type will be a subtype of that projection.

Kotlin provides so-called *star-projection* syntax for this:

- For `Foo<out T : TUpper>`, where `T` is a covariant type parameter with the upper bound `TUpper`, `Foo<*>` is equivalent to `Foo<out TUpper>`. This means that when the `T` is unknown, you can safely *read* values of `TUpper` from `Foo<*>`.
- For `Foo<in T>`, where `T` is a contravariant type parameter, `Foo<*>` is equivalent to `Foo<in Nothing>`. This means there is nothing you can *write* to `Foo<*>` in a safe way when `T` is unknown.
- For `Foo<T : TUpper>`, where `T` is an invariant type parameter with the upper bound `TUpper`, `Foo<*>` is equivalent to `Foo<out TUpper>` for reading values and to `Foo<in Nothing>` for writing values.

If a generic type has several type parameters, each of them can be projected independently. For example, if the type is declared as `interface Function<in T, out U>` you could use the following star-projections:

- `Function<*, String>` means `Function<in Nothing, String>`.
- `Function<Int, *>` means `Function<Int, out Any?>`.
- `Function<*, *>` means `Function<in Nothing, out Any?>`.

Star-projections are very much like Java's raw types, but safe.

Captured types

When you use a type projection, such as `out T` or `in T`, the compiler internally represents the unknown concrete type as a *captured type*. A captured type is an unknown type with known upper and lower bounds.

Captured types are non-denotable, so you can't write them directly in Kotlin code. Instead, you can most frequently see captured types in compiler diagnostics, such as `CapturedType(out X)`. For example, the following type mismatch diagnostic contains a captured type:

```
val array: Array<out CharSequence> = arrayOf("str")
val item: Int = array.get(0)
// Initializer type mismatch: expected 'Int', actual 'CapturedType(out CharSequence)'
```

The compiler uses the captured type's upper bound for read operations and its lower bound to determine which values are type-safe for write operations:

```
// The projected type is Array<out CharSequence>
val array: Array<out CharSequence> = arrayOf("Kotlin")

// The get() read operation uses the captured type's upper bound, CharSequence
val item = array.get(0)

// The set() write operation uses the captured type's lower bound, Nothing,
// which results in an error
array.set(0, "New value")
// Receiver type 'Array<out CharSequence>' contains out projection
// which prohibits the use of 'fun set(index: Int, value: T): Unit'
```

In this example:

- The variable `array` has the projected type `Array<out CharSequence>`. The compiler represents the projected type argument `out CharSequence` as a captured type with `CharSequence` as its upper bound and `Nothing` as its lower bound.
- For the `get()` operation, the compiler approximates the captured type to its upper bound, `CharSequence`, and infers `CharSequence` as the type of `item`.
- For the `set()` operation, the captured type has `Nothing` as its lower bound. Since `Nothing` has no instances, writing a value to the projected type isn't type-safe and results in an error.

Generic functions

Classes aren't the only declarations that can have type parameters. Functions can, too. Type parameters are placed *before* the name of the function:

```
fun <T> singletonList(item: T): List<T> {
    // ...
}

fun <T> T.basicToString(): String { // extension function
    // ...
}
```

To call a generic function, specify the type arguments at the call site *after* the name of the function:

```
val l = singletonList<Int>(1)
```

Type arguments can be omitted if they can be inferred from the context, so the following example works as well:

```
val l = singletonList(1)
```

Generic constraints

The set of all possible types that can be substituted for a given type parameter may be restricted by *generic constraints*.

Upper bounds

The most common type of constraint is an *upper bound*, which corresponds to Java's `extends` keyword:

```
fun <T : Comparable<T>> sort(list: List<T>) {  ... }
```

The type specified after a colon is the *upper bound*, indicating that only a subtype of `Comparable<T>` can be substituted for `T`. For example:

```
sort(listOf(1, 2, 3)) // OK. Int is a subtype of Comparable<Int>
sort(listOf(HashMap<Int, String>())) // Error: HashMap<Int, String> is not a subtype of
Comparable<HashMap<Int, String>>
```

The default upper bound (if there was none specified) is `Any?`. Only one upper bound can be specified inside the angle brackets. If the same type parameter needs more than one upper bound, you need a separate *where*-clause:

```
fun <T> copyWhenGreater(list: List<T>, threshold: T): List<String>
    where T : CharSequence,
          T : Comparable<T> {
    return list.filter { it > threshold }.map { it.toString() }
}
```

The passed type must satisfy all conditions of the `where` clause simultaneously. In the above example, the `T` type must implement *both* `CharSequence` and `Comparable`.

Definitely non-nullable types

To make interoperability with generic Java classes and interfaces easier, Kotlin supports declaring a generic type parameter as **definitely non-nullable**.

To declare a generic type `T` as definitely non-nullable, declare the type with `& Any`. For example: `T & Any`.

A definitely non-nullable type must have a nullable upper bound.

The most common use case for declaring definitely non-nullable types is when you want to override a Java method that contains `@NotNull` as an argument. For example, consider the `load()` method:

```
import org.jetbrains.annotations.*;

public interface Game<T> {
    public T save(T x) {}
    @NotNull
    public T load(@NotNull T x) {}
}
```

To override the `load()` method in Kotlin successfully, you need `T1` to be declared as definitely non-nullable:

```
interface ArcadeGame<T1> : Game<T1> {
    override fun save(x: T1): T1
    // T1 is definitely non-nullable
    override fun load(x: T1 & Any): T1 & Any
}
```

When working only with Kotlin, it's unlikely that you will need to declare definitely non-nullable types explicitly because Kotlin's type inference takes care of this for you.

Type erasure

The type safety checks that Kotlin performs for generic declaration usages are done at compile time. At runtime, the instances of generic types do not hold any information about their actual type arguments. The type information is said to be *erased*. For example, the instances of `Foo<Bar>` and `Foo<Baz?>` are erased to just `Foo<*>`.

Generics type checks and casts

Due to the type erasure, there is no general way to check whether an instance of a generic type was created with certain type arguments at runtime, and the compiler prohibits such `is`-checks such as `ints is List<Int>` or `list is T` (type parameter). However, you can check an instance against a star-projected type:

```
if (something is List<*>) {
    something.forEach { println(it) } // The items are typed as `Any?`
}
```

Similarly, when you already have the type arguments of an instance checked statically (at compile time), you can make an `is`-check or a cast that involves the non-generic part of the type. Note that angle brackets are omitted in this case:

```
fun handleStrings(list: MutableList<String>) {
    if (list is ArrayList) {
        // `list` is smart-cast to `ArrayList<String>`
    }
}
```

The same syntax but with the type arguments omitted can be used for casts that do not take type arguments into account: `list as ArrayList`.

The type arguments of generic function calls are also only checked at compile time. Inside the function bodies, the type parameters cannot be used for type checks, and type casts to type parameters (`foo as T`) are unchecked. The only exclusion is inline functions with reified type parameters, which have their actual type arguments inlined at each call site. This enables type checks and casts for the type parameters. However, the restrictions described above still apply for instances of generic types used inside checks or casts. For example, in the type check `arg is T`, if `arg` is an instance of a generic type itself, its type arguments are still erased.

```
inline fun <reified A, reified B> Pair<*, *>.asPairOf(): Pair<A, B>? {
    if (first !is A || second !is B) return null
    return first as A to second as B
}

val somePair: Pair<Any?, Any?> = "items" to listOf(1, 2, 3)

val stringToSomething = somePair.asPairOf<String, Any>()
val stringToInt = somePair.asPairOf<String, Int>()
val stringToList = somePair.asPairOf<String, List<*>>()
val stringToStringList = somePair.asPairOf<String, List<String>>() // Compiles but breaks type safety!
// Expand the sample for more details

fun main() {
    println("stringToSomething = " + stringToSomething)
    println("stringToInt = " + stringToInt)
    println("stringToList = " + stringToList)
    println("stringToStringList = " + stringToStringList)
    //println(stringToStringList?.second?.forEach() {it.length}) // This will throw ClassCastException
as list items are not String
}
```

Unchecked casts

Type casts to generic types with concrete type arguments such as `foo as List<String>` cannot be checked at runtime.
These unchecked casts can be used when type safety is implied by the high-level program logic but cannot be inferred directly by the compiler. See the example below.

```
fun readDictionary(file: File): Map<String, *> = file.inputStream().use {
    TODO("Read a mapping of strings to arbitrary elements.")
}

// We saved a map with `Int`s into this file
val intsFile = File("ints.dictionary")

// Warning: Unchecked cast: `Map<String, *>` to `Map<String, Int>`
val intsDictionary: Map<String, Int> = readDictionary(intsFile) as Map<String, Int>
```

A warning appears for the cast in the last line. The compiler can't fully check it at runtime and provides no guarantee that the values in the map are `Int`.

To avoid unchecked casts, you can redesign the program structure. In the example above, you could use the `DictionaryReader<T>` and `DictionaryWriter<T>` interfaces with type-safe implementations for different types. You can introduce reasonable abstractions to move unchecked casts from the call site to the implementation details. Proper use of generic variance can also help.

For generic functions, using reified type parameters makes casts like `arg as T` checked, unless `arg`'s type has *its own* type arguments that are erased.

An unchecked cast warning can be suppressed by annotating the statement or the declaration where it occurs with `@Suppress("UNCHECKED_CAST")`:

```
inline fun <reified T> List<*>.asListOfType(): List<T>? =
    if (all { it is T })
        @Suppress("UNCHECKED_CAST")
        this as List<T> else
        null
```

On the JVM: array types (`Array<Foo>`) retain information about the erased type of their elements, and type casts to an array type are partially checked: the nullability and actual type arguments of the element type are still erased. For example, the cast `foo as Array<List<String>?>` will succeed if `foo` is an array holding any `List<*>`, whether it is nullable or not.

Underscore operator for type arguments

The underscore operator `_` can be used for type arguments. Use it to automatically infer a type of the argument when other types are explicitly specified:

```
abstract class SomeClass<T> {
    abstract fun execute() : T
}

class SomeImplementation : SomeClass<String>() {
    override fun execute(): String = "Test"
}

class OtherImplementation : SomeClass<Int>() {
    override fun execute(): Int = 42
}

object Runner {
    inline fun <reified S: SomeClass<T>, T> run() : T {
        return S::class.java.getDeclaredConstructor().newInstance().execute()
    }
}

fun main() {
    // T is inferred as String because SomeImplementation derives from SomeClass<String>
    val s = Runner.run<SomeImplementation, _>()
    assert(s == "Test")

    // T is inferred as Int because OtherImplementation derives from SomeClass<Int>
    val n = Runner.run<OtherImplementation, _>()
    assert(n == 42)
}
```

Asynchronous programming techniques

For decades, as developers we are confronted with a problem to solve - how to prevent our applications from blocking. Whether we're developing desktop, mobile, or even backend applications, we want to avoid making the user wait or, even worse, create bottlenecks that prevent the application from scaling.

There have been many approaches to solving this problem, including:

- Threading
- Callbacks
- Futures, promises, and others
- Reactive Extensions
- Coroutines

Before explaining what coroutines are, let's briefly review some of the other solutions.

Threading

Threads are by far probably the most well-known approach to avoid applications from blocking.

```
fun postItem(item: Item) {
    val token = preparePost()
    val post = submitPost(token, item)
    processPost(post)
}

fun preparePost(): Token {
    // makes a request and consequently blocks the main thread
    return token
}
```

Let's assume in the code above that `preparePost` is a long-running process and consequently would block the user interface. What we can do is launch it in a separate thread. This would then allow us to avoid the UI from blocking. This is a very common technique, but has a series of drawbacks:

- Threads aren't cheap. Threads require context switches which are costly.
- Threads aren't infinite. The number of threads that can be launched is limited by the underlying operating system. In backend applications, this could cause a major bottleneck.
- Threads aren't always available. Some platforms, such as JavaScript, do not even support threads.
- Threads aren't easy. Debugging threads and avoiding race conditions are common problems we suffer in multithreaded programming.

Callbacks

With callbacks, the idea is to pass one function as a parameter to another function, and have this one invoked once the process has completed.

```
fun postItem(item: Item) {
    preparePostAsync { token →
        submitPostAsync(token, item) { post →
            processPost(post)
        }
    }
}

fun preparePostAsync(callback: (Token) → Unit) {
    // make request and return immediately
    // arrange callback to be invoked later
}
```

This in principle feels like a much more elegant solution, but once again has several issues:

- Difficulty of nested callbacks. Usually a function that is used as a callback, often ends up needing its own callback. This leads to a series of nested callbacks which lead to incomprehensible code. The pattern is often referred to as callback hell, or the pyramid of doom due to the triangular shape that indentations from these deeply nested callbacks create.
- Error handling is complicated. The nesting model makes error handling and propagation of these somewhat more complicated.

Callbacks are quite common in event-loop architectures such as JavaScript, but even there, generally people have moved away to using other approaches such as promises or reactive extensions.

Futures, promises, and others

The idea behind futures or promises (other terms may be used depending on the language or platform), is that when we make a call, we're *promised* that at some point the call will return a `Promise` object, which we can then operate on.

```
fun postItem(item: Item) {
    preparePostAsync()
        .thenCompose { token →
            submitPostAsync(token, item)
        }
        .thenAccept { post →
            processPost(post)
        }

}

fun preparePostAsync(): Promise<Token> {
    // makes request and returns a promise that is completed later
    return promise
}
```

This approach requires a series of changes in how we program, in particular:

- Different programming model. Similar to callbacks, the programming model moves away from a top-down imperative approach to a compositional model with chained calls. Traditional program structures such as loops, exception handling, etc. usually are no longer valid in this model.
- Different APIs. Usually there's a need to learn a completely new API such as `thenCompose` or `thenAccept`, which can also vary across platforms.
- Specific return type. The return type moves away from the actual data that we need and instead returns a new type `Promise` which has to be introspected.
- Error handling can be complicated. The propagation and chaining of errors aren't always straightforward.

Reactive extensions

Reactive Extensions (Rx) were introduced to C# by Erik Meijer. While it was definitely used on the .NET platform, it really didn't reach mainstream adoption until Netflix ported it over to Java, naming it RxJava. From then on, numerous ports have been provided for a variety of platforms including JavaScript (RxJS).

The idea behind Rx is to move towards what's called `observable streams` whereby we now think of data as streams (infinite amounts of data) and these streams can be observed. In practical terms, Rx is simply the Observer Pattern with a series of extensions which allow us to operate on the data.

In approach it's quite similar to Futures, but one can think of a Future as returning a discrete element, whereas Rx returns a stream. However, similar to the previous, it also introduces a complete new way of thinking about our programming model, famously phrased as

```
"everything is a stream, and it's observable"
```

This implies a different way to approach problems and quite a significant shift from what we're used to when writing synchronous code. One benefit as opposed to Futures is that given it's ported to so many platforms, generally we can find a consistent API experience no matter what we use, be it C#, Java, JavaScript, or any other language where Rx is available.

In addition, Rx does introduce a somewhat nicer approach to error handling.

Coroutines

Kotlin's approach to working with asynchronous code is using coroutines, which is the idea of suspendable computations, i.e. the idea that a function can suspend its execution at some point and resume later on.

However, one of the benefits of coroutines is that when it comes to the developer, writing non-blocking code is essentially the same as writing blocking code. The programming model itself doesn't really change.

Take for instance the following code:

```
fun postItem(item: Item) {
    launch {
        val token = preparePost()
        val post = submitPost(token, item)
        processPost(post)
    }
}

suspend fun preparePost(): Token {
    // makes a request and suspends the coroutine
    return suspendCoroutine { /* ... */ }
}
```

This code will launch a long-running operation without blocking the main thread. The `preparePost` is what's called a `suspendable function`, thus the keyword `suspend` prefixing it. What this means as stated above, is that the function will execute, pause execution and resume at some point in time.

- The function signature remains exactly the same. The only difference is `suspend` being added to it. The return type, however, is the type we want to be returned.
- The code is still written as if we were writing synchronous code, top-down, without the need of any special syntax, beyond the use of a function called `launch` which essentially kicks off the coroutine (covered in other tutorials).
- The programming model and APIs remain the same. We can continue to use loops, exception handling, etc. and there's no need to learn a complete set of new APIs.
- It is platform independent. Whether we're targeting JVM, JavaScript or any other platform, the code we write is the same. Under the covers, the compiler takes care of adapting it to each platform.

Coroutines are not a new concept, let alone invented by Kotlin. They've been around for decades and are popular in some other programming languages such as Go. What is important to note though is that the way they're implemented in Kotlin, most of the functionality is delegated to libraries. In fact, beyond the `suspend` keyword, no other keywords are added to the language. This is somewhat different from languages such as C# that have `async` and `await` as part of the syntax. With Kotlin, these are just library functions.

For more information, see the Coroutines reference.

Coroutines

Applications often need to perform multiple tasks at the same time, such as responding to user input, loading data, or updating the screen. To support this, they rely on concurrency, which allows operations to run independently without blocking each other.

The most common way to run tasks concurrently is by using threads, which are independent paths of execution managed by the operating system. However, threads are relatively heavy, and creating many of them can lead to performance issues.

To support efficient concurrency, Kotlin uses asynchronous programming built around *coroutines*, which let you write asynchronous code in a natural, sequential style using suspending functions. Coroutines are lightweight alternatives to threads. They can suspend without blocking system resources and are resource-friendly, making them better suited for fine-grained concurrency.

Most coroutine features are provided by the `kotlinx.coroutines` library, which includes tools for launching coroutines, handling concurrency, working with asynchronous streams, and more.

If you're new to coroutines in Kotlin, start with the Coroutine basics guide before diving into more complex topics. This guide introduces the key concepts of suspending functions, coroutine builders, and structured concurrency through simple examples:

Get started with coroutines

Check out the KotlinConf app for a sample project to see how coroutines are used in practice.

Coroutine concepts

The `kotlinx.coroutines` library provides the core building blocks for running tasks concurrently, structuring coroutine execution, and managing shared state.

Suspending functions and coroutine builders

Coroutines in Kotlin are built on suspending functions, which allow code to pause and resume without blocking a thread. The `suspend` keyword marks functions that can perform long-running operations asynchronously.

To launch new coroutines, use coroutine builders like `.launch()` and `.async()`. These builders are extension functions on `CoroutineScope`, which defines the coroutine's lifecycle and provides the coroutine context.

You can learn more about these builders in Coroutine basics and Composing suspend functions.

Coroutine context and behavior

Launching a coroutine from a `CoroutineScope` creates a context that governs its execution. Builder functions like `.launch()` and `.async()` automatically create a set of elements that define how the coroutine behaves:

- The `Job` interface tracks the coroutine's lifecycle and enables structured concurrency.
- `CoroutineDispatcher` controls where the coroutine runs, such as on a background thread or the main thread in UI applications.
- `CoroutineExceptionHandler` handles uncaught exceptions.

These, along with other possible elements, make up the *coroutine context*, which is inherited by default from the coroutine's parent. This context forms a hierarchy that enables structured concurrency, where related coroutines can be canceled together or handle exceptions as a group.

Asynchronous flow and shared mutable state

Kotlin provides several ways for coroutines to communicate. Use one of the following options based on how you want to share values between coroutines:

- `Flow` produces values only when a coroutine actively collects them.
- `Channel` allows multiple coroutines to send and receive values, with each value delivered to exactly one coroutine.
- `SharedFlow` continuously shares every value with all active collecting coroutines.

When multiple coroutines need to access or update the same data, they *share mutable state*. Without coordination, this can lead to race conditions, where operations interfere with each other in unpredictable ways. To safely manage shared mutable state, use `StateFlow` to wrap the shared data. Then, you can update it from one coroutine and collect its latest value from others.

For more information, see Flows, Channels, and the Coroutines and channels tutorial.

What's next

- Learn the fundamentals of coroutines, suspending functions, and builders in the Coroutine basics guide.
- Explore how to combine suspending functions and build coroutine pipelines in Composing suspending functions.
- Learn how to debug coroutines using built-in tools in IntelliJ IDEA.
- For flow-specific debugging, see the Debug Kotlin Flow using IntelliJ IDEA tutorial.
- Read the Guide to UI programming with coroutines to learn about coroutine-based UI development.
- Review best practices for using coroutines in Android.
- Check out the `kotlinx.coroutines` API reference.

Reflection

Reflection is a set of language and library features that allows you to introspect the structure of your program at runtime. Functions and properties are first-class citizens in Kotlin, and the ability to introspect them (for example, learning the name or the type of a property or function at runtime) is essential when using a functional or reactive style.

Kotlin/JS provides limited support for reflection features. Learn more about reflection in Kotlin/JS.

JVM dependency

On the JVM platform, the Kotlin compiler distribution includes the runtime component required for using the reflection features as a separate artifact, `kotlin-reflect.jar`. This is done to reduce the required size of the runtime library for applications that do not use reflection features.

To use reflection in a Gradle or Maven project, add the dependency on `kotlin-reflect`:

- In Gradle:

Kotlin

```
dependencies {
    implementation(kotlin("reflect"))
}
```

Groovy

```
dependencies {
    implementation "org.jetbrains.kotlin:kotlin-reflect:2.4.20"
}
```

- In Maven:

```
<dependencies>
    <dependency>
        <groupId>org.jetbrains.kotlin</groupId>
        <artifactId>kotlin-reflect</artifactId>
    </dependency>
</dependencies>
```

If you don't use Gradle or Maven, make sure you have `kotlin-reflect.jar` in the classpath of your project. In other supported cases (IntelliJ IDEA projects that use the command-line compiler), it is added by default. In the command-line compiler, you can use the `-no-reflect` compiler option to exclude `kotlin-reflect.jar` from the classpath.

Class references

The most basic reflection feature is getting the runtime reference to a Kotlin class. To obtain the reference to a statically known Kotlin class, you can use the *class literal* syntax:

```
val c = MyClass::class
```

The reference is a KClass type value.

> On JVM: a Kotlin class reference is not the same as a Java class reference. To obtain a Java class reference, use the `.java` property on a `KClass` instance.

Bound class references

You can get the reference to the class of a specific object with the same `::class` syntax by using the object as a receiver:

```
val widget: Widget = ...
assert(widget is GoodWidget) { "Bad widget: ${widget::class.qualifiedName}" }
```

You will obtain the reference to the exact class of an object, for example, `GoodWidget` or `BadWidget`, regardless of the type of the receiver expression (`Widget`).

Callable references

References to functions, properties, and constructors can also be called or used as instances of function types.

The common supertype for all callable references is `KCallable<out R>`, where `R` is the return value type. It is the property type for properties, and the constructed type for constructors.

Function references

When you have a named function declared as below, you can call it directly (`isOdd(5)`):

```
fun isOdd(x: Int) = x % 2 != 0
```

Alternatively, you can use the function as a function type value, that is, pass it to another function. To do so, use the `::` operator:

```
fun isOdd(x: Int) = x % 2 != 0

fun main() {
    val numbers = listOf(1, 2, 3)
    println(numbers.filter(::isOdd))
}
```

Here `::isOdd` is a value of function type `(Int) -> Boolean`.

Function references belong to one of the `KFunction<out R>` subtypes, depending on the parameter count. For instance, `KFunction3<T1, T2, T3, R>`.

`::` can be used with overloaded functions when the expected type is known from the context. For example:

```
fun main() {
    fun isOdd(x: Int) = x % 2 != 0
    fun isOdd(s: String) = s == "brillig" || s == "slithy" || s == "tove"

    val numbers = listOf(1, 2, 3)
    println(numbers.filter(::isOdd)) // refers to isOdd(x: Int)
}
```

Alternatively, you can provide the necessary context by storing the method reference in a variable with an explicitly specified type:

```
val predicate: (String) -> Boolean = ::isOdd   // refers to isOdd(x: String)
```

If you need to use a member of a class or an extension function, it needs to be qualified: `String::toCharArray`.

Even if you initialize a variable with a reference to an extension function, the inferred function type will have no receiver, but it will have an additional parameter accepting a receiver object. To have a function type with a receiver instead, specify the type explicitly:

```
val isEmptyStringList: List<String>.() -> Boolean = List<String>::isEmpty
```

Example: function composition

Consider the following function:

```
fun <A, B, C> compose(f: (B) -> C, g: (A) -> B): (A) -> C {
    return { x -> f(g(x)) }
}
```

It returns a composition of two functions passed to it: `compose(f, g) = f(g(*))`. You can apply this function to callable references:

```
fun <A, B, C> compose(f: (B) -> C, g: (A) -> B): (A) -> C {
    return { x -> f(g(x)) }
}

fun isOdd(x: Int) = x % 2 != 0

fun main() {
    fun length(s: String) = s.length

    val oddLength = compose(::isOdd, ::length)
    val strings = listOf("a", "ab", "abc")

    println(strings.filter(oddLength))
}
```

Property references

To access properties as first-class objects in Kotlin, use the `::` operator:

```
val x = 1

fun main() {
    println(::x.get())
    println(::x.name)
}
```

The expression `::x` evaluates to a `KProperty0<Int>` type property object. You can read its value using `get()` or retrieve the property name using the `name` property. For more information, see the docs on the `KProperty` class.

For a mutable property such as `var y = 1`, `::y` returns a value with the `KMutableProperty0<Int>` type which has a `set()` method:

```
var y = 1

fun main() {
    ::y.set(2)
    println(y)
}
```

A property reference can be used where a function with a single generic parameter is expected:

```
fun main() {
    val strs = listOf("a", "bc", "def")
    println(strs.map(String::length))
}
```

To access a property that is a member of a class, qualify it as follows:

```
fun main() {
    class A(val p: Int)
    val prop = A::p
    println(prop.get(A(1)))
}
```

For an extension property:

```
val String.lastChar: Char
    get() = this[length - 1]

fun main() {
    println(String::lastChar.get("abc"))
}
```

Interoperability with Java reflection

On the JVM platform, the standard library contains extensions for reflection classes that provide a mapping to and from Java reflection objects (see package `kotlin.reflect.jvm`). For example, to find a backing field or a Java method that serves as a getter for a Kotlin property, you can write something like this:

```
import kotlin.reflect.jvm.*

class A(val p: Int)

fun main() {
    println(A::p.javaGetter) // prints "public final int A.getP()"
    println(A::p.javaField)  // prints "private final int A.p"
}
```

To get the Kotlin class that corresponds to a Java class, use the `.kotlin` extension property:

```
fun getKClass(o: Any): KClass<Any> = o.javaClass.kotlin
```

Constructor references

Constructors can be referenced just like methods and properties. You can use them wherever the program expects a function type object that takes the same parameters as the constructor and returns an object of the appropriate type. Constructors are referenced by using the `::` operator and adding the class name. Consider the following function that expects a function parameter with no parameters and return type `Foo`:

```
class Foo

fun function(factory: () -> Foo) {
    val x: Foo = factory()
}
```

Using `::Foo`, the zero-argument constructor of the class `Foo`, you can call it like this:

```
function(::Foo)
```

Callable references to constructors are typed as one of the `KFunction<out R>` subtypes depending on the parameter count.

Bound function and property references

You can refer to an instance method of a particular object:

```
fun main() {
    val numberRegex = "\\d+".toRegex()
    println(numberRegex.matches("29"))

    val isNumber = numberRegex::matches
    println(isNumber("29"))
}
```

Instead of calling the method `matches` directly, the example uses a reference to it. Such a reference is bound to its receiver. It can be called directly (like in the example above) or used whenever a function type expression is expected:

```
fun main() {
    val numberRegex = "\\d+".toRegex()
    val strings = listOf("abc", "124", "a70")
    println(strings.filter(numberRegex::matches))
}
```

Compare the types of the bound and the unbound references. The bound callable reference has its receiver "attached" to it, so the type of the receiver is no longer a parameter:

```
val isNumber: (CharSequence) -> Boolean = numberRegex::matches

val matches: (Regex, CharSequence) -> Boolean = Regex::matches
```

A property reference can be bound as well:

```
fun main() {
    val prop = "abc"::length
    println(prop.get())
}
```

You don't need to specify `this` as the receiver: `this::foo` and `::foo` are equivalent.

Bound constructor references

A bound callable reference to a constructor of an inner class can be obtained by providing an instance of the outer class:

```
class Outer {
    inner class Inner
}

val o = Outer()
val boundInnerCtor = o::Inner
```

Destructuring declarations

Sometimes it is convenient to *destructure* an object into a number of variables, for example:

```
val (name, age) = person
```

This syntax is called a *destructuring declaration*. A destructuring declaration creates multiple variables at once. You have declared two new variables: `name` and `age`, and can use them independently:

```
println(name)
println(age)
```

A destructuring declaration is compiled down to the following code:

```
val name = person.component1()
val age = person.component2()
```

The `component1()` and `component2()` functions are another example of the *principle of conventions* widely used in Kotlin (see operators like `+` and `*`, `for`-loops as an example). Anything can be on the right-hand side of a destructuring declaration, as long as the required number of component functions can be called on it. And, of course, there can be `component3()` and `component4()` and so on.

> The `componentN()` functions need to be marked with the `operator` keyword to allow using them in a destructuring declaration.

Destructuring declarations also work in `for`-loops:

```
for ((a, b) in collection) { ... }
```

Variables `a` and `b` get the values returned by `component1()` and `component2()` called on elements of the collection.

Example: returning two values from a function

Assume that you need to return two things from a function - for example, a result object and a status of some sort. A compact way of doing this in Kotlin is to declare a data class and return its instance:

```
data class Result(val result: Int, val status: Status)
fun function(...): Result {
    // computations

    return Result(result, status)
}

// Now, to use this function:
val (result, status) = function(...)
```

Since data classes automatically declare `componentN()` functions, destructuring declarations work here.

> You could also use the standard class `Pair` and have `function()` return `Pair<Int, Status>`, but it's often better to have your data named properly.

Example: destructuring declarations and maps

Probably the nicest way to traverse a map is this:

```
for ((key, value) in map) {
    // do something with the key and the value
}
```

To make this work, you should

- Present the map as a sequence of values by providing an `iterator()` function.
- Present each of the elements as a pair by providing functions `component1()` and `component2()`.

And indeed, the standard library provides such extensions:

```
operator fun <K, V> Map<K, V>.iterator(): Iterator<Map.Entry<K, V>> = entrySet().iterator()
operator fun <K, V> Map.Entry<K, V>.component1() = getKey()
operator fun <K, V> Map.Entry<K, V>.component2() = getValue()
```

So you can freely use destructuring declarations in `for`-loops with maps (as well as collections of data class instances or similar).

Underscore for unused variables

If you don't need a variable in the destructuring declaration, you can place an underscore instead of its name:

```
val (_, status) = getResult()
```

The `componentN()` operator functions are not called for the components that are skipped in this way.

Destructuring in lambdas

You can use the destructuring declarations syntax for lambda parameters. If a lambda has a parameter of the `Pair` type (or `Map.Entry`, or any other type that has the appropriate `componentN` functions), you can introduce several new parameters instead of one by putting them in parentheses:

```
map.mapValues { entry -> "${entry.value}!" }
map.mapValues { (key, value) -> "$value!" }
```

Note the difference between declaring two parameters and declaring a destructuring pair instead of a parameter:

```
{ a -> ... } // one parameter
{ a, b -> ... } // two parameters
{ (a, b) -> ... } // a destructured pair
{ (a, b), c -> ... } // a destructured pair and another parameter
```

If a component of the destructured parameter is unused, you can replace it with the underscore to avoid inventing its name:

```
map.mapValues { (_, value) -> "$value!" }
```

You can specify the type for the whole destructured parameter or for a specific component separately:

```
map.mapValues { (_, value): Map.Entry<Int, String> -> "$value!" }

map.mapValues { (_, value: String) -> "$value!" }
```

Experimental

Name-based destructuring

Kotlin supports *name-based destructuring declarations*, where variables match properties by name instead of the position defined by `componentN()` functions in *position-based* destructuring.

> For more information about name-based destructuring, see the feature's KEEP.

In position-based destructuring, variables correspond to the order of `componentN()` functions, for example:

```
data class User(val username: String, val email: String)

fun main() {
    val user = User("alice", "alice@example.com")

    val (email, username) = user

    println(email)
    // alice

    println(username)
    // alice@example.com
}
```

In this example, because destructuring relies on the order of `componentN()` functions, `email` receives the value of `username`, and `username` receives the value of `email`.

With name-based destructuring, property names determine which values are extracted rather than the position of `componentN()` functions:

```
fun main() {
    val user = User("alice", "alice@example.com")

    // Uses name-based destructuring with explicit form
    (val mail = email, val name = username) = user

    println(name)
    // alice

    println(mail)
    // alice@example.com
}
```

Name-based destructuring is Experimental. When you enable this feature, it also introduces a new syntax for position-based destructuring using square brackets. Use this syntax for types where the order of elements matters, such as lists and other ordered collections, as well as unnamed tuples like `Pair` or `Triple`:

```
val point = Pair(10, 20)

// Uses position-based destructuring
val [x, y] = point
```

You can control how the compiler interprets destructuring declarations with the `-Xname-based-destructuring` compiler option.

It has the following modes:

- `only-syntax` enables the explicit form of name-based destructuring without changing the behavior of existing destructuring declarations.
- `name-mismatch` reports warnings when position-based destructuring in data classes uses variable names that don't match the property names.
- `complete` enables short-form name-based destructuring with parentheses and continues supporting position-based destructuring with square bracket syntax.

> Before enabling `complete` mode, review and resolve the warnings reported in `name-mismatch` mode. These warnings show which destructuring declarations the compiler interprets differently in `complete` mode and include suggestions for rewriting those declarations accordingly.

If you use `complete` mode, the short-form destructuring syntax with parentheses matches variables to property names instead of relying on position:

```
val (email, username) = user
```

To enable name-based destructuring in your project, add the compiler option to your build configuration file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xname-based-destructuring=only-syntax")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-Xname-based-destructuring=only-syntax</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

Backend development with Kotlin

Kotlin is a great fit for developing server-side applications. With Kotlin, you can write concise and expressive code while maintaining full compatibility with existing Java-based technology stacks.

Get started

Kotlin supports gradual migration of large codebases from Java to Kotlin. You can start writing tests or new production code in Kotlin while keeping other parts of your project in Java.

Configure your Java project to work with Kotlin and make use of the automated Java-to-Kotlin converter included in IntelliJ IDEA:

Introduce Kotlin to your Java project

Explore frameworks

Kotlin is fully compatible with all Java-based frameworks, so you can use your familiar technology stack while benefiting from Kotlin syntax. In addition to great IDE support, Kotlin offers framework-specific tooling, such as support for Spring and Ktor in IntelliJ IDEA with an Ultimate subscription.

Spring

Spring makes use of Kotlin's language features to offer more concise APIs. The online project generator allows you to quickly generate a new project in Kotlin.

Get started with Spring Boot and Kotlin

Ktor

Ktor is a JetBrains framework for creating web applications in Kotlin. It uses coroutines for high scalability and offers an easy-to-use idiomatic API.

Create a new Ktor project

Other frameworks

Here are some other examples of the backend frameworks for Kotlin:

Framework	Description
Quarkus	An open-sourced framework that provides first-class support for Kotlin. Quarkus was built from the ground up for Kubernetes and provides a cohesive full-stack framework by leveraging a growing list of hundreds of best-of-breed libraries.
Vert.x	A framework for building reactive web applications on the JVM. Vert.x offers dedicated support for Kotlin, including integration of Kotlin coroutines.
kotlinx.html	A DSL that can be used to build HTML in web applications. It serves as an alternative to traditional templating systems such as JSP and FreeMarker.
Micronaut	A modern JVM-based full-stack framework for building modular, easily testable microservices and serverless applications. Watch a webinar Micronaut for microservices with Kotlin and explore a detailed guide showing how you can use Kotlin extension functions in the Micronaut framework.

Framework	Description
http4k	A functional toolkit with a small footprint for Kotlin HTTP applications, written in pure Kotlin. http4k provides the CLI-enabled toolbox to generate fully formed project templates, and a web-based project wizard to bootstrap a working http4k application with selected backend, modules, and build tooling.
Javalin	A very lightweight web framework for Kotlin and Java which supports WebSockets, HTTP2, and async requests.

Deploy your applications

Kotlin applications can be deployed to any host that supports Java web applications, including Amazon Web Services (AWS), Google Cloud Platform (GCP), and many others.

- **AWS** provides a dedicated SDK for Kotlin to interact with its services. For serverless deployments, you can refer to AWS Lambda code examples for Kotlin.
- **Ktor** allows you to publish Kotlin applications to various cloud providers. For instance, you can follow Ktor tutorials to learn more about deploying to Google App Engine and other services.
- **Spring** applications are also compatible with most popular cloud providers. See how to deploy Spring Boot applications to the cloud in the official Spring documentation.

Join the community

- **Kotlin slack**: get an invitation and join the #spring and #server channels
- **Stack Overflow**: subscribe to the "kotlin", "spring-kotlin", or "ktor" tags
- **Kotlin YouTube channel**: subscribe and watch videos about Kotlin with Spring

Next steps

- Learn how to test your Java Maven project with Kotlin and JUnit
- Explore how to build asynchronous server applications with Ktor

Adding Kotlin to a Java project – tutorial

Kotlin is fully interoperable with Java, so you can gradually introduce it into your existing Java projects without having to rewrite everything.

In this tutorial, you'll learn how to:

- Set up Maven or Gradle build tools to compile both Java and Kotlin code.
- Organize Java and Kotlin source files in your project directories.
- Convert Java files to Kotlin using IntelliJ IDEA.

You can use any existing Java project for this tutorial or clone our public sample project with both Maven and Gradle build files already set up.

You can also hand over the conversion to your AI agent of choice using our prepared skill. Keep in mind that AI processing results are not entirely predictable.

Project configuration

To add Kotlin to a Java project, you need to configure the project to use both Kotlin and Java, depending on the build tool you use.

The project configuration ensures that both Kotlin and Java code are compiled properly and can reference each other seamlessly.

Maven

Starting with **IntelliJ IDEA 2025.3**, when you add your first Kotlin file to a Maven-based Java project, the IDE automatically updates your `pom.xml` file to include the Kotlin Maven plugin and standard dependencies.
You can still configure it manually if you want to customize versions or build phases.

To use Kotlin and Java together in a Maven project, apply the Kotlin Maven plugin and add Kotlin dependencies in your `pom.xml` file:

1. In the `<properties>` section, add the Kotlin version property:

```
<properties>
        <kotlin.version>2.4.20</kotlin.version>
    </properties>
```

2. In the `<dependencies>` section, add the required dependencies to the `<plugins>` section:

```
<dependencies>
        <!-- Add JUnit Jupiter engine for test runtime -->
        <dependency>
            <groupId>org.junit.jupiter</groupId>
            <artifactId>junit-jupiter-engine</artifactId>
            <scope>test</scope>
        </dependency>
        <dependency>
            <groupId>org.junit.jupiter</groupId>
            <artifactId>junit-jupiter-params</artifactId>
            <scope>test</scope>
        </dependency>
    </dependencies>
```

3. In the `<build><plugins>` section, add the Kotlin plugin:

```
<build>
        <pluginManagement><!-- Lock down plugin versions to avoid using Maven defaults (can be
moved to a parent pom file) -->
                <!-- No maven-compiler-plugin needed with Kotlin extensions -->
            </plugins>
            <!-- Activate Kotlin Maven plugin for main and test sources -->
            <plugin>
                <groupId>org.jetbrains.kotlin</groupId>
                <artifactId>kotlin-maven-plugin</artifactId>
                <version>${kotlin.version}</version>
                <extensions>true</extensions>
            </plugin>
        </plugins>
    </build>
```

Enabling `<extensions>true</extensions>` in the Kotlin Maven plugin helps to:

- Automatically add the `kotlin-stdlib` dependency to the project.
- Configure execution phases to compile Kotlin first, then Java.
- Reference Kotlin code in Java code and vice versa.
- Automatically align the JVM target version with the Java compiler version.

You don't need a separate `maven-compiler-plugin` in the `<build><pluginManagement>` section when using the Kotlin Maven plugin with extensions.

4. Reload the Maven project in your IDE.
5. Run tests to verify the configuration:

```
./mvnw clean test
```

Gradle

To use Kotlin and Java together in a Gradle project, apply the Kotlin JVM plugin and add Kotlin dependencies in your `build.gradle.kts` file:

1. In the `plugins {}` block, add the Kotlin JVM plugin:

```
plugins {
    // Other plugins
    kotlin("jvm") version "2.4.20"
}
```

2. Set the JVM toolchain version to match your Java version:

```
kotlin {
    jvmToolchain(17)
}
```

This ensures Kotlin uses the same JDK version as your Java code.

3. In the `dependencies {}` block, add the `kotlin("test")` library that provides Kotlin test utilities and integrates with JUnit:

```
dependencies {
    // Other dependencies

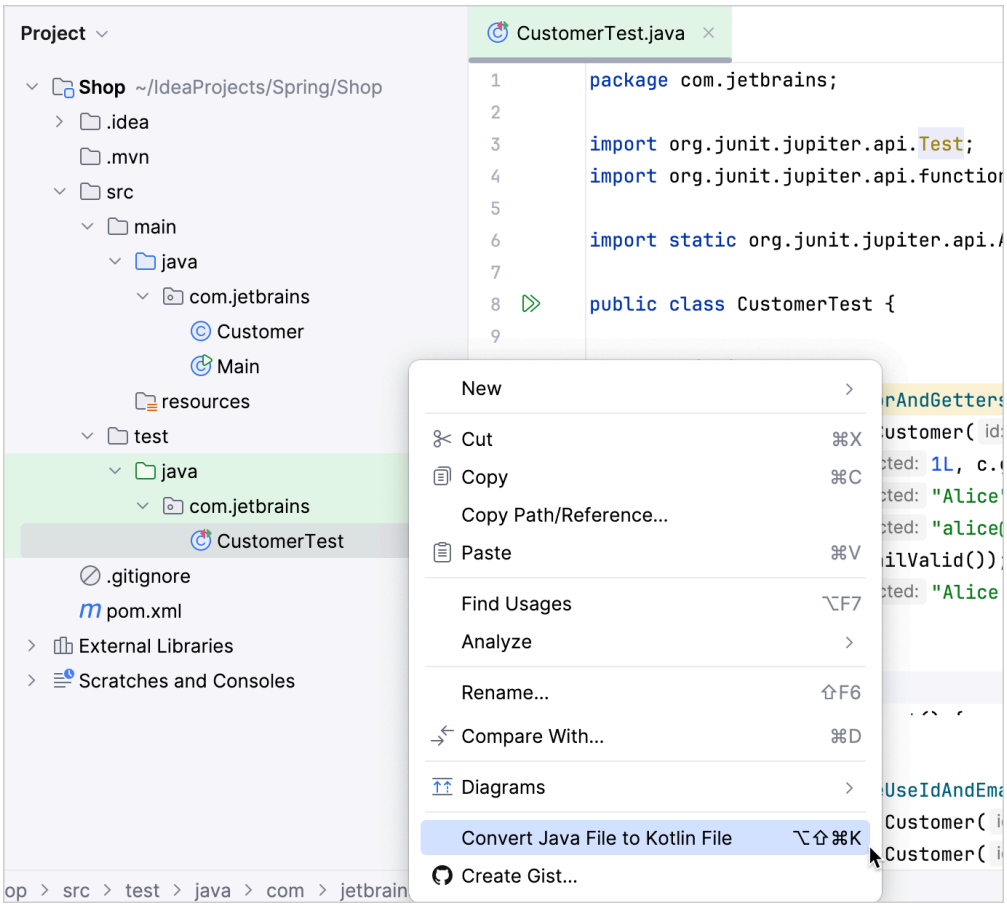
    testImplementation(kotlin("test"))
    // Other test dependencies
}
```

4. Reload the Gradle project in your IDE.
5. Run your tests to verify the configuration:

```
./gradlew clean test
```

Project structure

With this configuration, you can mix Java and Kotlin files in the same source directories:



```
src/
  ├── main/
  │    ├── java/          # Java and Kotlin production code
  │    └── kotlin/        # Additional Kotlin production code (optional)
  └── test/
       ├── java/          # Java and Kotlin test code
       └── kotlin/        # Additional Kotlin test code (optional)
```

You can create these directories manually or let IntelliJ IDEA create them when you add your first Kotlin file.

The Kotlin plugin automatically recognizes both `src/main/java` and `src/test/java` directories, so you can keep `.kt` and `.java` files in the same directories.

Convert Java files to Kotlin

The Kotlin plugin also bundles a Java to Kotlin converter (*J2K*) that automatically converts Java files to Kotlin. To use J2K on a file, click **Convert Java File to Kotlin File** in its context menu or in the **Code** menu of IntelliJ IDEA.

Convert Java to Kotlin

While the converter is not fool-proof, it does a pretty decent job of converting most boilerplate code from Java to Kotlin. However, some manual tweaking is sometimes required.

Explore compiler plugins

If you have a more complex project that uses Spring or Java Persistence API (JPA), you can use Kotlin compiler plugins that automatically adapt Kotlin's language features to framework expectations, reducing boilerplate:

- The `all-open` plugin automatically makes classes and their members `open` when used with specific annotations. This is particularly useful for frameworks like Spring that require classes to be non-final.

  For Spring, you can use a dedicated `kotlin-spring` plugin, which is a wrapper on top of `all-open`. It specifies Spring annotations automatically.

- The `no-arg` plugin generates an additional zero-argument constructor for classes with specific annotations. This allows JPA to instantiate classes that otherwise wouldn't have a default constructor.

  You can also use the `kotlin-jpa` plugin, which is a wrapper on top of `no-arg`. It specifies no-arg annotations automatically.

- The `power-assert` plugin improves the debugging experience by providing detailed failure messages with contextual information for assertions. It shows intermediate values and helps you understand why a test failed.

Next step

The easiest way to start using Kotlin in a Java project is by adding Kotlin tests first:

Add your first Kotlin test to your Java project

Test Java code using Kotlin and JUnit – tutorial

Kotlin is fully interoperable with Java, which means you can write tests for Java code using Kotlin and run them together with your existing Java tests in the same project.

In this tutorial, you'll learn how to:

- Configure a mixed Java–Kotlin project to run tests using JUnit.
- Add Kotlin tests that verify Java code.
- Run tests using Maven or Gradle.

Before you start, make sure you have:

- IntelliJ IDEA or VS Code with the installed Kotlin extension.
- Java 17 or later.

Configure the project

1. In your IDE, clone the sample project from version control:

   ```
   https://github.com/kotlin-hands-on/kotlin-junit-sample.git
   ```

2. Navigate to the `initial` module and review the project structure:

   ```
   kotlin-junit-sample/
   ├── initial/
   │   ├── src/
   │   │   ├── main/java/    # Java source code
   │   │   └── test/java/    # JUnit test in Java
   │   ├── pom.xml           # Maven configuration
   │   └── build.gradle.kts  # Gradle configuration
   ```

   The `initial` module contains a simple Todo application in Java with a single test.

3. In the same directory, open your build file and update its contents to support Kotlin:

Maven

```
<?xml version="1.0" encoding="UTF-8"?>
<project xmlns="http://maven.apache.org/POM/4.0.0" xmlns:xsi="http://www.w3.org/2001/XMLSchema-
instance"
         xsi:schemaLocation="http://maven.apache.org/POM/4.0.0 http://maven.apache.org/xsd/maven-
4.0.0.xsd">
    <modelVersion>4.0.0</modelVersion>

    <groupId>org.jetbrains.kotlin</groupId>
    <artifactId>kotlin-junit-complete</artifactId>
    <version>1.0-SNAPSHOT</version>

    <name>kotlin-junit-complete</name>
    <url>https://kotlinlang.org/docs/jvm-test-using-junit.htm</url>

    <properties>
        <project.build.sourceEncoding>UTF-8</project.build.sourceEncoding>
        <maven.compiler.release>17</maven.compiler.release>
        <jexer.version>1.6.0</jexer.version>
        <kotlin.version>2.4.20</kotlin.version>
    </properties>

    <dependencyManagement>
        <dependencies>
            <dependency>
                <groupId>org.junit</groupId>
                <artifactId>junit-bom</artifactId>
                <version>6.0.3</version>
                <type>pom</type>
                <scope>import</scope>
            </dependency>
        </dependencies>
    </dependencyManagement>

    <dependencies>
        <dependency>
            <groupId>org.junit.jupiter</groupId>
            <artifactId>junit-jupiter-api</artifactId>
            <scope>test</scope>
        </dependency>
        <!-- Add JUnit Jupiter engine for test runtime -->
        <dependency>
            <groupId>org.junit.jupiter</groupId>
            <artifactId>junit-jupiter-engine</artifactId>
            <scope>test</scope>
        </dependency>
        <!-- Optionally: parameterized tests support -->
        <dependency>
            <groupId>org.junit.jupiter</groupId>
            <artifactId>junit-jupiter-params</artifactId>
            <scope>test</scope>
        </dependency>
        <dependency>
            <groupId>com.gitlab.klamonte</groupId>
            <artifactId>jexer</artifactId>
            <version>${jexer.version}</version>
        </dependency>
    </dependencies>

    <build>
        <pluginManagement><!-- Lock down plugin versions to avoid using Maven defaults (can be
```

```
moved to a parent pom file) -->
            <plugins>
                <!-- Clean lifecycle, see https://maven.apache.org/ref/current/maven-
core/lifecycles.html#clean_Lifecycle -->
                <plugin>
                    <artifactId>maven-clean-plugin</artifactId>
                    <version>3.4.0</version>
                </plugin>
                <!-- Default lifecycle, jar packaging: see
https://maven.apache.org/ref/current/maven-core/default-
bindings.html#Plugin_bindings_for_jar_packaging -->
                <plugin>
                    <artifactId>maven-resources-plugin</artifactId>
                    <version>3.3.1</version>
                </plugin>
                <plugin>
                    <artifactId>maven-surefire-plugin</artifactId>
                    <version>3.3.0</version>
                </plugin>
                <plugin>
                    <artifactId>maven-jar-plugin</artifactId>
                    <version>3.4.2</version>
                </plugin>
                <plugin>
                    <artifactId>maven-install-plugin</artifactId>
                    <version>3.1.2</version>
                </plugin>
                <plugin>
                    <artifactId>maven-deploy-plugin</artifactId>
                    <version>3.1.2</version>
                </plugin>
                <!-- Site lifecycle, see https://maven.apache.org/ref/current/maven-
core/lifecycles.html#site_Lifecycle -->
                <plugin>
                    <artifactId>maven-site-plugin</artifactId>
                    <version>3.12.1</version>
                </plugin>
                <plugin>
                    <artifactId>maven-project-info-reports-plugin</artifactId>
                    <version>3.6.1</version>
                </plugin>
                <!-- No maven-compiler-plugin needed with Kotlin extensions -->
            </plugins>
        </pluginManagement>
        <plugins>
            <!-- Activate Kotlin Maven plugin for main and test sources -->
            <plugin>
                <groupId>org.jetbrains.kotlin</groupId>
                <artifactId>kotlin-maven-plugin</artifactId>
                <version>${kotlin.version}</version>
                <extensions>true</extensions>
            </plugin>
        </plugins>
    </build>
</project>
```

- In the `<properties>` section, set the Kotlin version.
- In the `<dependencies>` section, add JUnit Jupiter dependencies to run tests.
- In the `<build><plugins>` section, apply `kotlin-maven-plugin` with `<extensions>` set to `true`. It automatically adds corresponding executions and the `kotlin-stdlib` dependency to the build.

- You don't need to add `maven-compiler-plugin` to the `<build><pluginManagement>` section when using the Kotlin Maven plugin with extensions.

Gradle

```
// build.gradle.kts
group = "org.jetbrains.kotlin"
version = "1.0-SNAPSHOT"
description = "kotlin-junit-complete"
java.sourceCompatibility = JavaVersion.VERSION_17

plugins {
    application
    kotlin("jvm") version "2.4.20"
}

kotlin {
    jvmToolchain(17)
}

application {
    mainClass.set("org.jetbrains.kotlin.junit.App")
}

repositories {
    mavenCentral()
}

dependencies {
    implementation("com.gitlab.klamonte:jexer:1.6.0")

    testImplementation(kotlin("test"))
    testImplementation(libs.org.junit.jupiter.junit.jupiter.api)
    testImplementation(libs.org.junit.jupiter.junit.jupiter.params)
    testRuntimeOnly(libs.org.junit.jupiter.junit.jupiter.engine)
    testRuntimeOnly(libs.org.junit.platform.junit.platform.launcher)
}

tasks.test {
    useJUnitPlatform()
}
```

- In the `plugins {}` block, add the `kotlin("jvm")` plugin.
- Set the JVM toolchain version to match your Java version.
- In the `dependencies {}` block, add the `kotlin.test` library that provides Kotlin's test utilities and integrates with JUnit.

Kotlin/JVM supports the latest stable JUnit version, JUnit 6. You can find it in the `gradle/libs.versions.toml` version catalog.

If you generally prefer using the version catalog, you can even add the `kotlin("jvm")` plugin there:

```
# gradle/libs.versions.toml
[versions]
kotlin = "2.4.20"
junit = "6.0.3"

[libraries]
org-junit-jupiter-junit-jupiter-api = { module = "org.junit.jupiter:junit-jupiter-api", version.ref
= "junit" }
org-junit-jupiter-junit-jupiter-params = { module = "org.junit.jupiter:junit-jupiter-params",
version.ref = "junit" }
org-junit-jupiter-junit-jupiter-engine = { module = "org.junit.jupiter:junit-jupiter-engine",
version.ref = "junit" }
org-junit-platform-junit-platform-launcher = { module = "org.junit.platform:junit-platform-
launcher" }

[plugins]
kotlinJvm = { id = "org.jetbrains.kotlin.jvm", version.ref = "kotlin" }
```

4. Reload the build file in your IDE.

For more detailed instructions on build file setup, see Project configuration.

Add your first Kotlin test

The `TodoItemTest.java` test in `initial/src/test/java` already verifies the app basics: item creation, defaults, unique IDs, and state changes.

You can expand the test coverage by adding a Kotlin test that verifies repository-level behavior:

1. Navigate to the same test source directory, `initial/src/test/java`.
2. Create a `TodoRepositoryTest.kt` file in the same package as the Java test.
3. Create the test class with field declarations and setup function:

```
package org.jetbrains.kotlin.junit

import org.junit.jupiter.api.BeforeEach
import org.junit.jupiter.api.Assertions
import org.junit.jupiter.api.Test
import org.junit.jupiter.api.DisplayName

internal class TodoRepositoryTest {
    lateinit var repository: TodoRepository
    lateinit var testItem1: TodoItem
    lateinit var testItem2: TodoItem

    @BeforeEach
    fun setUp() {
        repository = TodoRepository()
        testItem1 = TodoItem("Task 1", "Description 1")
        testItem2 = TodoItem("Task 2", "Description 2")
    }
}
```

- JUnit annotations work the same in Kotlin as in Java.
- In Kotlin, the `lateinit` keyword allows declaring non-null properties that are initialized later. This helps to avoid having to use nullable types (`TodoRepository?`) in your tests.

4. Add a test inside the `TodoRepositoryTest` class to check the initial repository state and its size:

```
@Test
@DisplayName("Should start with empty repository")
fun shouldStartEmpty() {
    Assertions.assertEquals(0, repository.size())
    Assertions.assertTrue(repository.all.isEmpty())
}
```

- Unlike Java static import, Jupiter's `Assertions` is imported as a class and used as a qualifier for assertion functions.
- Instead of `.getAll()` calls, you can access Java getters as properties in Kotlin with `repository.all`.

5. Write another test to verify copy behavior for all items:

```
@Test
@DisplayName("Should return defensive copy of items")
fun shouldReturnDefensiveCopy() {
    repository.add(testItem1)

    val items1 = repository.all
    val items2 = repository.all

    Assertions.assertNotSame(items1, items2)
    Assertions.assertThrows(
        UnsupportedOperationException::class.java
    ) { items1.clear() }
    Assertions.assertEquals(1, repository.size())
}
```

- To get a Java class object from a Kotlin class, use `::class.java`.
- You can split complex assertions across multiple lines without using any special continuation characters.

6. Add a test to verify finding items by ID:

```
@Test
@DisplayName("Should find item by ID")
fun shouldFindItemById() {
    repository.add(testItem1)
    repository.add(testItem2)

     val found = repository.getById(testItem1.id())

     Assertions.assertTrue(found.isPresent)
     Assertions.assertEquals(testItem1, found.get())
}
```

Kotlin works smoothly with the Java `Optional` API. It automatically converts getter methods to properties, that's why the `isPresent()` method is accessed here as a property.

7. Write a test to verify the item removal mechanism:

```kotlin
@Test
 @DisplayName("Should remove item by ID")
 fun shouldRemoveItemById() {
     repository.add(testItem1)
     repository.add(testItem2)

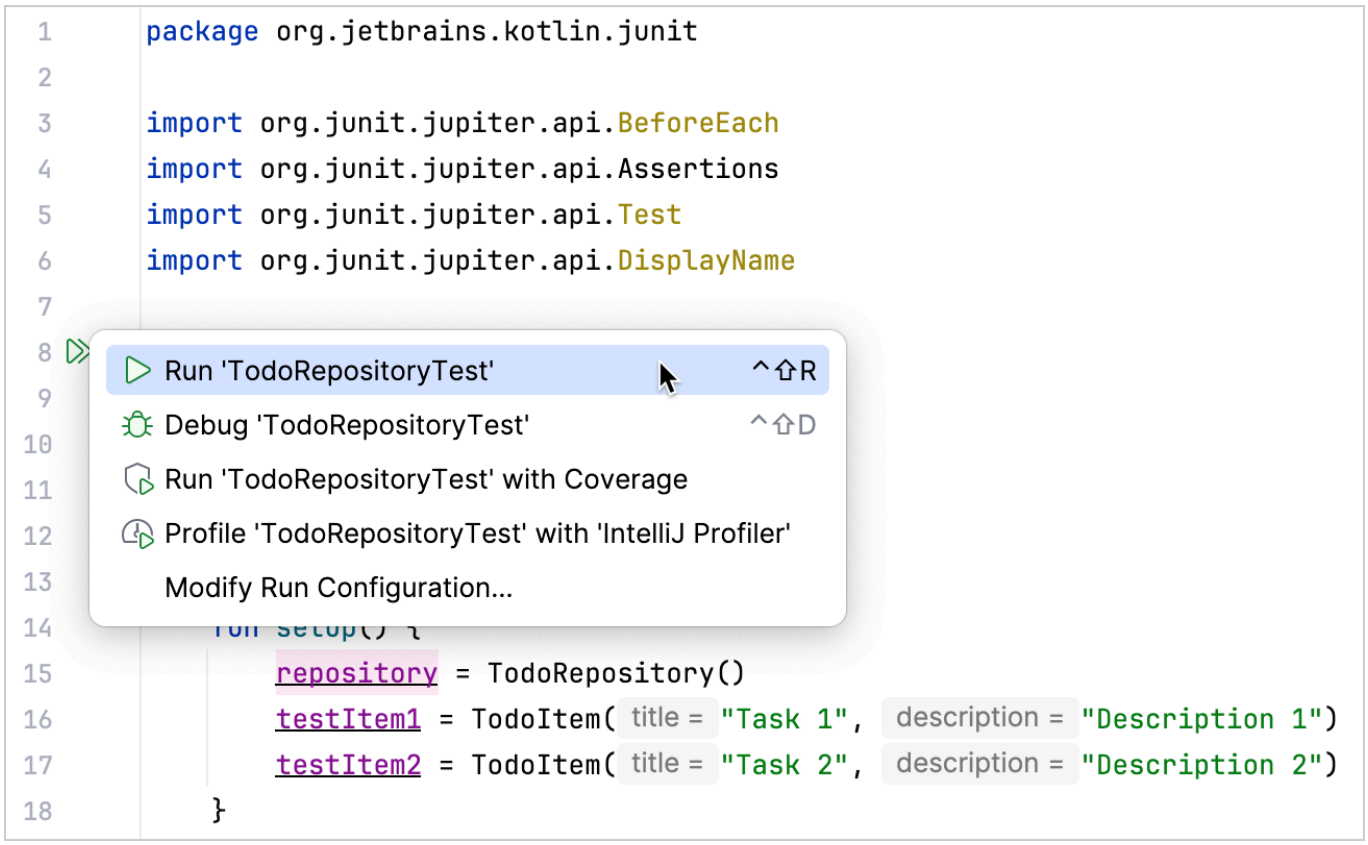
     val removed = repository.remove(testItem1.id())

     Assertions.assertTrue(removed)
     Assertions.assertEquals(1, repository.size())
     Assertions.assertTrue(repository.getById(testItem1.id()).isEmpty)
     Assertions.assertTrue(repository.getById(testItem2.id()).isPresent)
 }

 @Test
 @DisplayName("Should return false when removing non-existent item")
 fun shouldReturnFalseForNonExistentRemoval() {
     repository.add(testItem1)

     val removed = repository.remove("non-existent-id")

     Assertions.assertFalse(removed)
     Assertions.assertEquals(1, repository.size())
 }
```



In Kotlin, you can chain method calls and property access, for example `repository.getById(id).isEmpty`.

> You can add even more tests to the `TodoRepositoryTest` test class to cover additional functionality. See the full source code in the sample project's `complete` module.

Run tests

Run both Java and Kotlin tests to verify your project works as expected:

1. Run the test using the gutter icon:

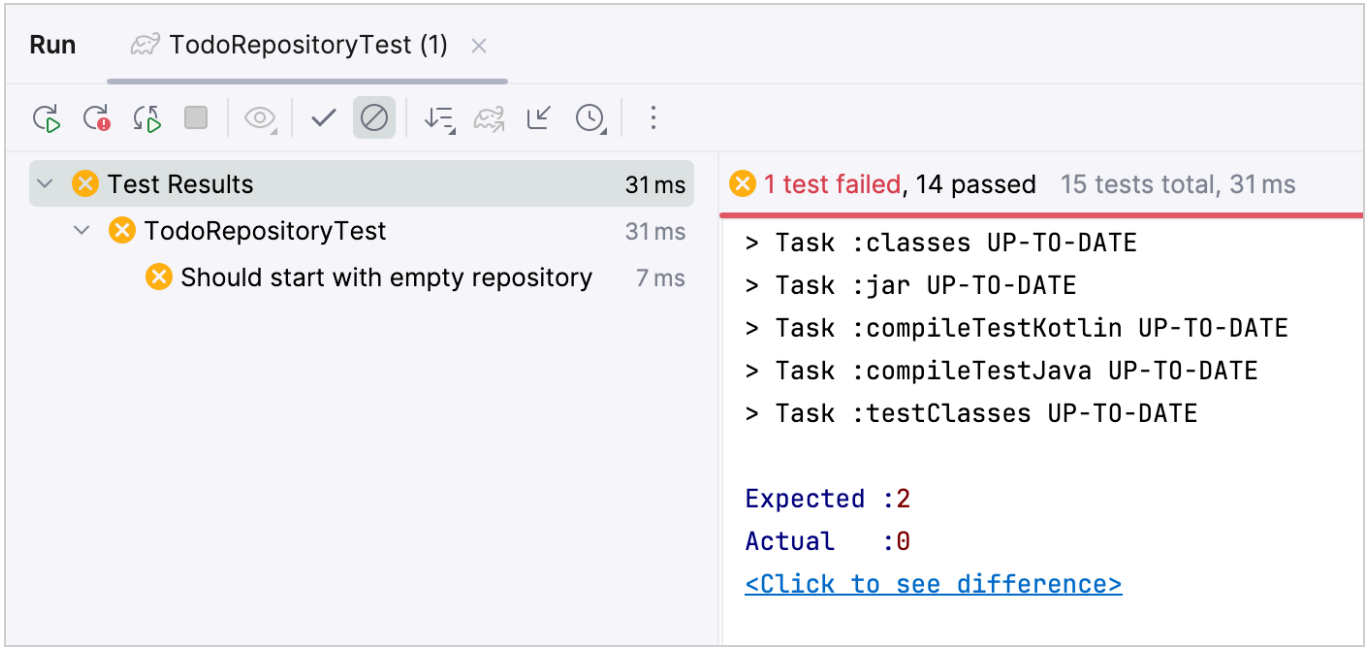
Run the test

You can also run all project tests from the `initial` directory using the command line:

Maven

```
mvn test
```

Gradle



```
./gradlew test
```

2. Check that the test works correctly by changing one of the variable values. For example, modify the `shouldAddItem` test to expect an incorrect repository size:

```
@Test
@DisplayName("Should add item to repository")
fun shouldAddItem() {
    repository.add(testItem1)

    Assertions.assertEquals(2, repository.size())  // Changed from 1 to 2
    Assertions.assertTrue(repository.all.contains(testItem1))
}
```

3. Run the test again and verify that it fails:

Check the test result. The test has failed

You can find the fully configured project with tests in the sample project's `complete` module.

What's next

Learn more about testing Kotlin projects with Maven.

Test Kotlin projects with Maven

Kotlin integrates seamlessly with the Maven ecosystem, allowing you to use industry-standard tools to verify your backend applications. In this guide, you'll learn how to create tests with JUnit and use Maven plugins to run unit and integration tests.

For a detailed guide to setting up your Maven project to use both Kotlin and Java, see Project configuration.

Create tests with JUnit

JUnit is the standard testing framework for Kotlin backend development. While Kotlin supports multiple JUnit versions, most modern projects should use JUnit 6.

To create a test in Kotlin using JUnit, use the `@Test` annotation from the `kotlin.test` or JUnit package.

Add dependency

The `kotlin-test` library is the easiest way to start. It provides a common set of assertions and automatically pulls in the necessary JUnit artifacts.

JUnit 5 and later

For all new projects, use the `kotlin-test-junit5` artifact. It provides full support for JUnit, including features like nested tests and parallel execution. Kotlin/JVM supports the latest stable JUnit version, JUnit 6.

Update your `pom.xml` file as follows:

```
<dependencies>
    <dependency>
        <groupId>org.jetbrains.kotlin</groupId>
        <artifactId>kotlin-test-junit5</artifactId>
        <version>2.4.20</version>
        <scope>test</scope>
    </dependency>
</dependencies>
```

Despite its name, `kotlin-test-junit5` supports all latest JUnit versions, including JUnit 6.

JUnit 4

If you'd like to use an earlier version of JUnit, for example, for a legacy project, use the `kotlin-test-junit` artifact that utilizes JUnit 4:

```
<!-- pom.xml -->
<dependencies>
    <dependency>
        <groupId>org.jetbrains.kotlin</groupId>
        <artifactId>kotlin-test-junit</artifactId>
        <version>2.4.20</version>
        <scope>test</scope>
    </dependency>
</dependencies>
```

For a detailed guide on using JUnit for testing and a sample project, see the Test Java code with Kotlin tutorial.

Write unit tests

Unit tests verify isolated parts of your code, such as individual functions or classes. By convention, unit tests are named with the `*Test` suffix. For example:

```
import kotlin.test.Test
import kotlin.test.assertEquals

class OrderServiceTest {
    @Test
    fun `calculate total should sum item prices`() {
        val service = OrderService()
        val result = service.calculateTotal(listOf(10.0, 25.0))
        assertEquals(35.0, result)
    }
}
```

Write integration tests

Integration tests verify interaction between components, like a service and a database. By convention, integration tests are named with the `*IT` suffix. For example:

```
import kotlin.test.Test
import kotlin.test.assertNotNull

class UserRepositoryIT {
    @Test
    fun saveFindUser() {
        // Example integration with a database or service
        val repository = UserRepository()
        repository.save(User("KotlinUser"))

        val user = repository.findByName("KotlinUser")
        assertNotNull(user)
    }
}
```

Run tests

In Maven projects, test execution is typically split between two plugins: Surefire and Failsafe to ensure a clean build lifecycle.

With Surefire plugin

The Surefire plugin handles *unit tests*. It runs all Kotlin and Java tests that follow the `*Test` naming pattern.

By default, it executes during the `test` phase of the build lifecycle and fails the build immediately if a test fails.

```
<plugin>
    <groupId>org.apache.maven.plugins</groupId>
    <artifactId>maven-surefire-plugin</artifactId>
    <version>3.5.5</version>
</plugin>
```

To run only your unit tests, use the following command:

```
mvn test
```

With Failsafe plugin

The Failsafe plugin handles *integration tests*. It runs all Kotlin and Java tests that follow the `*IT` naming pattern.

Unlike Surefire, Failsafe allows the build to continue if a test fails during the `integration-test` phase, allowing the `post-integration-test` phase tasks (like stopping a Docker container) to run. The build finally fails during the `verify` phase if there were any test failures.

```
<plugin>
    <groupId>org.apache.maven.plugins</groupId>
    <artifactId>maven-failsafe-plugin</artifactId>
    <version>3.5.5</version>
    <executions>
        <execution>
            <goals>
                <goal>integration-test</goal>
                <goal>verify</goal>
            </goals>
        </execution>
    </executions>
</plugin>
```

To run both unit and integration tests, use the following command:

```
mvn verify
```

Get detailed failure messages

The Kotlin Power-assert compiler plugin generates detailed failure messages that display intermediate values in your assertions, giving you the full diagrams in the console output.

1. To enable Power-assert, add the following configuration to your project's `pom.xml` :

```
<properties>
    <kotlin.version>2.4.20</kotlin.version>
    <kotlin.compiler.jdkRelease>17</kotlin.compiler.jdkRelease>
</properties>

<dependencies>
    <dependency>
        <groupId>org.jetbrains.kotlin</groupId>
        <artifactId>kotlin-test-junit5</artifactId>
        <version>${kotlin.version}</version>
        <scope>test</scope>
    </dependency>
</dependencies>

<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <version>${kotlin.version}</version>
            <extensions>true</extensions>
            <executions>
                <execution>
                    <id>compile</id>
                    <phase>process-sources</phase>
                    <goals>
                        <goal>compile</goal>
                    </goals>
                </execution>
                <execution>
                    <id>test-compile</id>
                    <phase>process-test-sources</phase>
                    <goals>
                        <goal>test-compile</goal>
                    </goals>
                </execution>
            </executions>
            <configuration>
                <!-- Specify the Power-assert plugin -->
                <compilerPlugins>
                    <plugin>power-assert</plugin>
                </compilerPlugins>
                <!-- Specify the functions to transform -->
                <pluginOptions>
                    <option>power-assert:function=kotlin.test.assertEquals</option>
                    <option>power-assert:function=kotlin.test.assertTrue</option>
                </pluginOptions>
            </configuration>
            <!-- Add the Power-assert plugin dependency -->
            <dependencies>
                <dependency>
                    <groupId>org.jetbrains.kotlin</groupId>
                    <artifactId>kotlin-maven-power-assert</artifactId>
                    <version>${kotlin.version}</version>
                </dependency>
            </dependencies>
        </plugin>
    </plugins>
</build>
```

- In the `<properties>` section, set the Kotlin version and the target JDK release version, for example, JDK 17.
- In the `<dependencies>` section, add `kotlin-test-junit5` for running tests.

- In the `<build><plugins>` section, configure `kotlin-maven-plugin` with the `power-assert` compiler plugin. List the assertion functions you want to transform under `<pluginOptions>` and add the Power-assert plugin dependency.

2. Create a test file, `UserProfileBackendTest.kt`, in the `src/test/kotlin` directory:

```
import kotlin.test.Test
import kotlin.test.assertEquals

class UserProfileBackendTest {

    data class UserProfile(val id: Long, val email: String)

    @Test
    fun `verify backend entity mapping matches`() {
        // Define expected object state
        val expectedRecord = UserProfile(id = 451L, email = "admin-dev@company.internal")

        // Simulate a mismatched backend response
        val actualRecord = UserProfile(id = 451L, email = "admin-prod@company.com")

        // Use a standard kotlin.test assertion
        assertEquals(expectedRecord, actualRecord, "Profile configurations out of sync")
    }
}
```

3. Run the test and verify the output:

```
mvn test
```

The console displays the full Power-assert diagram, showing the difference between the expected and actual values at each position in the expression:

```
Profile configurations out of sync
assertEquals(expectedRecord, actualRecord, "Profile configurations out of sync")
             |               |
             |               UserProfile(id=451, email=admin-prod@company.com)
             UserProfile(id=451, email=admin-dev@company.internal)
```

Explore other testing frameworks

Besides JUnit, you can use other popular frameworks to make Kotlin tests more idiomatic and readable:

Library	Description
AssertJ	Fluent assertion library with chainable assertions.
Mockito-Kotlin	Kotlin wrapper for Mockito that provides helper functions and better integration with the Kotlin type system.
MockK	Native Kotlin mocking library that supports Kotlin-specific features, including coroutines and extension functions.

Library	Description
Kotest	Assertion library for Kotlin offering multiple assertion styles and extensive matcher support.
Strikt	Assertion library for Kotlin with type-safe assertions and support for data classes.

What's next

- Explore the features of the `kotlin.test` library.
- Learn more about the Power-assert compiler plugin.

Use annotation processors in Kotlin projects

Annotation processors analyze your source code at compile time to generate boilerplate code, validate usage, or produce other artifacts. Kotlin supports two ways to work with annotation processors:

- The kapt compiler plugin works by generating stub files from Kotlin source code and then running the Java annotation processors on those stubs. This extra stub-generation step makes the build time slower and means kapt can't understand Kotlin-specific constructs, such as extension functions or null safety.

  kapt supports both Maven and Gradle. It's recommended for all Maven projects and for Gradle projects with processor libraries that haven't yet adopted KSP, such as MapStruct.

- The KSP framework reads Kotlin source code directly through a Kotlin-first API, without generating stubs. It understands Kotlin-specific features natively and runs builds faster than kapt.

  Currently, KSP has official support only for Gradle. It's recommended for writing your own processors and working with KSP-compatible libraries like Dagger.

Use kapt with Java annotation processors

kapt lets you use existing Java annotation processors in Kotlin projects without any changes to the processors themselves.

The example below shows how to use the MapStruct annotation processor, which generates type-safe mapper implementations between Java beans at compile time.

1. In your build file, apply the `kapt` plugin and add MapStruct to the `dependencies` section:

Maven

```xml
<properties>
    <kotlin.compiler.jvmTarget>11</kotlin.compiler.jvmTarget>
    <mapstruct.version>1.6.3</mapstruct.version>
</properties>

<dependencies>
    <dependency>
        <groupId>org.mapstruct</groupId>
        <artifactId>mapstruct</artifactId>
        <version>${mapstruct.version}</version>
    </dependency>
</dependencies>

<plugin>
    <groupId>org.jetbrains.kotlin</groupId>
    <artifactId>kotlin-maven-plugin</artifactId>
    <version>${kotlin.version}</version>
    <extensions>true</extensions>
    <executions>
        <execution>
            <id>kapt</id>
            <goals>
                <goal>kapt</goal>
            </goals>
            <configuration>
                <sourceDirs>
                    <sourceDir>src/main/kotlin</sourceDir>
                    <sourceDir>src/main/java</sourceDir>
                </sourceDirs>
                <aptMode>stubs</aptMode>
                <annotationProcessorPaths>
                    <annotationProcessorPath>
                        <groupId>org.mapstruct</groupId>
                        <artifactId>mapstruct-processor</artifactId>
                        <version>${mapstruct.version}</version>
                    </annotationProcessorPath>
                </annotationProcessorPaths>
            </configuration>
        </execution>
    </executions>
</plugin>
```

- Add the execution of the `kapt` goal from `kotlin-maven-plugin` **before** the `compile` execution.
- Configure the mode of annotation processing using the `aptMode` option.

Gradle Kotlin

```kotlin
plugins {
    kotlin("kapt") version "2.4.20"
}

dependencies {
    implementation("org.mapstruct:mapstruct:1.6.3")
    kapt("org.mapstruct:mapstruct-processor:1.6.3")
}
```

Gradle Groovy

```
plugins {
    id "org.jetbrains.kotlin.kapt" version "2.4.20"
}

dependencies {
    implementation "org.mapstruct:mapstruct:1.6.3"
    kapt "org.mapstruct:mapstruct-processor:1.6.3"
}
```

2. Define your data classes and a mapper interface:

```
import org.mapstruct.Mapper
import org.mapstruct.factory.Mappers

data class UserDto(val id: Long, val firstName: String, val lastName: String)

data class UserEntity(val id: Long, val firstName: String, val lastName: String)

@Mapper
interface UserMapper {
    fun toDto(entity: UserEntity): UserDto
    fun toEntity(dto: UserDto): UserEntity

    companion object : UserMapper by Mappers.getMapper(UserMapper::class.java)
}
```

3. Build the project. MapStruct generates the `UserMapperImpl` class in the generated sources' directory. Use the `UserMapper` companion object to call the generated implementation:

```
fun main() {
    val entity = UserEntity(id = 1L, firstName = "John", lastName = "Doe")
    val dto = UserMapper.toDto(entity)
    println(dto)
    // UserDto(id=1, firstName=John, lastName=Doe)
}
```

Use KSP in Gradle projects

With KSP, you can use existing annotation processors in Gradle projects and create your own processors that generate code based on annotations in your source code.

Use KSP with Java annotation processors

For Gradle projects, use KSP with the compatible annotation processors. KSP is faster than kapt and can understand Kotlin-specific features natively. See the list of libraries that already support KSP.

The example below shows how to use Dagger, a compile-time dependency injection framework that generates the wiring code for your dependency graph.

1. In your `build.gradle(.kts)` file, apply the KSP plugin and add Dagger to the `dependencies` block:

Kotlin

```
// build.gradle.kts

plugins {
    kotlin("jvm") version "2.4.20"
    id("com.google.devtools.ksp") version "2.3.10"
}

dependencies {
    implementation("com.google.dagger:dagger:2.59.2")
    ksp("com.google.dagger:dagger-compiler:2.59.2")
}
```

Groovy

```
// build.gradle

plugins {
    id 'org.jetbrains.kotlin.jvm' version '2.4.20'
    id 'com.google.devtools.ksp' version '2.3.10'
}

dependencies {
    implementation 'com.google.dagger:dagger:2.59.2'
    ksp 'com.google.dagger:dagger-compiler:2.59.2'
}
```

ℹ To find the latest version of KSP, check the GitHub Releases page.

2. Annotate your Kotlin classes with Dagger annotations:

```
import javax.inject.Inject
import javax.inject.Singleton
import dagger.Component
import dagger.Module
import dagger.Provides

@Singleton
class UserRepository @Inject constructor() {
    fun getUser(): String = "John Doe"
}

@Module
class AppModule {
    @Provides
    @Singleton
    fun provideUserRepository(): UserRepository = UserRepository()
}

@Singleton
@Component(modules = [AppModule::class])
interface AppComponent {
    fun userRepository(): UserRepository
}
```

3. Build the project. Dagger generates implementation classes, such as `DaggerAppComponent` in the `build/generated/ksp` directory. Use the generated class in your code:

```
fun main() {
    val appComponent = DaggerAppComponent.create()
    val userRepository = appComponent.userRepository()
    println("User: ${userRepository.getUser()}")
    // User: John Doe
}
```

For more information on Dagger support for KSP, see its documentation.

Create your own annotation processor

You can use the KSP API to write your own annotation processors that generate code at compile time. A new processor requires three modules:

- An `annotation` module that declares the custom annotation.
- A `processor` module that implements the `SymbolProcessor` and `SymbolProcessorProvider` factories. `SymbolProcessor` contains the main logic, while `SymbolProcessorProvider` creates the processor and registers the provider in the `META-INF/services/` path.
- An `app` module that applies the KSP plugin depends on the processor, and uses the annotation.

For complete step-by-step instructions, see the KSP quickstart.

What's next

- Learn more about kapt configuration
- Get started with KSP
- See how to migrate from kapt to KSP

Code quality tools in Kotlin projects

Code quality tools help you enforce coding standards, detect bugs early, measure test coverage, and maintain code quality across your Kotlin projects. This guide shows how to integrate popular tools like ktlint, detekt, SonarQube, SonarCloud, and Kover into your backend project for Maven or Gradle.

Code formatting with ktlint

ktlint is a Kotlin linter and formatter that enforces the official Kotlin coding conventions with no extra configuration.

ktlint checks rules such as indentation, spacing around operators, import ordering, and trailing commas. If a violation is found, the build fails with a message indicating the file and line number. Besides reporting violations, ktlint can also automatically fix straightforward issues.

To integrate ktlint into your project:

1. Add the plugin to your build file:

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>com.github.gantsign.maven</groupId>
    <artifactId>ktlint-maven-plugin</artifactId>
    <version>3.7.1</version>
    <executions>
        <execution>
            <id>check</id>
            <goals>
                <goal>check</goal>
            </goals>
        </execution>
    </executions>
</plugin>
```

Gradle

```
// build.gradle.kts
plugins {
    id("org.jlleitschuh.gradle.ktlint") version "12.3.0"
}
```

2. Run the linter to check your code style:

Maven

```
mvn ktlint:check
```

Gradle

```
./gradlew ktlintCheck
```

3. (Optional) You can also add an `.editorconfig` file to the root of your project to customize rules. For example, to allow wildcard imports and disable trailing comma enforcement:

```
[*.{kt,kts}]
ij_kotlin_imports_layout = *
ktlint_standard_trailing-comma-on-call-site = disabled
ktlint_standard_trailing-comma-on-declaration-site = disabled
```

By default, ktlint follows the official Kotlin coding conventions. If you prefer the Android Kotlin style guide, which differs noticeably from the Kotlin conventions, set the code style to `android_studio` in your `.editorconfig` file:

```
[*.{kt,kts}]
ktlint_code_style = android_studio
```

4. To automatically fix formatting issues, run:

Maven

```
mvn ktlint:format
```

Gradle

```
./gradlew ktlintFormat
```

For more information on available features and rules, see the ktlint documentation.

Code analysis with detekt

detekt is a static code analysis tool for Kotlin that detects code smells, complexity issues, and potential bugs.

To integrate detekt into your project:

1. Add the plugin to your build file:

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>com.github.ozsie</groupId>
    <artifactId>detekt-maven-plugin</artifactId>
    <version>1.23.8</version>
    <executions>
        <execution>
            <phase>verify</phase>
            <goals>
                <goal>check</goal>
            </goals>
        </execution>
    </executions>
</plugin>
```

Gradle

```
// build.gradle.kts
plugins {
    id("io.gitlab.arturbosch.detekt") version "1.23.8"
}
```

2. Generate a default `detekt.yml` configuration file:

Maven

```
mvn detekt:generate-config
```

Gradle

```
./gradlew detektGenerateConfig
```

3. Open the `detekt.yml` file and customize the rules in the generated file, for example:

```
complexity:
  LongMethod:
    threshold: 50
style:
  MagicNumber:
    active: false
```

4. Reference the configuration file in your build file so that detekt can apply the new rules:

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>com.github.ozsie</groupId>
    <artifactId>detekt-maven-plugin</artifactId>
    <version>1.23.8</version>
    <configuration>
        <config>detekt.yml</config>
        <report>
            <report>txt:reports/detekt.txt</report>
            <report>xml:reports/detekt.xml</report>
        </report>
    </configuration>
    <executions>
        <execution>
            <phase>verify</phase>
            <goals>
                <goal>check</goal>
            </goals>
        </execution>
    </executions>
</plugin>
```

Gradle

```
// build.gradle.kts
detekt {
    toolVersion = "1.23.8"
    config.setFrom(file("config/detekt/detekt.yml"))
    buildUponDefaultConfig = true
}
```

5. Run the analysis:

Maven

```
mvn detekt:check
```

Gradle

```
./gradlew detekt
```

detekt produces a report listing all rule violations with their severity, file location, and a description of the issue. By default, Gradle outputs reports to `build/reports/detekt`, while Maven outputs to the `reports/detekt` directory in the project root.

For more information, see the detekt documentation for Gradle and Maven.

Code quality with SonarSource

SonarQube and SonarCloud from SonarSource provide deep static analysis for Kotlin projects, including bug detection, vulnerability scanning, and code coverage tracking through a web dashboard.

To analyze your project with SonarQube:

1. Add the plugin to your build file:

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>org.sonarsource.scanner.maven</groupId>
    <artifactId>sonar-maven-plugin</artifactId>
    <version>5.7.0.6970</version>
</plugin>
```

Gradle

```
// build.gradle.kts
plugins {
    id("org.sonarqube") version "6.2.0.5505"
}

sonar {
    properties {
        property("sonar.projectKey", "my-project")
        property("sonar.host.url", "http://localhost:9000")
    }
}
```

2. (Optional) Configure analysis properties. For example, to make the build wait for the quality gate result and fail if the gate is not passed, add the `sonar.qualitygate.wait` property:

Maven

```
mvn verify sonar:sonar \
  -Dsonar.qualitygate.wait=true \
  -Dsonar.projectKey=my-project \
  -Dsonar.host.url=http://localhost:9000 \
  -Dsonar.token=YOUR_TOKEN
```

Gradle

```
// build.gradle.kts
sonar {
    properties {
        property("sonar.qualitygate.wait", "true")
    }
}
```

Quality gate rules (such as minimum coverage thresholds and allowed issue counts) are defined in the SonarQube or SonarCloud web interface under **Quality Gates**, not in the build file.

3. Run the analysis against your SonarQube server:

Maven

```
mvn verify sonar:sonar \
  -Dsonar.projectKey=my-project \
  -Dsonar.host.url=http://localhost:9000 \
  -Dsonar.token=YOUR_TOKEN
```

For SonarCloud, replace the host URL with `https://sonarcloud.io` and provide your organization key:

```
mvn verify sonar:sonar \
  -Dsonar.projectKey=my-project \
  -Dsonar.organization=my-org \
  -Dsonar.host.url=https://sonarcloud.io \
  -Dsonar.token=YOUR_TOKEN
```

To run the analysis, use the `sonar` task and provide your authentication token:

Gradle

```
./gradlew sonar \
  -Dsonar.token=YOUR_TOKEN
```

By default, the analysis is run against a local SonarQube server. To use SonarCloud, update the `sonar {}` block in your `build.gradle.kts` to use `https://sonarcloud.io` and add your organization key:

```
sonar {
    properties {
        property("sonar.projectKey", "example-project")
        property("sonar.organization", "example-org")
        property("sonar.host.url", "https://sonarcloud.io")
    }
}
```

4. Open the SonarQube or SonarCloud dashboard to review the results. The dashboard shows issues grouped by type (bug, vulnerability, code smell) and severity.

For more information, see the SonarSource documentation.

Code coverage with Kover

Kover is the official JetBrains code coverage tool for Kotlin. It measures which lines and branches of your code are covered by tests and generates human-readable reports.

Unlike JaCoCo, Kover correctly interprets Kotlin-specific constructs such as inline functions and data classes, so it reports accurate coverage numbers without false negatives caused by compiler-generated bytecode.

To integrate Kover into your project:

1. Add the plugin to your build file:

Maven

```
<!-- pom.xml -->
<plugin>
    <groupId>org.jetbrains.kotlinx</groupId>
    <artifactId>kover-maven-plugin</artifactId>
    <version>0.9.8</version>
    <executions>
        <execution>
            <id>instr</id>
            <goals>
                <goal>instrumentation</goal>
            </goals>
        </execution>
        <execution>
            <id>kover-verify</id>
            <goals>
               <goal>verify</goal>
            </goals>
        </execution>
        <execution>
            <id>kover-report-xml</id>
            <goals>
                <goal>report-xml</goal>
            </goals>
        </execution>
        <execution>
            <id>kover-report-html</id>
            <goals>
                <goal>report-html</goal>
            </goals>
        </execution>
    </executions>
</plugin>
```

Gradle

```
// build.gradle.kts
plugins {
    id("org.jetbrains.kotlinx.kover") version "0.9.8"
}
```

2. Run your tests to collect coverage data and generate the report:

Maven

```
mvn verify
```

Gradle

```
./gradlew koverVerify koverHtmlReport
```

3. Open the HTML report generated in the `target/site/kover/html/` directory (`build/reports/kover/html/` for Gradle) to review line-by-line coverage.
4. (Optional) To enforce a minimum coverage threshold that fails the build if the conditions are not met, you can add a coverage verification configuration to your build file. For example:

Maven

```
<!-- pom.xml -->
<configuration>
  <!-- Create new coverage verification rule -->
  <rules>
      <rule>
          <bounds>
              <bound>
                  <minValue>50</minValue>
                  <coverageUnits>LINE</coverageUnits>
                  <aggregationForGroup>COVERED_PERCENTAGE</aggregationForGroup>
              </bound>
          </bounds>
      </rule>
  </rules>
</configuration>
```

Gradle

```
// build.gradle.kts
// Add a `kover` configuration block
import kotlinx.kover.gradle.plugin.dsl.*

kover {
    reports {
        total {
            log {
                aggregationForGroup = AggregationType.COVERED_PERCENTAGE
                coverageUnits = CoverageUnit.LINE
            }
            verify {
                rule {
                    minBound(50)
                }
            }
        }
    }
}
```

For more information on configuring verification rules, see the Kover documentation for Maven and Gradle.

Other tools

Besides ktlint, detekt, SonarQube, SonarCloud, and Kover, try out other tools to improve Kotlin code quality:

Tool	Description
CodeQL	Semantic code analysis engine by GitHub. Supports Kotlin and integrates with GitHub Actions to find security vulnerabilities automatically.
Semgrep	Fast, lightweight static analysis tool that supports custom rules. Can be used to enforce patterns or detect anti-patterns in Kotlin code.
PMD	Source code analyzer that supports Kotlin (via its CPD copy-paste detector) and detects common programming flaws and duplicate code.

What's next

- Run tests in Maven projects
- Configure a Kotlin project with Maven

Get started with Spring Boot and Kotlin

Get started with Spring Boot and Kotlin by completing this tutorial: it walks you through the process of creating a simple application with Spring Boot and adding a database to store the information.

Going through these four steps, you'll learn a lot of essential features of the Kotlin language:

1. Create a Spring Boot project
2. Add a data class to Spring Boot project
3. Add database support for the Spring Boot project
4. Use Spring Data CrudRepository for database access

Next step

Create a Spring Boot project with Kotlin

The first part of the tutorial shows how to create a Spring Boot project with Gradle in IntelliJ IDEA using the Project Wizard.

> This tutorial doesn't require using Gradle as the build system. You can follow the same steps if you use Maven.

Before you start

Download and install the latest version of IntelliJ IDEA and use an Ultimate subscription.

> If you use IntelliJ IDEA without an Ultimate subscription or you use another IDE, you can generate a Spring Boot project using a web-based project generator.

Create a Spring Boot project

Create a new Spring Boot project with Kotlin by using the Project Wizard in IntelliJ IDEA:

1. In IntelliJ IDEA, select **File** | **New** | **Project**.
2. In the panel on the left, select **Spring Boot** in the **Generators** section.
3. Specify the following fields and options in the **New Project** window:
   - **Name**: demo
   - **Language**: Kotlin
   - **Type**: Gradle - Kotlin

     > This option specifies the build system and the DSL.

   - **Package name**: com.example.demo
   - **JDK**: Java JDK

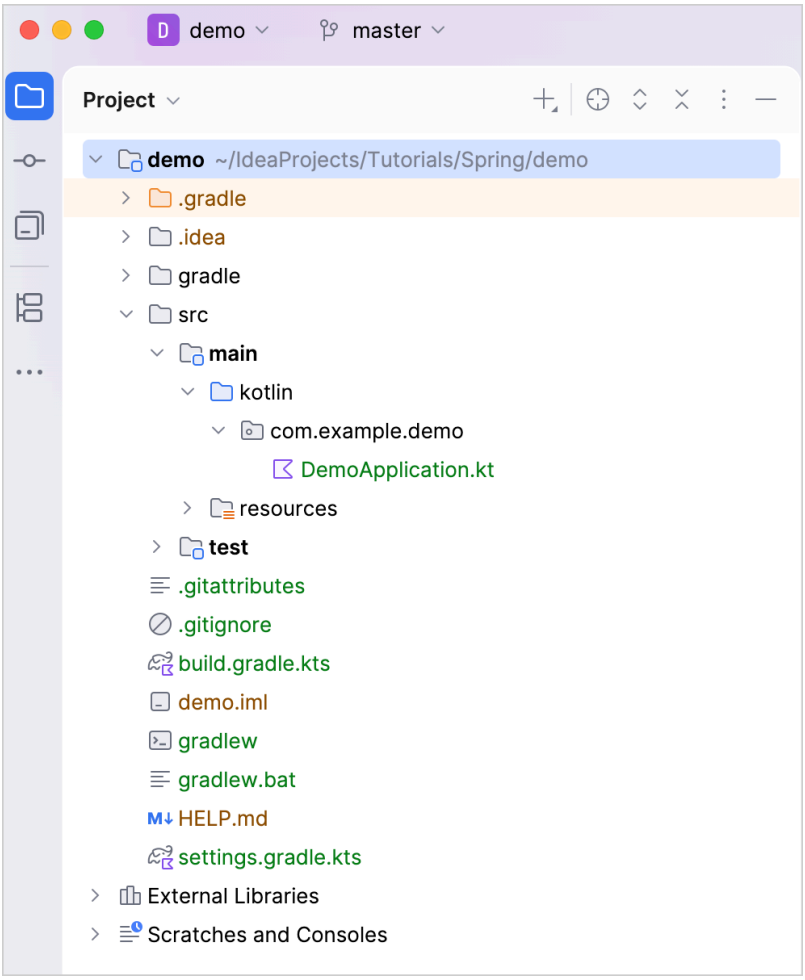
     > This tutorial uses **Amazon Corretto version 23**. If you don't have a JDK installed, you can download it from the dropdown list.

   - **Java**: 17

     > If you don't have Java 17 installed, you can download it from the JDK dropdown list.

Create Spring Boot project

4. Ensure that you have specified all the fields and click **Next**.
5. Select the following dependencies that will be required for the tutorial:
   - **Web | Spring Web**
   - **SQL | Spring Data JDBC**
   - **SQL | H2 Database**



Set up Spring Boot project

6. Click **Create** to generate and set up the project.

> The IDE will generate and open a new project. It may take some time to download and import the project dependencies.

7. After this, you can observe the following structure in the **Project view**:

Set up Spring Boot project

The generated Gradle project corresponds to the Maven's standard directory layout:

- There are packages and classes under the `main/kotlin` folder that belong to the application.
- The entry point to the application is the `main()` method of the `DemoApplication.kt` file.

Explore the project Gradle build file

Open the `build.gradle.kts` file: it is the Gradle Kotlin build script, which contains a list of the dependencies required for the application.

The Gradle file is standard for Spring Boot, but it also contains necessary Kotlin dependencies, including the kotlin-spring Gradle plugin – `kotlin("plugin.spring")`.

Here is the full script with the explanation of all parts and dependencies:

```
// build.gradle.kts
plugins {
    kotlin("jvm") version "2.3.21" // The version of Kotlin to use
    kotlin("plugin.spring") version "2.3.21" // The Kotlin Spring plugin
    id("org.springframework.boot") version "4.1.1"
    id("io.spring.dependency-management") version "1.1.7"
}

group = "com.example"
version = "0.0.1-SNAPSHOT"

java {
    toolchain {
        languageVersion = JavaLanguageVersion.of(17)
    }
}

repositories {
    mavenCentral()
}

dependencies {
    implementation("org.springframework.boot:spring-boot-h2console")
    implementation("org.springframework.boot:spring-boot-starter-data-jdbc")
    implementation("org.springframework.boot:spring-boot-starter-webmvc")
    implementation("org.jetbrains.kotlin:kotlin-reflect") // Kotlin reflection library, required for
working with Spring
    implementation("tools.jackson.module:jackson-module-kotlin") // Jackson extensions for Kotlin for
working with JSON
    runtimeOnly("com.h2database:h2")
    testImplementation("org.springframework.boot:spring-boot-starter-data-jdbc-test")
    testImplementation("org.springframework.boot:spring-boot-starter-webmvc-test")
    testImplementation("org.jetbrains.kotlin:kotlin-test-junit5")
    testRuntimeOnly("org.junit.platform:junit-platform-launcher")
}

kotlin {
    compilerOptions {
        freeCompilerArgs.addAll("-Xjsr305=strict", "-Xannotation-default-target=param-property") // `-
Xjsr305=strict` enables the strict mode for JSR-305 annotations
    }
}

tasks.withType<Test> {
    useJUnitPlatform()
}
```

As you can see, there are a few Kotlin-related artifacts added to the Gradle build file:

1. In the `plugins` block, there are two Kotlin artifacts:
    - The `kotlin("jvm")` plugin defines the version of Kotlin to be used in the project.
    - The Kotlin Spring compiler plugin, `kotlin("plugin.spring")`, adds the `open` modifier to Kotlin classes to make them compatible with Spring Framework features
2. In the `dependencies` block, a few Kotlin-related modules are listed:
    - The `tools.jackson.module:jackson-module-kotlin` module adds support for serialization and deserialization of Kotlin classes and data classes.

- `org.jetbrains.kotlin:kotlin-reflect` is a Kotlin reflection library that enables full support for the reflection features.

3. After the dependencies section, you can see the `kotlin` plugin configuration block. This is where you can add extra arguments to the compiler to enable or disable various language features.

Learn more about the Kotlin compiler options in Compiler options in the Kotlin Gradle plugin.

Explore the generated Spring Boot application

Open the `DemoApplication.kt` file:

```
// DemoApplication.kt
package com.example.demo

import org.springframework.boot.autoconfigure.SpringBootApplication
import org.springframework.boot.runApplication

@SpringBootApplication
class DemoApplication

fun main(args: Array<String>) {
    runApplication<DemoApplication>(*args)
}
```

Declaring classes – class DemoApplication

Right after package declaration and import statements you can see the first class declaration, `class DemoApplication`.

In Kotlin, if a class doesn't include any members (properties or functions), you can omit the class body (`{}`) for good.

@SpringBootApplication annotation

`@SpringBootApplication annotation` is a convenience annotation in a Spring Boot application. It enables Spring Boot's auto-configuration, component scan, and be able to define an extra configuration on their "application class".

Program entry point – main()

The `main()` function is the entry point to the application.

It is declared as a top-level function outside the `DemoApplication` class. The `main()` function invokes the Spring's `runApplication(*args)` function to start the application with the Spring Framework.

Variable arguments – args: Array<String>

If you check the declaration of the `runApplication()` function, you will see that the parameter of the function is marked with `vararg` modifier: `vararg args: String`. This means that you can pass a variable number of String arguments to the function.

The spread operator – (*args)

The `args` is a parameter to the `main()` function declared as an array of Strings. Since there is an array of strings, and you want to pass its content to the function, use the spread operator (prefix the array with a star sign `*`).

Create a controller

The application is ready to run, but let's update its logic first.

In the Spring application, a controller is used to handle the web requests. In the same package, next to the `DemoApplication.kt` file, create the `MessageController.kt` file with the `MessageController` class as follows:

```
// MessageController.kt
package com.example.demo

import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.RequestParam
import org.springframework.web.bind.annotation.RestController

@RestController
class MessageController {
    @GetMapping("/")
    fun index(@RequestParam("name") name: String) = "Hello, $name!"
}
```

@RestController annotation

You need to tell Spring that `MessageController` is a REST Controller, so you should mark it with the `@RestController` annotation.

This annotation means this class will be picked up by the component scan because it's in the same package as our `DemoApplication` class.

@GetMapping annotation

`@GetMapping` marks the functions of the REST controller that implement the endpoints corresponding to HTTP GET calls:

```
@GetMapping("/")
      fun index(@RequestParam("name") name: String) = "Hello, $name!"
```

@RequestParam annotation

The function parameter `name` is marked with `@RequestParam` annotation. This annotation indicates that a method parameter should be bound to a web request parameter.

Hence, if you access the application at the root and supply a request parameter called "name", like `/?name=<your-value>`, the parameter value will be used as an argument for invoking the `index()` function.

Single-expression functions – index()

Since the `index()` function contains only one statement you can declare it as a single-expression function.

This means the curly braces can be omitted and the body is specified after the equals sign `=`.

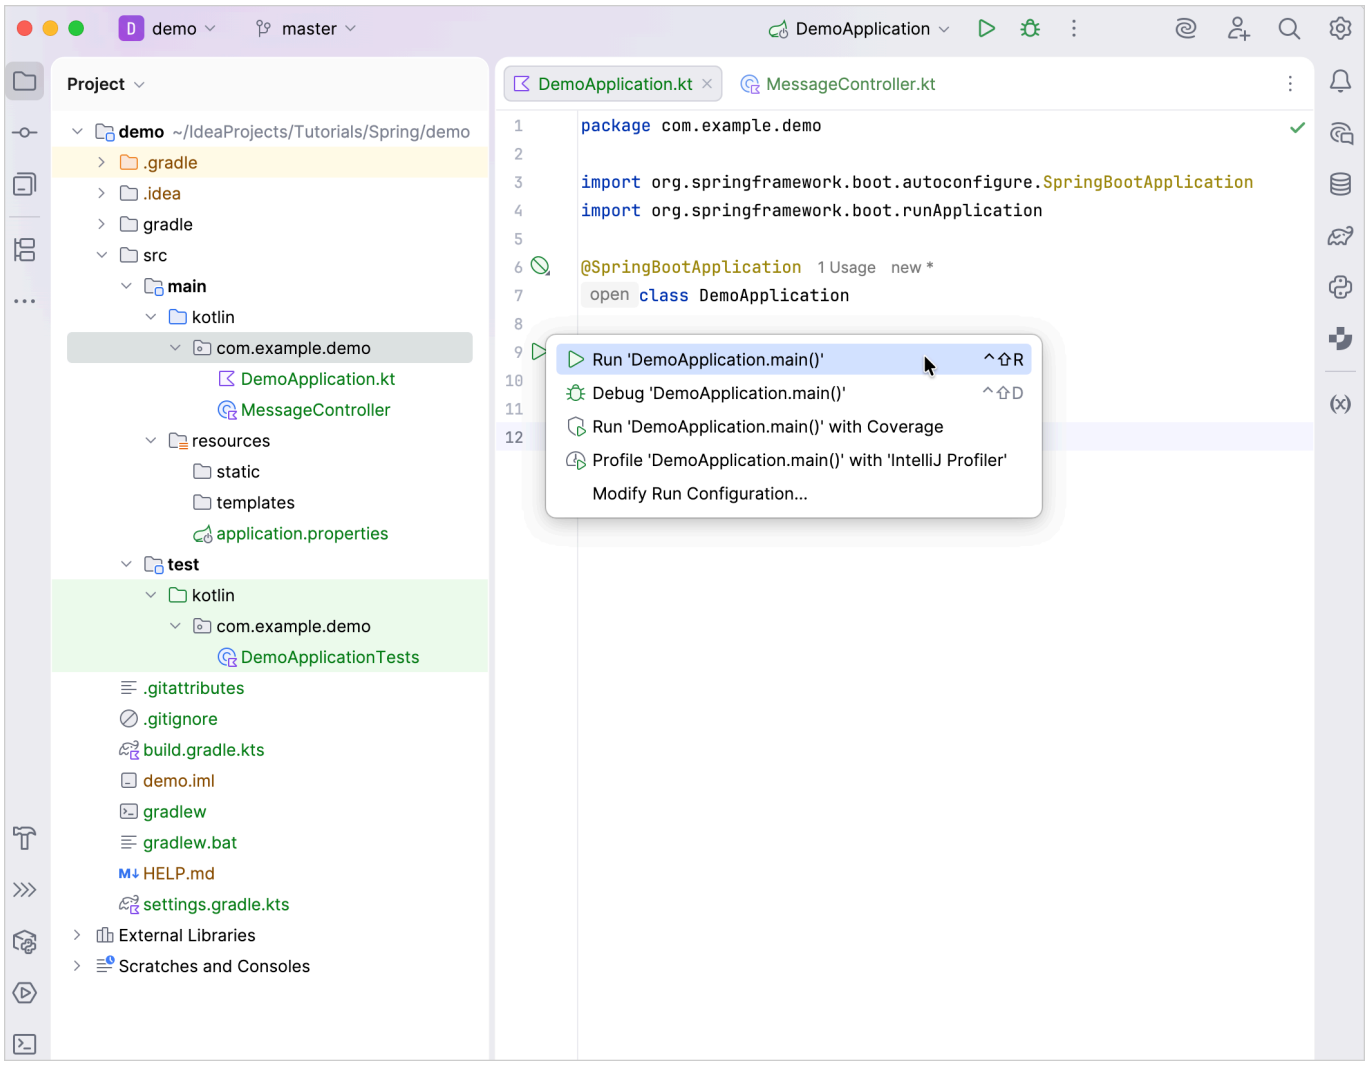
Type inference for function return types

The `index()` function does not declare the return type explicitly. Instead, the compiler infers the return type by looking at the result of the statement on the right-hand side from the equals sign `=`.

The type of `Hello, $name!` expression is `String`, hence the return type of the function is also `String`.

String templates – $name

`Hello, $name!` expression is called a String template in Kotlin.



String templates are String literals that contain embedded expressions.

This is a convenient replacement for String concatenation operations.

Run the application

The Spring application is now ready to run:

1. In the `DemoApplication.kt` file, click the green **Run** icon in the gutter beside the `main()` method:

Run Spring Boot application

> You can also run the `./gradlew bootRun` command in the terminal.

This starts the local server on your computer.

2. Once the application starts, open the following URL:

```
http://localhost:8080?name=John
```

You should see "Hello, John!" printed as a response:

Spring Application response

Next step

In the next part of the tutorial, you'll learn about Kotlin data classes and how you can use them in your application.

- Next step

Add a data class to Spring Boot project

In this part of the tutorial, you'll add some more functionality to the application and discover more Kotlin language features, such as data classes. It requires changing the `MessageController` class to respond with a JSON document containing a collection of serialized objects.

Update your application

1. In the same package, next to the `DemoApplication.kt` file, create a `Message.kt` file.
2. In the `Message.kt` file, create a data class with two properties: `id` and `text`:

```
// Message.kt
package com.example.demo

data class Message(val id: String?, val text: String)
```

`Message` class will be used for data transfer: a list of serialized `Message` objects will make up the JSON document that the controller is going to respond to the browser request.

Data classes – data class Message
The main purpose of data classes in Kotlin is to hold data. Such classes are marked with the `data` keyword, and some standard functionality and some utility functions are often mechanically derivable from the class structure.

In this example, you declared `Message` as a data class as its main purpose is to store the data.

val and var properties

Properties in Kotlin classes can be declared either as:

- mutable, using the `var` keyword
- read-only, using the `val` keyword

The `Message` class declares two properties using `val` keyword, the `id` and `text`. The compiler will automatically generate the getters for both of these properties. It will not be possible to reassign the values of these properties after an instance of the `Message` class is created.

Nullable types – String?
Kotlin provides built-in support for nullable types. In Kotlin, the type system distinguishes between references that can hold `null` (nullable references) and those that cannot (non-nullable references).
For example, a regular variable of type `String` cannot hold `null`. To allow nulls, you can declare a variable as a nullable string by writing `String?`.

The `id` property of the `Message` class is declared as a nullable type this time. Hence, it is possible to create an instance of `Message` class by passing `null` as a value for `id`:

```
Message(null, "Hello!")
```

3. In the `MessageController.kt` file, instead of the `index()` function, create the `listMessages()` function returning a list of `Message` objects:

```
// MessageController.kt
package com.example.demo

import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController

@RestController
@RequestMapping("/")
class MessageController {
    @GetMapping
    fun listMessages() = listOf(
        Message("1", "Hello!"),
        Message("2", "Bonjour!"),
        Message("3", "Privet!"),
    )
}
```

Collections – listOf()
The Kotlin Standard Library provides implementations for basic collection types: sets, lists, and maps.
Each collection type can be read-only or mutable:

- A read-only collection comes with operations for accessing collection elements.
- A mutable collection comes also with write operations for adding, removing, and updating its elements.

The corresponding factory functions are also provided by the Kotlin Standard Library to create instances of such collections.

In this tutorial, you use the `listOf()` function to create a list of `Message` objects. This is the factory function to create a read-only list of objects: you can't add or remove elements from the list.
If it is required to perform write operations on the list, call the `mutableListOf()` function to create a mutable list instance.

Trailing comma

A trailing comma is a comma symbol after the last item of a series of elements:

```
Message("3", "Privet!"),
```

This is a convenient feature of Kotlin syntax and is entirely optional – your code will still work without them.

In the example above, creating a list of `Message` objects includes the trailing comma after the last `listOf()` function argument.

The response from `MessageController` will now be a JSON document containing a collection of `Message` objects.

> Any controller in the Spring application renders a JSON response by default if the Jackson library is on the classpath. As you specified the `spring-boot-starter-webmvc` dependency in the `build.gradle.kts` file, you received Jackson as a *transitive* dependency. Hence, the application responds with a JSON document if the endpoint returns a data structure that can be serialized to JSON.

Here is a complete code of the `DemoApplication.kt`, `MessageController.kt`, and `Message.kt` files:

```
// DemoApplication.kt
package com.example.demo

import org.springframework.boot.autoconfigure.SpringBootApplication
import org.springframework.boot.runApplication

@SpringBootApplication
class DemoApplication

fun main(args: Array<String>) {
    runApplication<DemoApplication>(*args)
}
```

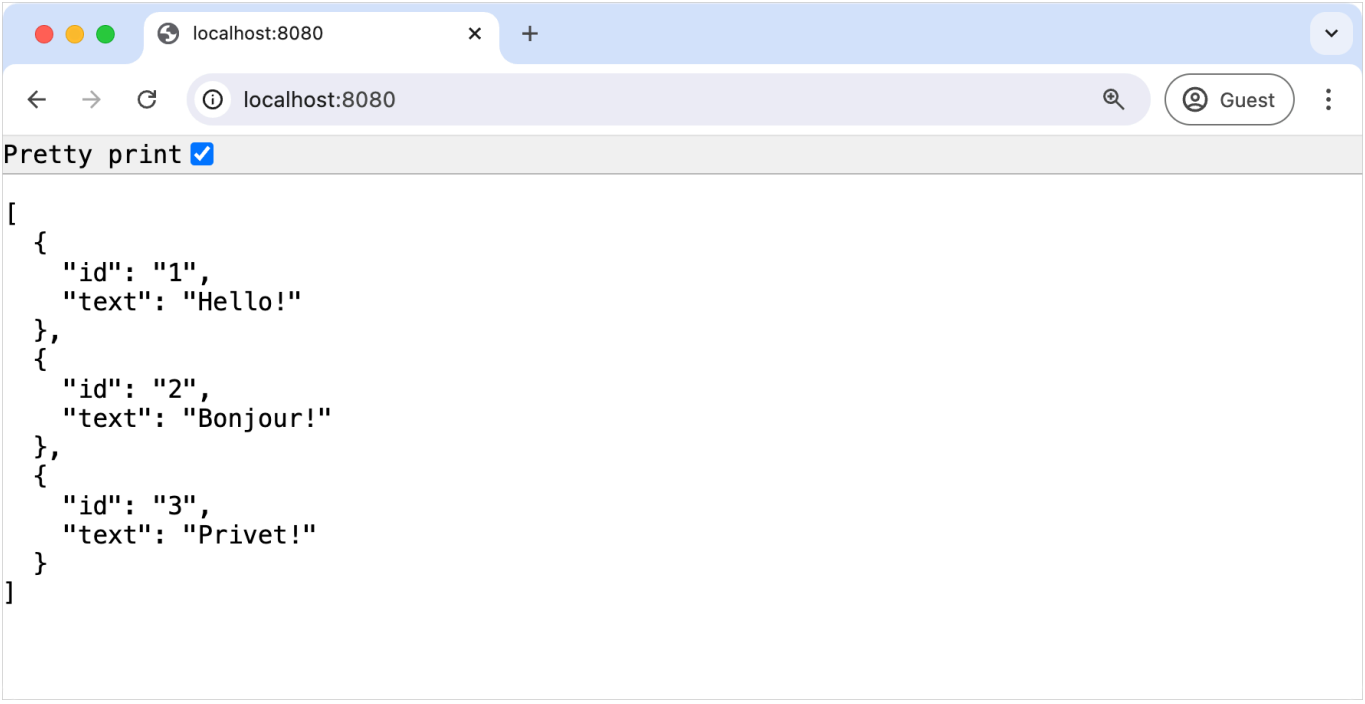
```
// MessageController.kt
package com.example.demo

import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController

@RestController
@RequestMapping("/")
class MessageController {
    @GetMapping
    fun listMessages() = listOf(
        Message("1", "Hello!"),
        Message("2", "Bonjour!"),
        Message("3", "Privet!"),
    )
}
```

```
// Message.kt
package com.example.demo

data class Message(val id: String?, val text: String)
```



Run the application

The Spring application is ready to run:

1. Run the application again.
2. Once the application starts, open the following URL:

   ```
   http://localhost:8080
   ```

   You will see a page with a collection of messages in JSON format:

Run the application

Next step

In the next part of the tutorial, you'll add and configure a database to your project and make HTTP requests.

Previous step

Next step

Add database support for Spring Boot project

In this part of the tutorial, you'll add and configure a database to your project using *Java Database Connectivity* (JDBC). In JVM applications, you use JDBC to interact with databases. For convenience, the Spring Framework provides the `JdbcTemplate` class that simplifies the use of JDBC and helps to avoid common errors.

Add database support

The common practice in Spring Framework-based applications is to implement the database access logic within the so-called *service* layer – this is where business logic lives. In Spring, you should mark classes with the

`@Service` annotation to imply that the class belongs to the service layer of the application. In this application, you will create the `MessageService` class for this purpose.

In the same package, create the `MessageService.kt` file and the `MessageService` class as follows:

```
// MessageService.kt
package com.example.demo

import org.springframework.stereotype.Service
import org.springframework.jdbc.core.JdbcTemplate

@Service
class MessageService(private val db: JdbcTemplate) {
    fun findMessages(): List<Message> = db.query("select * from messages") { response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }

    fun save(message: Message): Message {
        db.update(
            "insert into messages values ( ?, ? )",
            message.id, message.text
        )
        return message
    }
}
```

Constructor argument and dependency injection – (private val db: JdbcTemplate)

A class in Kotlin has a primary constructor. It can also have one or more secondary constructors. The primary constructor is a part of the class header, and it goes after the class name and optional type parameters. In our case, the constructor is `(val db: JdbcTemplate)`.

`val db: JdbcTemplate` is the constructor's argument:

```
@Service
      class MessageService(private val db: JdbcTemplate)
```

Trailing lambda and SAM conversion

The `findMessages()` function calls the `query()` function of the `JdbcTemplate` class. The `query()` function takes two arguments: an SQL query as a String instance, and a callback that will map one object per row:

```
db.query("...", RowMapper { ... } )
```

The `RowMapper` interface declares only one method, so it is possible to implement it via lambda expression by omitting the name of the interface. The Kotlin compiler knows the interface that the lambda expression needs to be converted to because you use it as a parameter for the function call. This is known as SAM conversion in Kotlin:

```
db.query("...", { ... } )
```

After the SAM conversion, the query function ends up with two arguments: a String at the first position, and a lambda expression at the last position. According to the Kotlin convention, if the last parameter of a function is a function, then a lambda expression passed as the corresponding argument can be placed outside the parentheses. Such syntax is also known as trailing lambda:

```
db.query("...") { ... }
```

Underscore for unused lambda argument

For a lambda with multiple parameters, you can use the underscore `_` character to replace the names of the parameters you don't use.

Hence, the final syntax for the query function call looks like this:

```
db.query("select * from messages") { response, _ ->
          Message(response.getString("id"), response.getString("text"))
      }
```

Update the MessageController class

Update `MessageController.kt` to use the new `MessageService` class:

```
// MessageController.kt
package com.example.demo

import org.springframework.http.ResponseEntity
import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.PostMapping
import org.springframework.web.bind.annotation.RequestBody
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController
import java.net.URI

@RestController
@RequestMapping("/")
class MessageController(private val service: MessageService) {
    @GetMapping
    fun listMessages() = service.findMessages()

    @PostMapping
    fun post(@RequestBody message: Message): ResponseEntity<Message> {
        val savedMessage = service.save(message)
        return ResponseEntity.created(URI("/${savedMessage.id}")).body(savedMessage)
    }
}
```

@PostMapping annotation

The method responsible for handling HTTP POST requests needs to be annotated with `@PostMapping` annotation. To be able to convert the JSON sent as HTTP Body content into an object, you need to use the `@RequestBody` annotation for the method argument. Thanks to having the Jackson library in the classpath of the application, the conversion happens automatically.

ResponseEntity

`ResponseEntity` represents the whole HTTP response: status code, headers, and body.

Using the `created()` method you configure the response status code (201) and set the location header indicating the context path for the created resource.

Update the MessageService class

The `id` for `Message` class was declared as a nullable String:

```
data class Message(val id: String?, val text: String)
```

It would not be correct to store the `null` as an `id` value in the database though: you need to handle this situation gracefully.

Update your code of the `MessageService.kt` file to generate a new value when the `id` is `null` while storing the messages in the database:

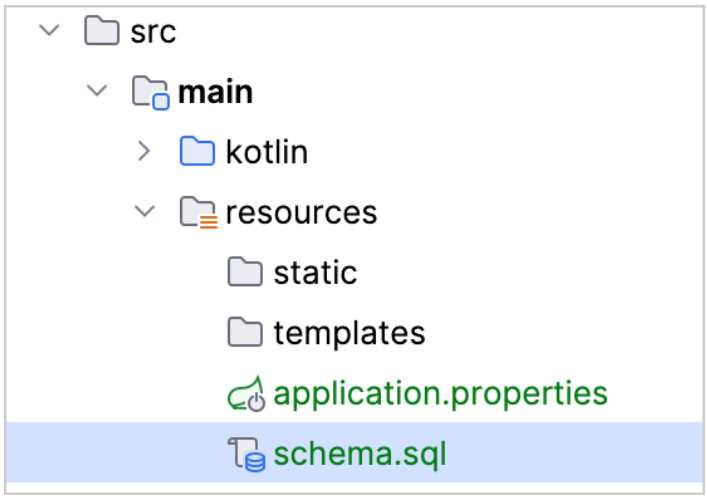
```
// MessageService.kt
package com.example.demo

import org.springframework.stereotype.Service
import org.springframework.jdbc.core.JdbcTemplate
import java.util.UUID

@Service
class MessageService(private val db: JdbcTemplate) {
    fun findMessages(): List<Message> = db.query("select * from messages") { response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }

    fun save(message: Message): Message {
        val id = message.id ?: UUID.randomUUID().toString() // Generate new id if it is null
        db.update(
            "insert into messages values ( ?, ? )",
            id, message.text
        )
        return message.copy(id = id) // Return a copy of the message with the new id
    }
}
```

Elvis operator – ?:



The code `message.id ?: UUID.randomUUID().toString()` uses the Elvis operator (if-not-null-else shorthand) `?:`. If the expression to the left of `?:` is not `null`, the Elvis operator returns it; otherwise, it returns the expression to the right. Note that the expression on the right-hand side is evaluated only if the left-hand side is `null`.

The application code is ready to work with the database. It is now required to configure the data source.

Configure the database

Configure the database in the application:

1. Create the `schema.sql` file in the `src/main/resources` directory. It will store the database object definitions:

Create database schema

2. Update the `src/main/resources/schema.sql` file with the following code:

```
-- schema.sql
CREATE TABLE IF NOT EXISTS messages (
id       VARCHAR(60)  PRIMARY KEY,
text     VARCHAR      NOT NULL
);
```

It creates the `messages` table with two columns: `id` and `text`. The table structure matches the structure of the `Message` class.

3. Open the `application.properties` file located in the `src/main/resources` folder and add the following application properties:

```
spring.application.name=demo
spring.datasource.driver-class-name=org.h2.Driver
spring.datasource.url=jdbc:h2:file:./data/testdb
spring.datasource.username=name
spring.datasource.password=password
spring.sql.init.schema-locations=classpath:schema.sql
spring.sql.init.mode=always
```

These settings enable the database for the Spring Boot application.
See the full list of common application properties in the Spring documentation.

Add messages to database via HTTP request

You should use an HTTP client to work with previously created endpoints. In IntelliJ IDEA, use the embedded HTTP client:

1. Run the application. Once the application is up and running, you can execute POST requests to store messages in the database.
2. Create the `requests.http` file in the project root folder and add the following HTTP requests:

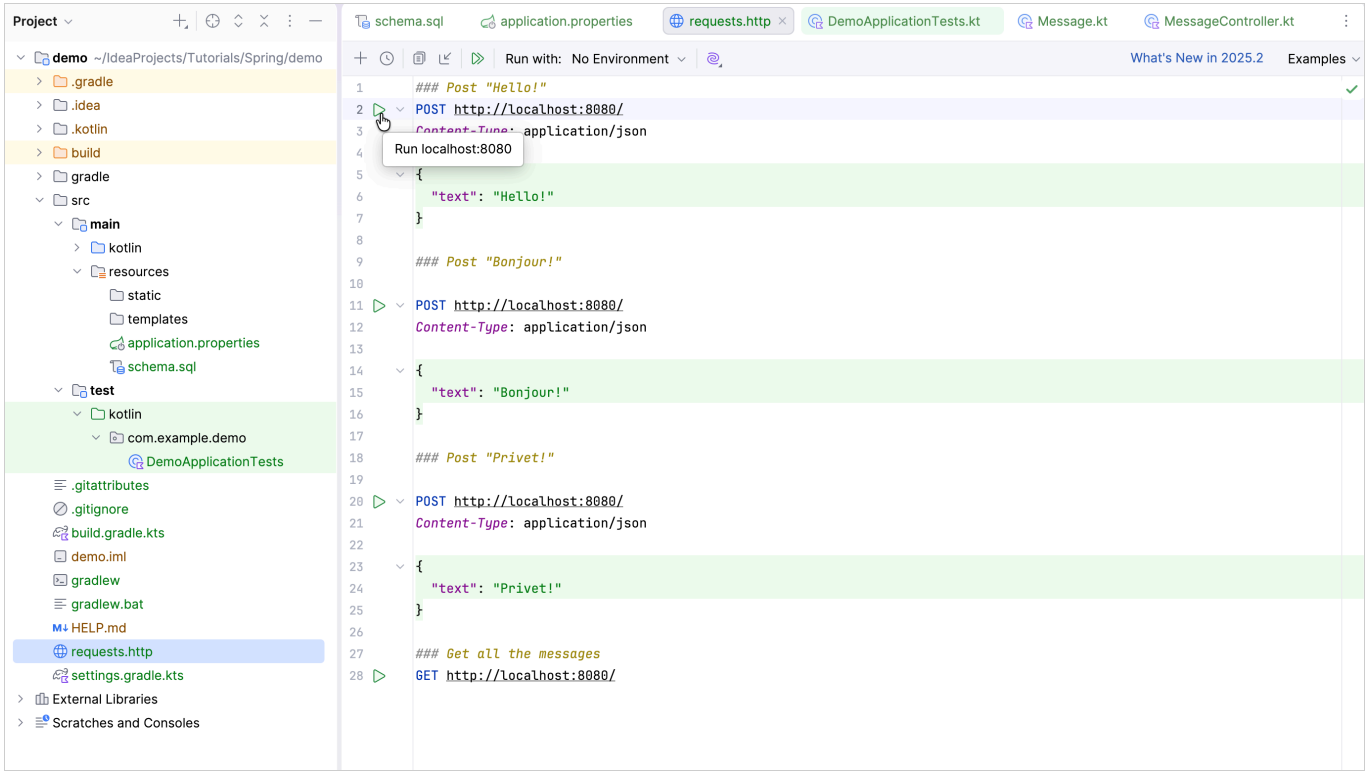
```
### Post "Hello!"
POST http://localhost:8080/
Content-Type: application/json

{
  "text": "Hello!"
}

### Post "Bonjour!"

POST http://localhost:8080/
Content-Type: application/json

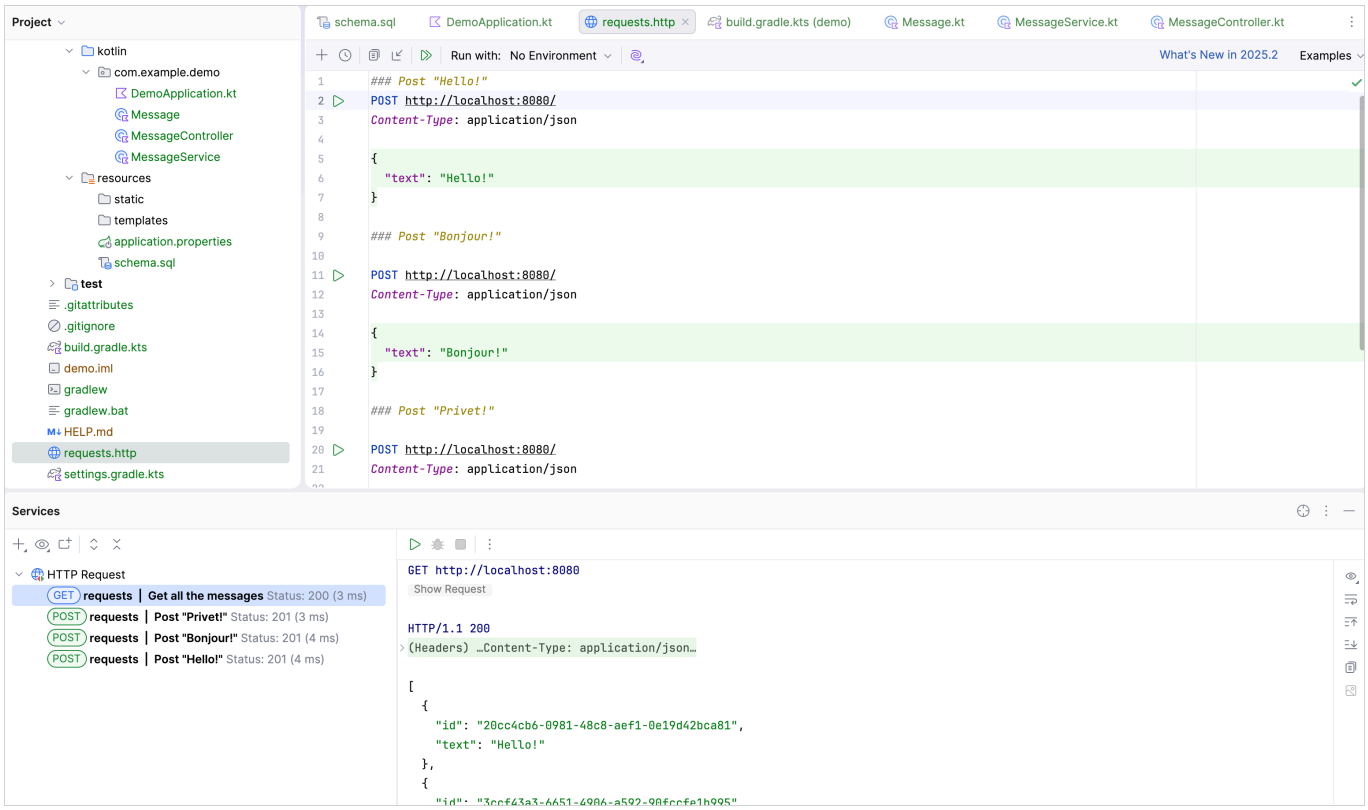
{
  "text": "Bonjour!"
}



### Post "Privet!"

POST http://localhost:8080/
Content-Type: application/json

{
  "text": "Privet!"
}



### Get all the messages
GET http://localhost:8080/
```

3. Execute all POST requests. Use the green **Run** icon in the gutter next to the request declaration. These requests write the text messages to the database:

Execute POST request

4. Execute the GET request and see the result in the **Run** tool window:

Execute GET requests

Alternative way to execute requests

You can also use any other HTTP client or the cURL command-line tool. For example, run the following commands in the terminal to get the same result:

```
curl -X POST --location "http://localhost:8080" -H "Content-Type: application/json" -d "{ \"text\": \"Hello!\" }"

curl -X POST --location "http://localhost:8080" -H "Content-Type: application/json" -d "{ \"text\": \"Bonjour!\" }"

curl -X POST --location "http://localhost:8080" -H "Content-Type: application/json" -d "{ \"text\": \"Privet!\" }"

curl -X GET --location "http://localhost:8080"
```

Retrieve messages by id

Extend the functionality of the application to retrieve the individual messages by id.

1. In the `MessageService` class, add the new function `findMessageById(id: String)` to retrieve the individual messages by id:

```kotlin
// MessageService.kt
package com.example.demo

import org.springframework.stereotype.Service
import org.springframework.jdbc.core.JdbcTemplate
import org.springframework.jdbc.core.query
import java.util.*

@Service
class MessageService(private val db: JdbcTemplate) {
    fun findMessages(): List<Message> = db.query("select * from messages") { response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }

    fun findMessageById(id: String): Message? = db.query("select * from messages where id = ?", id)
{ response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }.singleOrNull()

    fun save(message: Message): Message {
        val id = message.id ?: UUID.randomUUID().toString() // Generate new id if it is null
        db.update(
            "insert into messages values ( ?, ? )",
            id, message.text
        )
        return message.copy(id = id) // Return a copy of the message with the new id
    }
}
```

vararg argument position in the parameter list
The `query()` function takes three arguments:

- SQL query string that requires a parameter to run
- `id`, which is a parameter of type String
- `RowMapper` instance, which implemented by a lambda expression

The second parameter for the `query()` function is declared as a variable argument (`vararg`). In Kotlin, the position of the variable arguments parameter is not required to be the last in the parameters list.

singleOrNull() function
The `singleOrNull()` function returns a single element, or `null` if the array is empty or has more than one element with the same value.

> The `.query()` function used to fetch the message by its id is a Kotlin extension function provided by the Spring Framework. It requires an additional import `import org.springframework.jdbc.core.query` as demonstrated in the code above.

2. Add the new `index(...)` function with the `id` parameter to the `MessageController` class:

```kotlin
// MessageController.kt
package com.example.demo

import org.springframework.http.ResponseEntity
import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.PathVariable
import org.springframework.web.bind.annotation.PostMapping
import org.springframework.web.bind.annotation.RequestBody
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController
import java.net.URI

@RestController
@RequestMapping("/")
class MessageController(private val service: MessageService) {
    @GetMapping
    fun listMessages() = ResponseEntity.ok(service.findMessages())

    @PostMapping
    fun post(@RequestBody message: Message): ResponseEntity<Message> {
        val savedMessage = service.save(message)
        return ResponseEntity.created(URI("/${savedMessage.id}")).body(savedMessage)
    }

    @GetMapping("/{id}")
    fun getMessage(@PathVariable id: String): ResponseEntity<Message> =
        service.findMessageById(id).toResponseEntity()

    private fun Message?.toResponseEntity(): ResponseEntity<Message> =
        // If the message is null (not found), set response code to 404
        this?.let { ResponseEntity.ok(it) } ?: ResponseEntity.notFound().build()
}
```

Retrieving a value from the context path

The message `id` is retrieved from the context path by the Spring Framework as you annotated the new function by `@GetMapping("/{id}")`. By annotating the function argument with `@PathVariable`, you tell the framework to use the retrieved value as a function argument. The new function makes a call to `MessageService` to retrieve the individual message by its id.

Extension function with nullable receiver

Extensions can be defined with a nullable receiver type. If the receiver is `null`, then `this` is also `null`. So when defining an extension with a nullable receiver type, it is recommended performing a `this == null` check inside the function body.

You can also use the null-safe invocation operator (`?.`) to perform the null check as in the `toResponseEntity()` function above:

```kotlin
this?.let { ResponseEntity.ok(it) }
```

ResponseEntity

`ResponseEntity` represents the HTTP response, including the status code, headers, and body. It is a generic wrapper that allows you to send customized HTTP responses back to the client with more control over the content.

Here is a complete code of the application:

```kotlin
// DemoApplication.kt
package com.example.demo

import org.springframework.boot.autoconfigure.SpringBootApplication
import org.springframework.boot.runApplication

@SpringBootApplication
class DemoApplication

fun main(args: Array<String>) {
    runApplication<DemoApplication>(*args)
}
```

```kotlin
// Message.kt
package com.example.demo

data class Message(val id: String?, val text: String)
```

```kotlin
// MessageService.kt
package com.example.demo

import org.springframework.stereotype.Service
import org.springframework.jdbc.core.JdbcTemplate
import org.springframework.jdbc.core.query
import java.util.*

@Service
class MessageService(private val db: JdbcTemplate) {
    fun findMessages(): List<Message> = db.query("select * from messages") { response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }

    fun findMessageById(id: String): Message? = db.query("select * from messages where id = ?", id) {
response, _ ->
        Message(response.getString("id"), response.getString("text"))
    }.singleOrNull()

    fun save(message: Message): Message {
        val id = message.id ?: UUID.randomUUID().toString()
        db.update(
            "insert into messages values ( ?, ? )",
            id, message.text
        )
        return message.copy(id = id)
    }
}
```

```kotlin
// MessageController.kt
package com.example.demo

import org.springframework.http.ResponseEntity
import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.PathVariable
import org.springframework.web.bind.annotation.PostMapping
import org.springframework.web.bind.annotation.RequestBody
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController
import java.net.URI

@RestController
@RequestMapping("/")
class MessageController(private val service: MessageService) {
    @GetMapping
    fun listMessages() = ResponseEntity.ok(service.findMessages())

    @PostMapping
    fun post(@RequestBody message: Message): ResponseEntity<Message> {
        val savedMessage = service.save(message)
        return ResponseEntity.created(URI("/${savedMessage.id}")).body(savedMessage)
    }

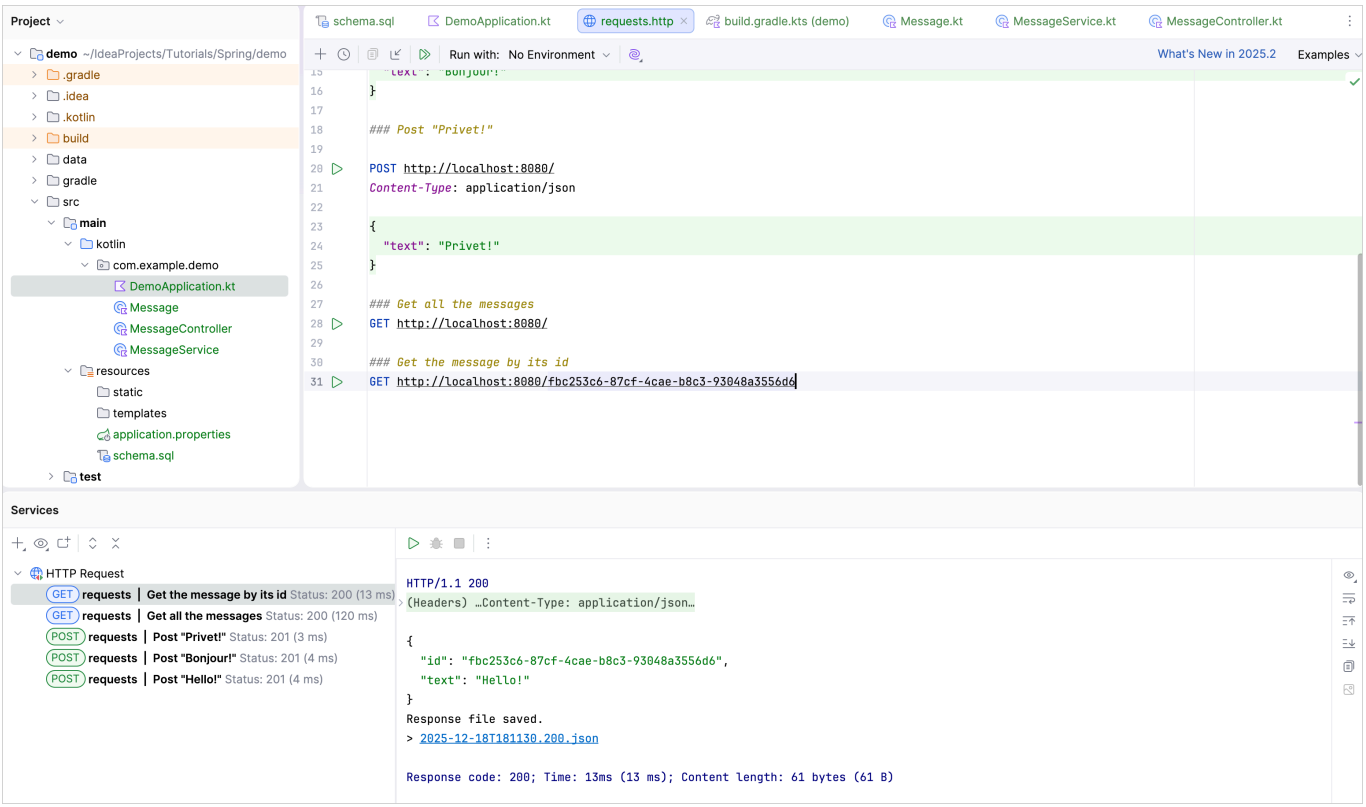
    @GetMapping("/{id}")
    fun getMessage(@PathVariable id: String): ResponseEntity<Message> =
        service.findMessageById(id).toResponseEntity()

    private fun Message?.toResponseEntity(): ResponseEntity<Message> =
        this?.let { ResponseEntity.ok(it) } ?: ResponseEntity.notFound().build()
}
```

Run the application

The Spring application is ready to run:

1. Run the application again.
2. Open the `requests.http` file and add the new GET request:



```
### Get the message by its id
GET http://localhost:8080/id
```

3. Execute the GET request to retrieve all the messages from the database.
4. In the **Run** tool window, copy one of the ids and add it to the request, like this:

```
### Get the message by its id
GET http://localhost:8080/f910aa7e-11ee-4215-93ed-1aeeac822707
```

> Put your message id instead of the mentioned above.

5. Execute the GET request and see the result in the **Run** tool window:

Retrieve message by its id

Next step

The final step shows you how to use a more popular connection to the database using Spring Data.

Previous step

Next step

Use Spring Data CrudRepository for database access

In this part, you will migrate the service layer to use the Spring Data `CrudRepository` instead of `JdbcTemplate` for database access. *CrudRepository* is a Spring Data interface for generic CRUD operations on a repository of a specific type. It provides several methods out of the box for interacting with a database.

Update your application

First, you need to adjust the `Message` class for work with the `CrudRepository` API:

1. Add the `@Table` annotation to the `Message` class to declare mapping to a database table.
   Add the `@Id` annotation before the `id` field.

> These annotations also require additional imports.

```kotlin
// Message.kt
package com.example.demo

import org.springframework.data.annotation.Id
import org.springframework.data.relational.core.mapping.Table

@Table("MESSAGES")
data class Message(@Id val id: String?, val text: String)
```

In addition, to make the use of the `Message` class more idiomatic, you can set the default value for `id` property to null and flip the order of the data class properties:

```kotlin
@Table("MESSAGES")
data class Message(val text: String, @Id val id: String? = null)
```

Now if you need to create a new instance of the `Message` class, you can only specify the `text` property as a parameter:

```kotlin
val message = Message("Hello") // id is null
```

2. Declare an interface for the `CrudRepository` that will work with the `Message` data class. Create the `MessageRepository.kt` file and add the following code to it:

```kotlin
// MessageRepository.kt
package com.example.demo

import org.springframework.data.repository.CrudRepository

interface MessageRepository : CrudRepository<Message, String>
```

3. Update the `MessageService` class. It will now use the `MessageRepository` instead of executing SQL queries:

```kotlin
// MessageService.kt
package com.example.demo

import org.springframework.data.repository.findByIdOrNull
import org.springframework.stereotype.Service

@Service
class MessageService(private val db: MessageRepository) {
    fun findMessages(): List<Message> = db.findAll().toList()

    fun findMessageById(id: String): Message? = db.findByIdOrNull(id)

    fun save(message: Message): Message = db.save(message)
}
```

Extension functions
The `findByIdOrNull()` function is an extension function for `CrudRepository` interface in Spring Data JDBC.

CrudRepository save() function
This function works with an assumption that the new object doesn't have an id in the database. Hence, the id should be null for insertion.

If the id isn't null, `CrudRepository` assumes that the object already exists in the database and this is an update operation as opposed to an insert operation. After the insert operation, the `id` will be generated by the data store and assigned back to the `Message` instance.

4. Update the messages table definition to generate the ids for the inserted objects. Since `id` is a string, you can use the `RANDOM_UUID()` function to generate the id value by default:

```
-- schema.sql
CREATE TABLE IF NOT EXISTS messages (
    id      VARCHAR(60)  DEFAULT RANDOM_UUID() PRIMARY KEY,
    text    VARCHAR      NOT NULL
);
```

5. Update the name of the database in the `application.properties` file located in the `src/main/resources` folder:

```
spring.application.name=demo
spring.datasource.driver-class-name=org.h2.Driver
spring.datasource.url=jdbc:h2:file:./data/testdb2
spring.datasource.username=name
spring.datasource.password=password
spring.sql.init.schema-locations=classpath:schema.sql
spring.sql.init.mode=always
```

Here is the complete code of the application:

```
// DemoApplication.kt
package com.example.demo

import org.springframework.boot.autoconfigure.SpringBootApplication
import org.springframework.boot.runApplication

@SpringBootApplication
class DemoApplication

fun main(args: Array<String>) {
    runApplication<DemoApplication>(*args)
}
```

```
// Message.kt
package com.example.demo

import org.springframework.data.annotation.Id
import org.springframework.data.relational.core.mapping.Table

@Table("MESSAGES")
data class Message(val text: String, @Id val id: String? = null)
```

```
// MessageRepository.kt
package com.example.demo

import org.springframework.data.repository.CrudRepository

interface MessageRepository : CrudRepository<Message, String>
```

```kotlin
// MessageService.kt
package com.example.demo

import org.springframework.data.repository.findByIdOrNull
import org.springframework.stereotype.Service

@Service
class MessageService(private val db: MessageRepository) {
    fun findMessages(): List<Message> = db.findAll().toList()

    fun findMessageById(id: String): Message? = db.findByIdOrNull(id)

    fun save(message: Message): Message = db.save(message)
}
```

```kotlin
// MessageController.kt
package com.example.demo

import org.springframework.http.ResponseEntity
import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.PathVariable
import org.springframework.web.bind.annotation.PostMapping
import org.springframework.web.bind.annotation.RequestBody
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RestController
import java.net.URI

@RestController
@RequestMapping("/")
class MessageController(private val service: MessageService) {
    @GetMapping
    fun listMessages() = ResponseEntity.ok(service.findMessages())

    @PostMapping
    fun post(@RequestBody message: Message): ResponseEntity<Message> {
        val savedMessage = service.save(message)
        return ResponseEntity.created(URI("/${savedMessage.id}")).body(savedMessage)
    }

    @GetMapping("/{id}")
    fun getMessage(@PathVariable id: String): ResponseEntity<Message> =
        service.findMessageById(id).toResponseEntity()

    private fun Message?.toResponseEntity(): ResponseEntity<Message> =
        // If the message is null (not found), set response code to 404
        this?.let { ResponseEntity.ok(it) } ?: ResponseEntity.notFound().build()
}
```

Run the application

Congratulations! The application is ready to run again. After replacing `JdbcTemplate` with `CrudRepository`, the functionality remains the same, so the application works just as before.

You can now run the POST and GET HTTP requests from the `requests.http` file and get the same results.

- Previous step

What's next

Get your personal language map to help you navigate Kotlin features and track your progress in studying the language:

Get the Kotlin language map

- Check out the Spring Framework documentation.
- Create a simple web application with protected resources in the Securing a web application tutorial.
- Complete the Building web applications with Spring Boot and Kotlin tutorial.

Create a task manager app with Spring Boot and Claude

In this tutorial, you'll learn how to use Claude to create a Kotlin app to manage tasks. The tutorial uses Spring Boot to manage the backend infrastructure, while Claude plans and develops the application.

If you prefer to create an app without the help of AI, you can follow our Create a web app with Kotlin and Spring Boot tutorial.

As with any AI-powered tool, Claude can make mistakes. Review Claude's changes carefully and only use it with code you trust. For more information on Claude's security policy, see Claude Code Docs.

Set up the environment

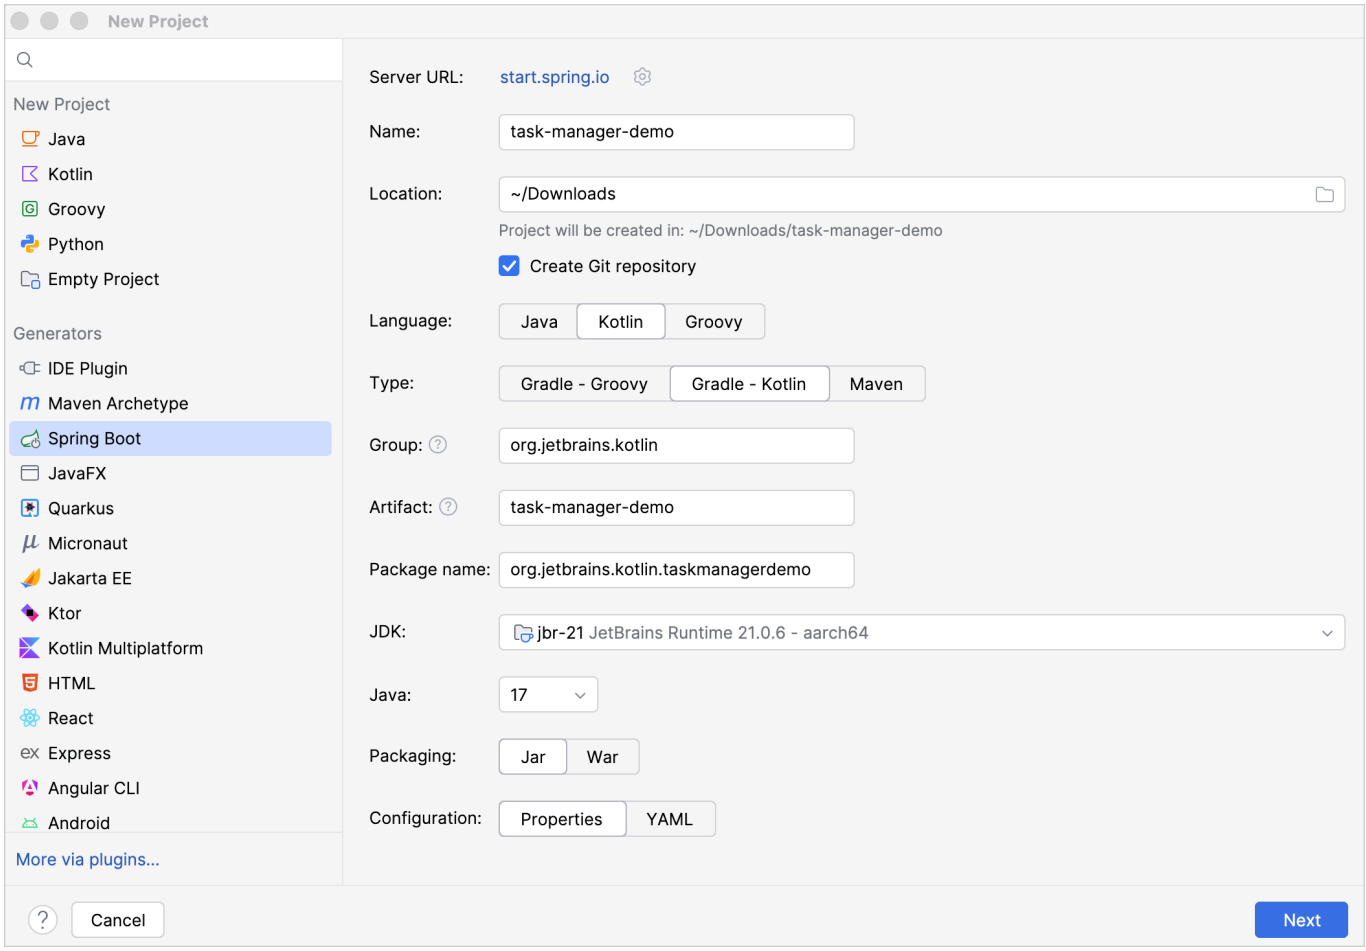
This tutorial uses Claude through the JetBrains AI Assistant, but you can also work through the tutorial steps using Claude Code in the terminal.

1. Download and install the latest version of IntelliJ IDEA.
2. Install the JetBrains AI Assistant.
3. Activate Claude Agent in one of the following ways:
   - Using a JetBrains AI subscription
   - Using an API key
   - Using Anthropic Console

Create a project

You can also create a Spring Boot project using Spring's web-based project generator.

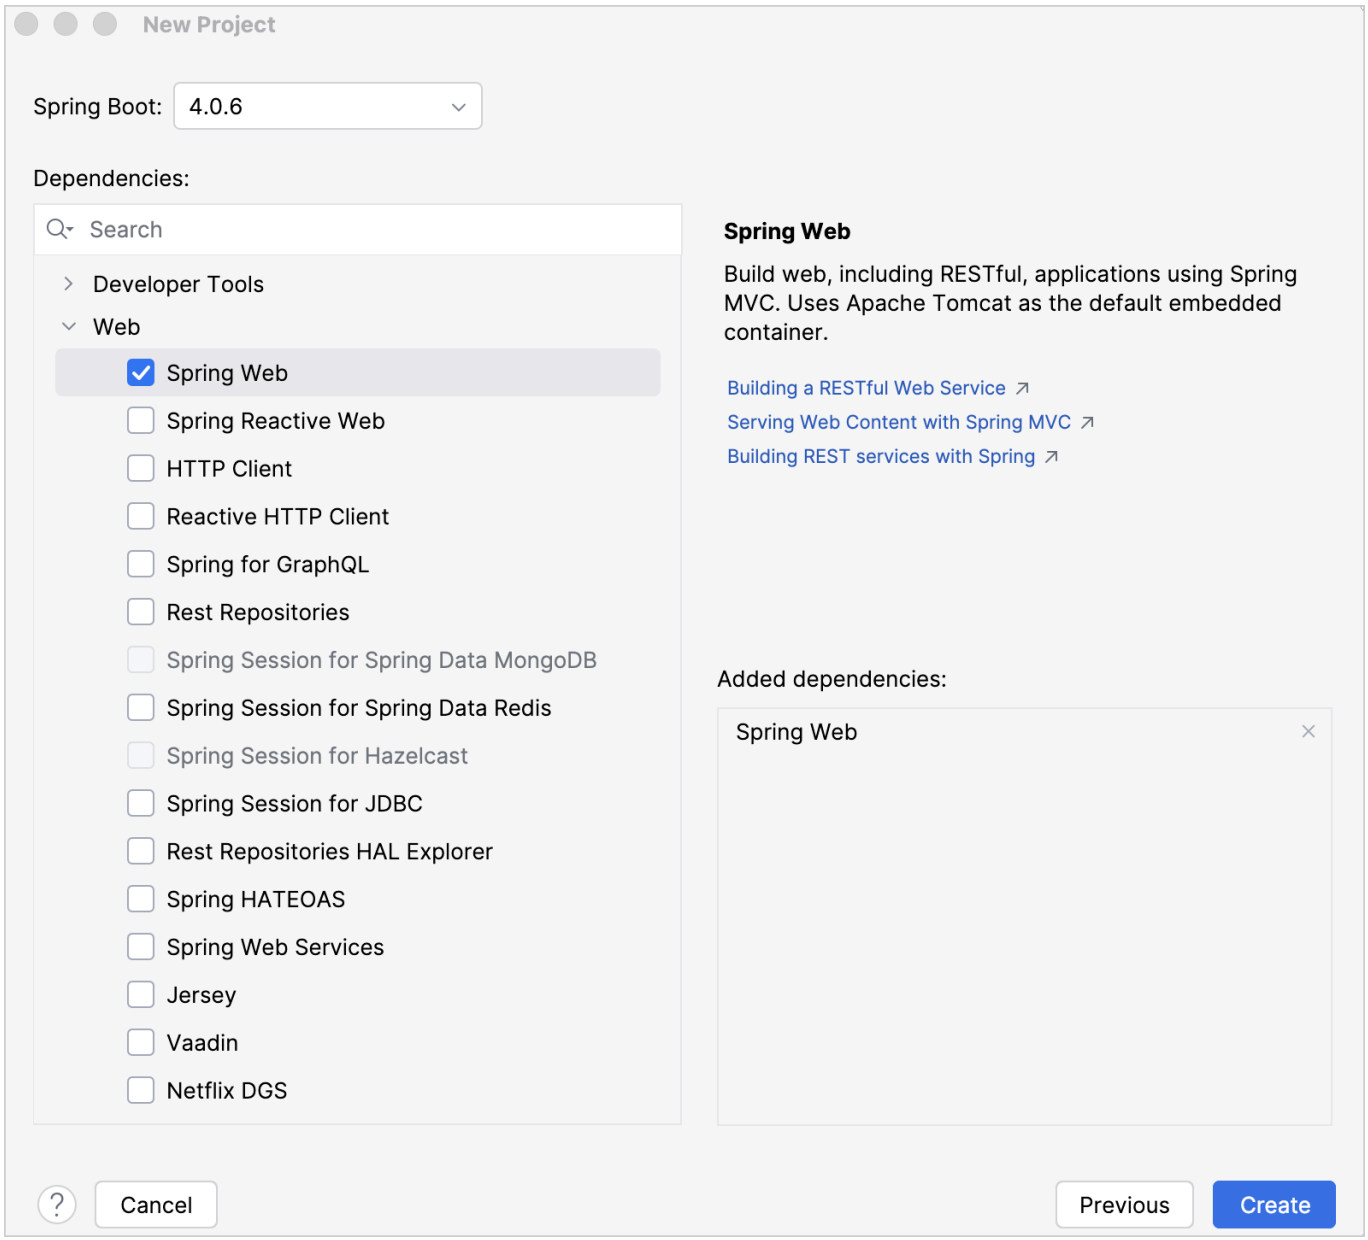
Create a new Spring Boot project in IntelliJ IDEA:



1. In IntelliJ IDEA, select **File** | **New** | **Project**.
2. In the panel on the left, select **New Project** | **Spring Boot**.
3. Specify the following fields and options in the **New Project** window:

- **Name**: task-manager-demo
- **Language**: Kotlin
- **Type**: Gradle - Kotlin

> This option specifies the build system and the DSL.



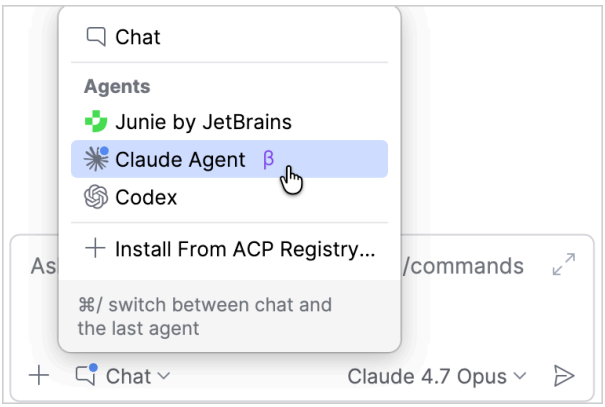
- **Package name**: org.jetbrains.kotlin.taskmanagerdemo
- **JDK**: jbr-21
- **Java**: 17

> If you don't have these Java and JDK versions installed, you can download them from the dropdown lists.

Create Spring Boot project

4. Make sure that you specified all the fields, then click **Next**.
5. Select the latest stable Spring Boot version in the **Spring Boot** field.
6. Select the **Web | Spring Web** dependency.

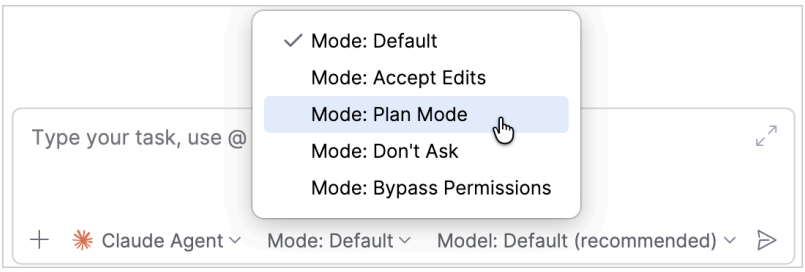
Set up Spring Boot project



7. Click **Create** to generate and set up the project.

   The IDE generates and opens the new project. It may take some time to download and import the project dependencies.

Create a development plan



In your project:

1. Open the **AI Chat** tool window. By default, the **Chat** mode is selected. Select **Claude Agent**.

Select Claude Agent

2. Click **Mode: Default** and select **Mode: Plan Mode**. Claude Agent is now ready to plan without executing actions.

Select Plan Mode

> For more information about the different operation modes, see Select operation mode.

3. Write a prompt asking Claude to create a task manager app. Share some details on what you think it should include. For example:

```
I'd like to create a task manager application for managing tasks, such as a grocery list.
It should have a basic UI and include categories, due dates, priorities, and status tracking.

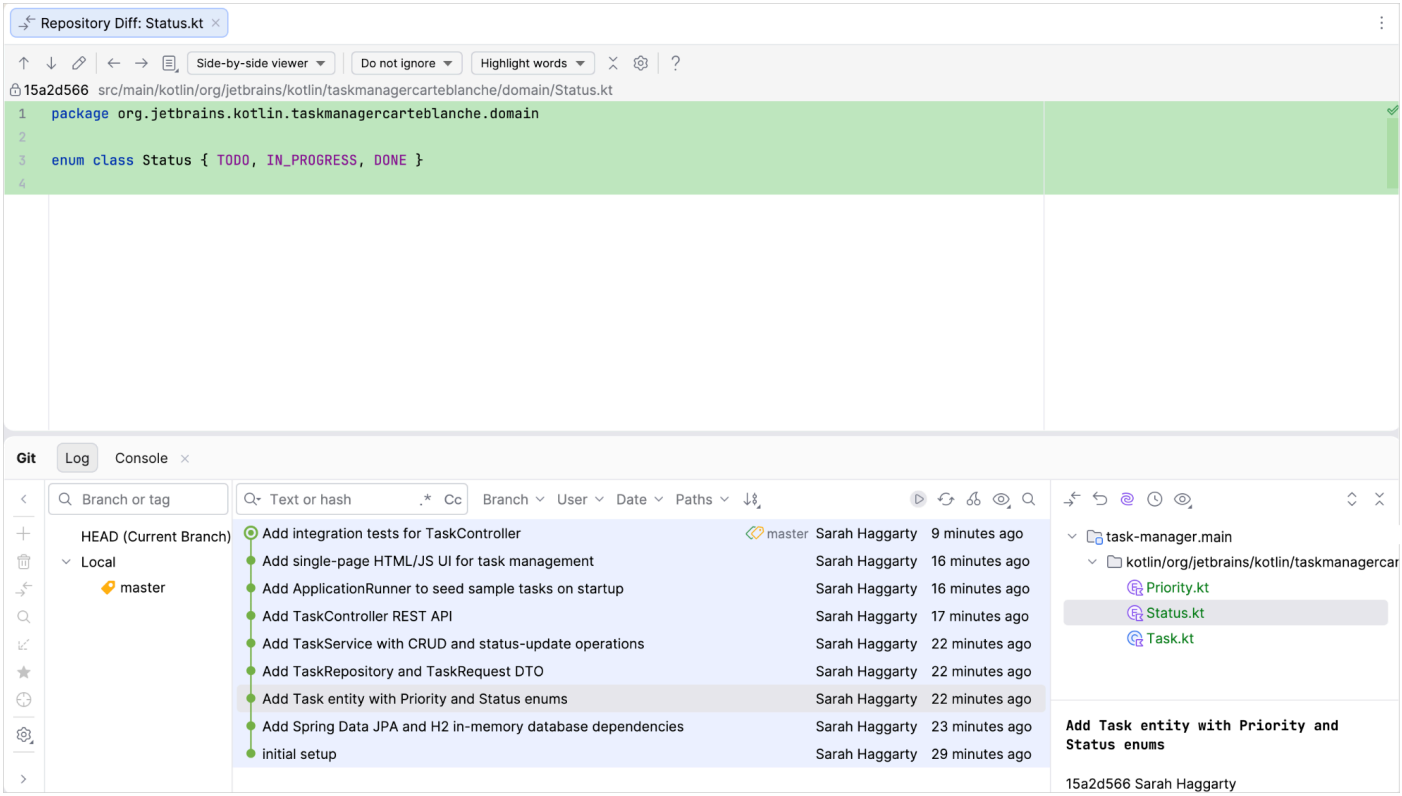
Use VCS while working. Work step by step and create commits at each stage so I can review the
changes afterward.
```

> For guidance on how to design your prompt, see Claude Code best practices.

Claude explores the existing project structure and suggests a plan.

4. Review the plan carefully before proceeding. If you want to make some modifications, select **No, keep planning** and share your follow-up comments.
5. When you're ready to proceed, select the **Yes ...** option that fits how much control you want over Claude's changes.

Ready to code



> For more information on the different options, see Claude Code permission modes.

6. Claude exits **Plan Mode** and begins working. Wait until the work is complete.

Review the commits

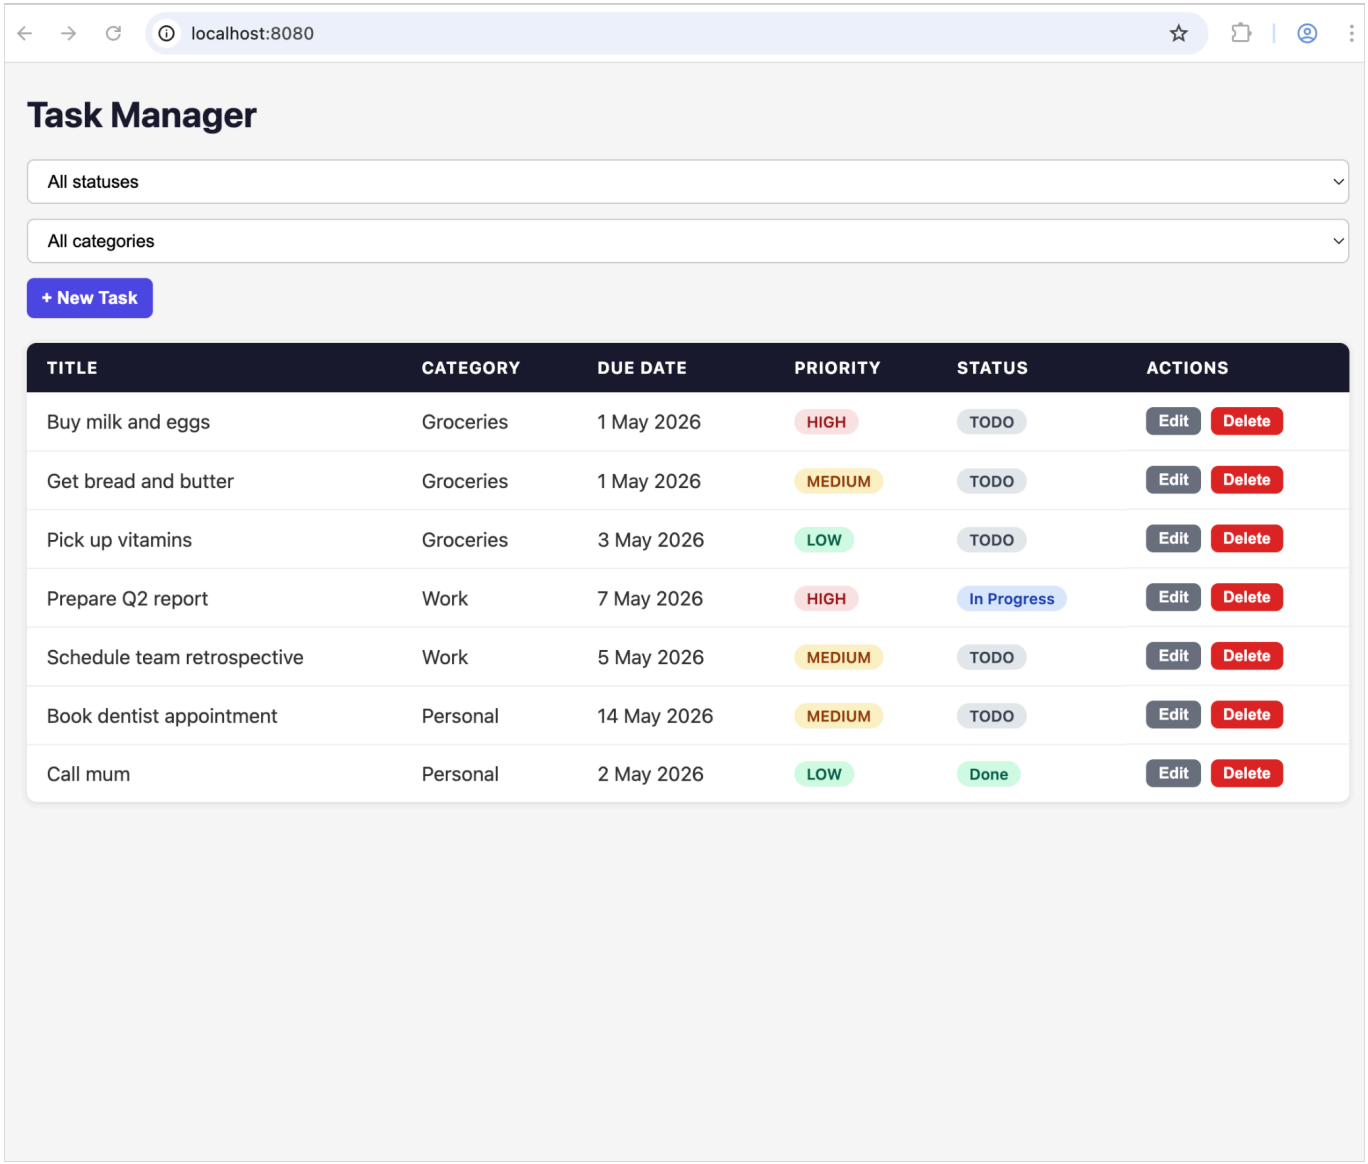
Before running the app, review the generated changes carefully:

1. Open the **Git** tool window to see the list of commits.
2. Select a commit and double-click each modified file to review the diff in IntelliJ IDEA's side-by-side viewer.

Side-by-side viewer

Run the app

Once you are happy with the changes, run the app:



1. Run the `bootRun` Gradle task or enter the following command in the terminal:

```
./gradlew bootRun
```

2. In a browser, open the localhost URL. The default is usually:

```
http://localhost:8080
```

You should now see the basic UI that Claude created.

Run the app

Since Claude designs the UI, your UI may look different from the version in this tutorial.

Test the app

Now it's time for you to test the app.

Test the UI manually

Start by testing the UI functionality. Try some simple actions:

1. Create a task and test the form fields.
2. Edit a task to check that changes persist.
3. Change the status of a task.
4. Delete a task.
5. Change the category of a task.

If any of these actions don't work, send a new prompt to Claude asking it to investigate and fix the problem.

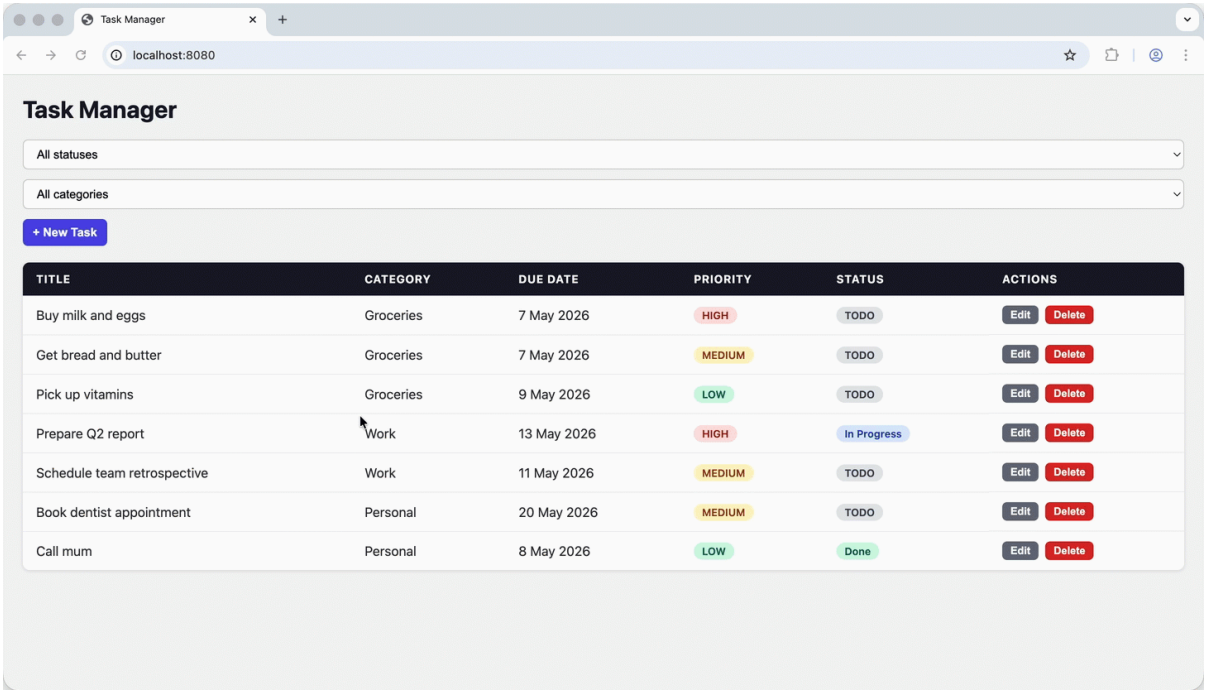
Run unit tests

Claude also creates some tests automatically. Check that all the tests pass by running:

```
./gradlew test
```

Alternatively, in the `src/test` directory, open a test and click the run icon in the gutter. A successful test shows .

If any test doesn't work, send a new prompt to Claude asking it to investigate and fix the problem.



Make refinements

Now that the initial task is complete, you can make refinements. For example, let's improve the UI so users can edit tasks directly in the list.

You can send a prompt like:

```
As a next step, allow users to edit tasks inline. For example, let users click on a task title to edit
it directly in the list,
and update fields like priority, due date, or status without leaving the current view.
This change should make the app feel faster and more intuitive to use.
```

Just as before, Claude explores the existing project structure and suggests a plan. After you accept the plan, wait for Claude to finish, review the changes, and then run the app again.

Congratulations! You used Claude to plan, build, test, and refine a Kotlin Spring Boot application directly in IntelliJ IDEA.

What's next?

- Check out our tutorial on using Junie with Kotlin AI skills

Overview

Kotlin, through Kotlin Multiplatform, offers two approaches for web development:

- JavaScript-based (using the Kotlin/JS compiler)
- WebAssembly-based (using the Kotlin/Wasm compiler)

Both approaches let you share code in your web app, but they support different use cases. They also differ in technical aspects such as target browser support.

Kotlin/JS

Kotlin/JS enables running Kotlin apps in JavaScript (JS) environments by transpiling your code, standard library, and all the supported dependencies into JS.

When developing with Kotlin/JS, you can run your apps either in the browser or the Node.js environment.

> For information about configuring Kotlin/JS targets, see the Configure a Gradle project guide.

Kotlin/JS use cases

Kotlin/JS is suitable when your goal is to:

- Share business logic with a JavaScript/TypeScript codebase.
- Build non-shareable web apps with Kotlin.

Share business logic with a JavaScript/TypeScript codebase

If you need to share Kotlin code (such as domain or data logic) with a native JavaScript/TypeScript app, the Kotlin/JS target offers:

- Direct interoperability with JavaScript/TypeScript.
- Minimal overhead in interoperability (for example, avoiding unnecessary data copying). This allows the shared code to integrate smoothly into a JS-based workflow.

Build web apps with Kotlin without sharing the code

For projects where the web app is implemented entirely in Kotlin, without sharing it with other platforms (iOS, Android, or Desktop), an HTML-based solution provides better control.

HTML-based solutions improve SEO and accessibility. They also provide better browser integration, including features such as find on page and page translation.

For HTML-based solutions, Kotlin/JS supports multiple approaches:

- Using Compose HTML-based frameworks, such as Kobweb or Kilua, to build UIs with a Compose-style architecture.
- Using React-based solutions with Kotlin wrappers to implement React components in Kotlin.

Beta

Kotlin/Wasm

Kotlin/Wasm compiles Kotlin code into WebAssembly (Wasm), enabling apps to run across environments and devices that support Wasm while meeting Kotlin's requirements.

In browsers, Kotlin/Wasm lets you build web apps with Compose Multiplatform. Outside the browser, it runs in standalone Wasm virtual machines, using the WebAssembly System Interface (WASI) to access platform APIs.

When developing with Kotlin/Wasm, you can target:

- `wasmJs`: for running in browsers or Node.js.
- `wasmWasi`: for running in Wasm environments supporting WASI, such as Wasmtime, WasmEdge, and so on.

For information about configuring Kotlin/Wasm targets, see the Configure a Gradle project guide.

Kotlin/Wasm use cases

Use Kotlin/Wasm if you want to share both logic and UI across multiple platforms.

Build cross-platform apps with Compose Multiplatform

If you want to share both logic and UI across multiple platforms, including web, Kotlin/Wasm with Compose Multiplatform provides a shared UI layer:

- Ensuring a consistent UI implementation for all platforms.
- Using Wasm for improved rendering and smoother UI updates, such as responsive animations.
- Supporting the latest version of the WebAssembly Garbage Collection (WasmGC) proposal, which allows Kotlin/Wasm to run on all major modern browsers.

Choose your web approach

The table below summarizes the recommended target based on your use case:

Use case	Recommended target	Description
Sharing business logic, but using web-native UI	Kotlin/JS	Offers straightforward interop with JS and minimal overhead.
Sharing both UI and business logic	Kotlin/Wasm	Provides better performance for rendering with Compose Multiplatform.

Use case	Recommended target	Description
Non-shareable UI	Kotlin/JS	Allows building UIs with HTML-based frameworks like Kobweb, Kilua, or React, using existing JS ecosystems and tooling.

If you need guidance on selecting the appropriate target, join our Slack community. You can ask about platform differences, performance considerations, and recommended practices for specific use cases.

Compatibility mode for web targets

You can enable compatibility mode for your web app to ensure it works on all browsers out of the box. In this mode, you can build the UI with Wasm for modern browsers, while older ones fall back to JS.

Compatibility mode is achieved through cross-compilation for both the `js` and `wasmJs` targets. See more information about compatibility mode for web and how to enable it.

Kotlin/JavaScript

Kotlin/JavaScript (Kotlin/JS) lets you transpile your Kotlin code, the Kotlin standard library, and any compatible dependencies to JavaScript. This way, your Kotlin applications can run in any environment that supports JavaScript.

Use Kotlin/JS through the Kotlin Multiplatform Gradle plugin (`kotlin.multiplatform`) to configure and manage Kotlin projects targeting JavaScript from a single place.

The Kotlin Multiplatform Gradle plugin gives you access to features such as controlling your application's bundling and adding JavaScript dependencies directly from npm. To get an overview of the available configuration options, see Set up a Kotlin/JS project.

The current implementation of Kotlin/JS targets the ES5 and ES2015 standards.

Use cases for Kotlin/JS

Here are some common ways to use Kotlin/JS:

- **Sharing common logic between frontend and JVM backend**

  If your backend is written in Kotlin or another JVM-compatible language, you can share common code between your web application and the backend. This includes data-transfer objects (DTOs), validation and authentication rules, abstractions for REST API endpoints, and more.

- **Sharing common logic between Android, iOS, and web clients**

  You can share business logic between your web interface and mobile applications for Android and iOS, while keeping native user interfaces. This avoids duplicating common functionality such as REST API abstractions, user authentication, form validation, and domain models.

- **Building frontend web applications using Kotlin/JS**

Use Kotlin to develop traditional web frontends while integrating with existing tools and libraries:

- If you are familiar with Android development, you can build web applications with Compose-based frameworks like Kobweb or Kilua.
- Build fully type-safe React applications with Kotlin/JS using the Kotlin wrappers for common JavaScript libraries provided by JetBrains. The Kotlin wrappers (`kotlin-wrappers`) offer abstractions and integrations for React and other JavaScript frameworks.

  These wrappers also support complementary libraries, like React Redux, React Router, and styled-components. You can also use third-party React components and component libraries through interoperability with the JavaScript ecosystem.
- Use Kotlin/JS frameworks, which integrate with the Kotlin ecosystem and support concise and expressive code.

- **Building multiplatform applications that support older browsers**

  With Compose Multiplatform, you can use Kotlin to build applications and reuse mobile and desktop user interfaces in your web projects. While Kotlin/Wasm is the primary target for this purpose, you can extend support to older browsers by also targeting Kotlin/JS.
- **Building server-side and serverless applications using Kotlin/JS**

  The Node.js target in Kotlin/JS lets you create applications for server-side or serverless environments on a JavaScript runtime. This offers a fast startup and low memory usage. The `kotlinx-nodejs` library provides type-safe access to the Node.js API from Kotlin.

Depending on your use case, Kotlin/JS projects can use compatible libraries from the Kotlin ecosystem and third-party libraries from the JavaScript and TypeScript ecosystems.

To use third-party libraries from your Kotlin code, you can create your own type-safe wrappers or use community-maintained wrappers. Additionally, you can use the Kotlin/JS dynamic type, which lets you skip strict typing and library wrappers, at the cost of type safety.

Kotlin/JS is also compatible with the most common module systems: ESM, CommonJS, UMD, and AMD. This allows you to produce and consume modules and integrate with the JavaScript ecosystem in a structured manner.

Share your use cases

The list in Use cases for Kotlin/JS isn't exhaustive. Feel free to experiment with different approaches and find the best fit for your project.

Share your use cases, experiences, and questions with the Kotlin/JS community in the #javascript channel on Kotlin Slack.

Get started with Kotlin/JS

Explore the fundamentals and initial steps to start working with Kotlin/JS:

- If you're new to Kotlin, start by reviewing the basic syntax and exploring the Kotlin tour.
- Check out the list of Kotlin/JS sample projects for inspiration. These samples contain useful code snippets and patterns that can help you get started with your projects.
- If you’re new to Kotlin/JS, start with the setup guide before exploring more advanced topics.

Would you like to try Kotlin/JS yourself?

Get started with Kotlin/JS

Sample projects for Kotlin/JS

The following table lists a set of sample projects demonstrating various Kotlin/JS use cases, architectures, and code-sharing strategies:

Project	Description
Petclinic with common code between Spring and Angular	Demonstrates how to avoid code duplication in enterprise applications by sharing data-transfer objects, validation and authentication rules, and abstractions for REST API endpoints. The code is shared between a Spring Boot backend and a Angular frontend.
Fullstack Conference CMS	Showcases multiple code-sharing approaches, ranging from the simplest to all-in code sharing between Ktor, Jetpack Compose, and Vue.js applications.
Todo App on a Compose-HTML-based Kobweb framework	Shows how to create a to-do list application by reusing an approach familiar to Android developers. It builds a client UI application powered by the Kobweb framework.
Simple logic sharing between Android, iOS, and web	Contains a template for building a project with common logic in Kotlin, which is consumed in platform-native UI applications on Android (Jetpack Compose), iOS (SwiftUI), and web (React).
Full-stack collaborative to-do list	Shows how to create a to-do list application for collaborative work using Kotlin Multiplatform with JS and JVM targets. It uses Ktor for the backend, and Kotlin/JS with React for the frontend.

Kotlin/JS frameworks

Kotlin/JS frameworks simplify web development by providing ready-to-use components, routing, state management, and other tools for building modern web applications.

Check the available frameworks for Kotlin/JS written by different authors.

Join the Kotlin/JS community

You can join the #javascript channel in the official Kotlin Slack to chat with the community and the Kotlin/JS team.

What's next

- Set up a Kotlin/JS project
- Run Kotlin/JS projects
- Debug Kotlin/JS code
- Run tests in Kotlin/JS

Get started with Kotlin/JS

This tutorial shows how to create a web application for the browser using Kotlin/JavaScript (Kotlin/JS). To create your app, choose the tool that best fits your workflow:

- IntelliJ IDEA: clone the project template from version control and work on it in IntelliJ IDEA.
- Gradle build system: create build files for your project manually to better understand how the setup works under the hood.

> Besides targeting the browser, with Kotlin/JS you can compile for other environments. For more information, see Execution environments.

Create your application in IntelliJ IDEA

To create your Kotlin/JS web application, you can use IntelliJ IDEA.

Set up the environment

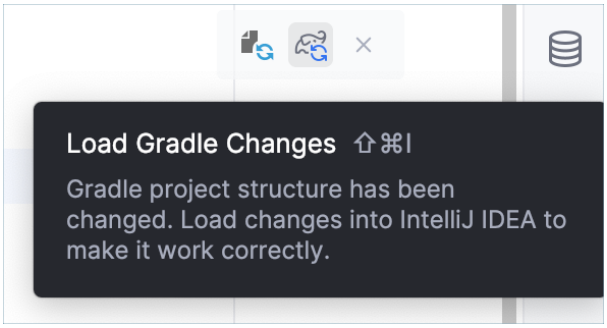
1. Download and install the latest version of IntelliJ IDEA.
2. Install the Kotlin Multiplatform IDE plugin (not to be confused with the Kotlin Multiplatform Gradle plugin).

Create your project

1. In IntelliJ IDEA, select **File** | **New** | **Project from Version Control**.
2. Enter the URL of the Kotlin/JS template project:

   ```
   https://github.com/Kotlin/kmp-js-wizard
   ```

3. Click **Clone**.



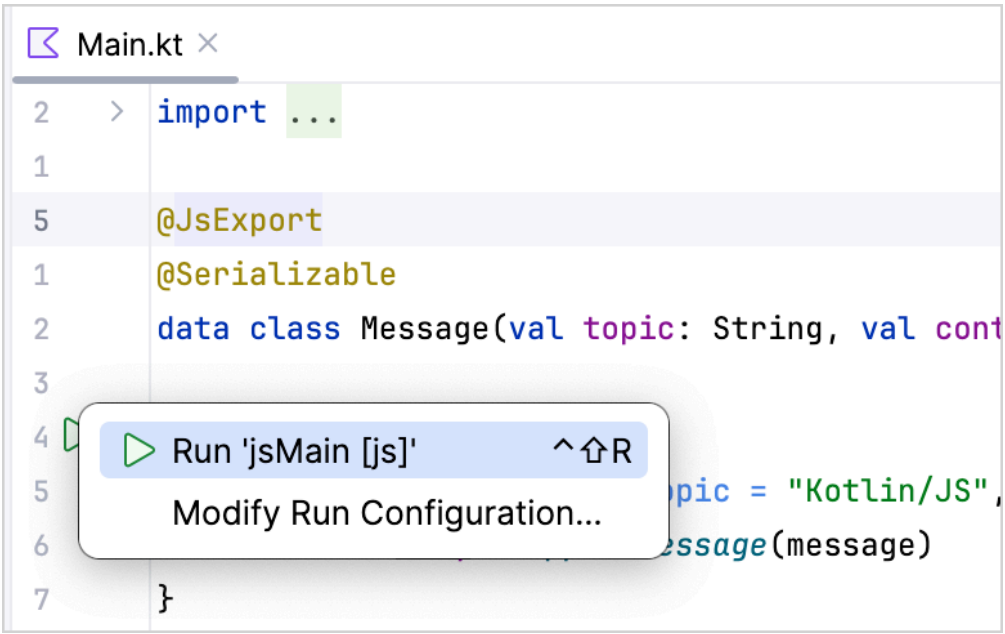
Configure your project

1. Open the `kmp-js-wizard/gradle/libs.versions.toml` file. It contains the version catalog for project dependencies.
2. Make sure the Kotlin version matches the version of the Kotlin Multiplatform Gradle plugin, which is required to create a web application targeting Kotlin/JS:

   ```
   [versions]
   kotlin = "2.4.20"

   [plugins]
   kotlin-multiplatform = { id = "org.jetbrains.kotlin.multiplatform", version.ref = "kotlin" }
   ```

3. Synchronize the Gradle files (if you updated the `libs.versions.toml` file). Click the **Load Gradle Changes** icon that appears in your build file.



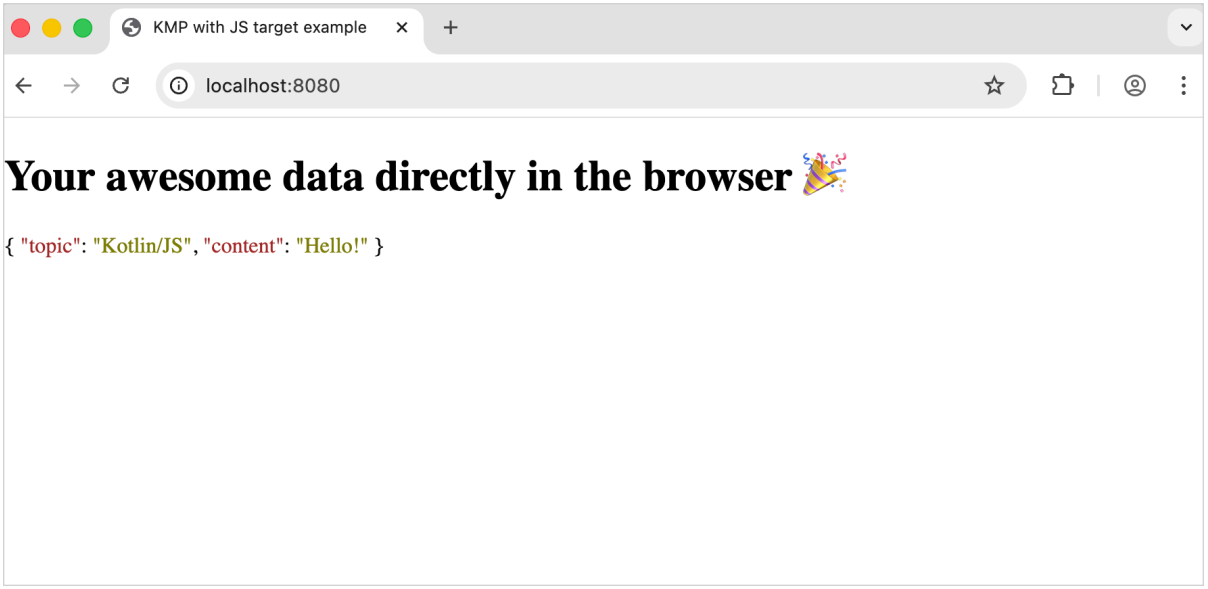
Load the Gradle changes button

Alternatively, click the refresh button in the Gradle tool window.

For more information about the Gradle configuration for multiplatform projects, see the Multiplatform Gradle DSL reference.

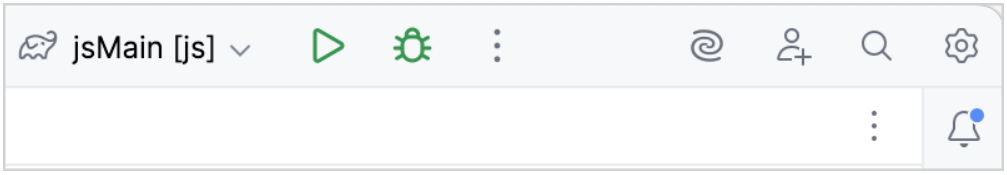
Build and run the application

1. Open the `src/jsMain/kotlin/Main.kt` file.
   - The `src/jsMain/kotlin/` directory contains the main Kotlin source files for the JavaScript target of your project.
   - The `Main.kt` file includes code that uses the `kotlinx.browser` API to render "Hello, Kotlin/JS!" on the browser page.
2. Click the **Run** icon in the `main()` function to run the code.



Run the application

The web application opens automatically in your browser. Alternatively, you can open the following URL in your browser when the run is finished:

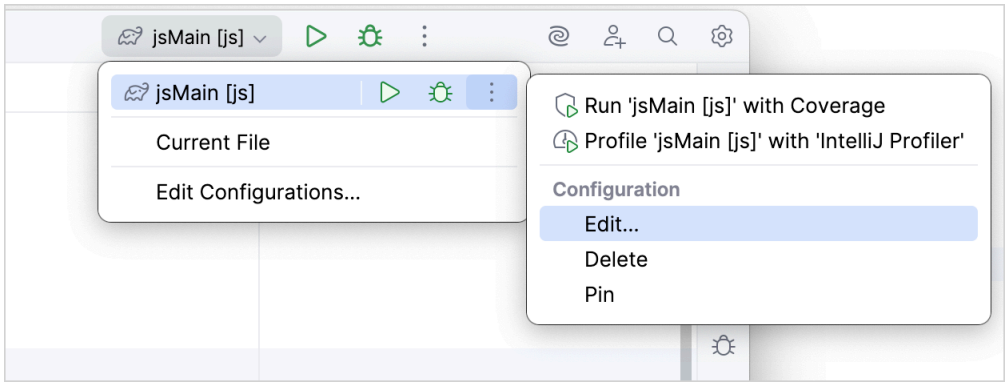


```
http://localhost:8080/
```

You can see the web application:

Application output

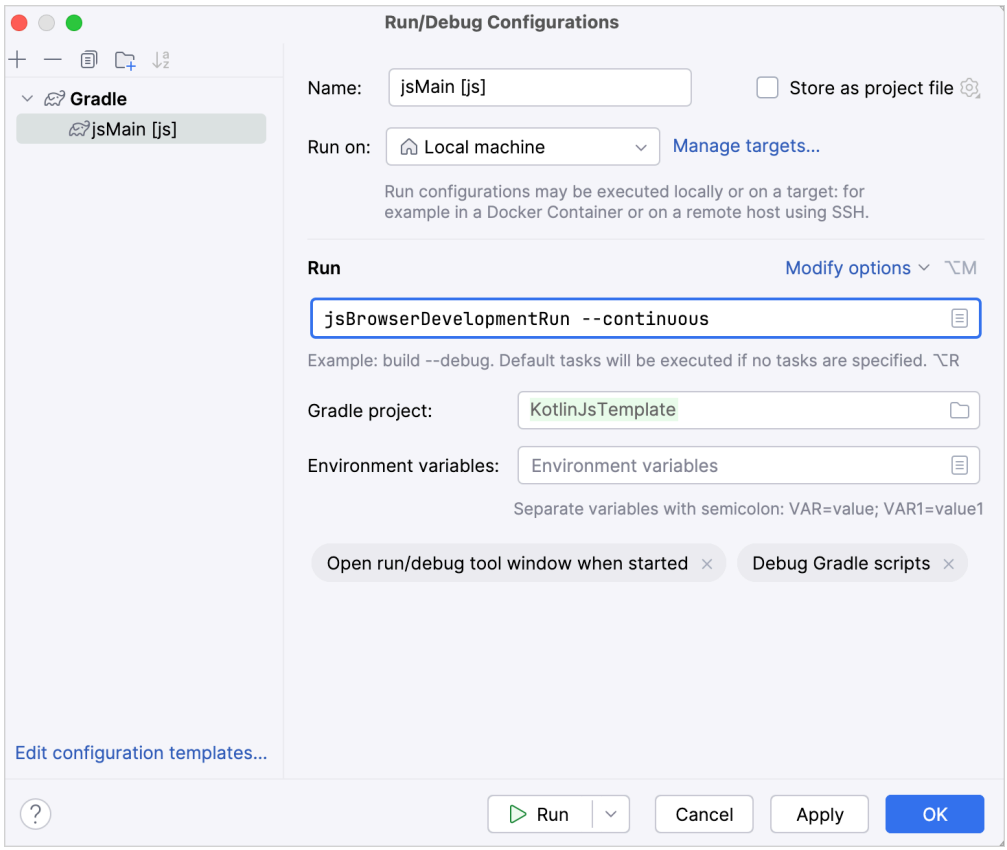
After you run the application for the first time, IntelliJ IDEA creates its corresponding run configuration (**jsMain [js]**) at the top bar:



Gradle run configuration

> In IntelliJ IDEA with an Ultimate subscription, you can use the JS Debugger to debug code directly from the IDE.

Enable continuous build



Gradle can automatically rebuild your project whenever you make changes:

1. Select **jsMain [js]** in the list of run configurations and click **More Actions** | **Edit**.

Gradle edit run configuration

2. In the **Run/Debug Configurations** dialog, enter `jsBrowserDevelopmentRun --continuous` within the **Run** field.

Continuous run configuration

3. Click **OK**.

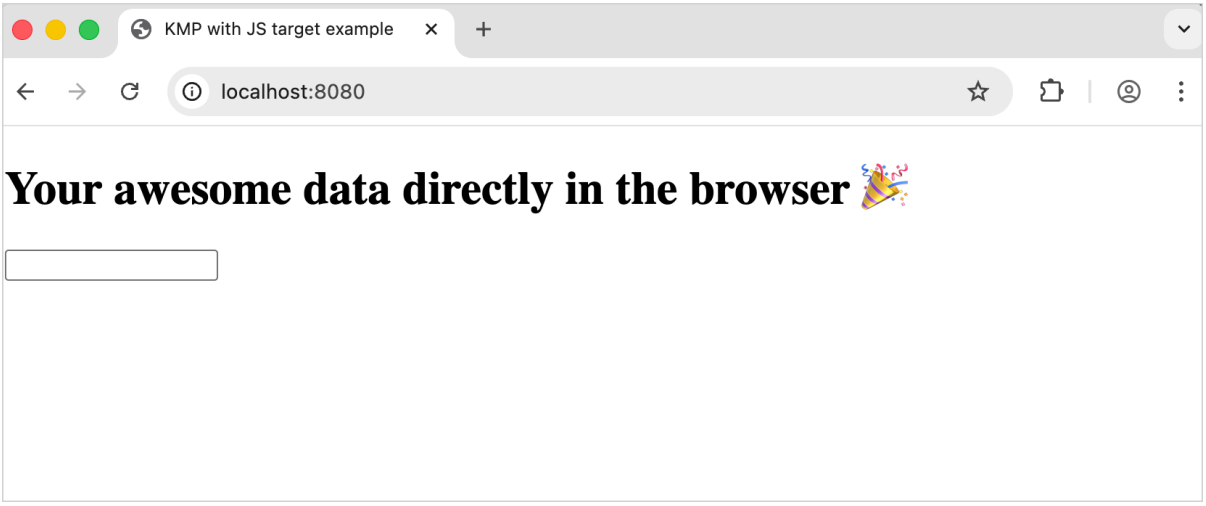
Now, when you run the application and make any changes, Gradle automatically performs incremental builds for the project and hot-reloads the browser whenever you save (Ctrl + S/Cmd + S) or change a class file.

Modify the application

Modify the application to add a feature that counts the number of letters in a word.

Add an input element

1. In the `src/jsMain/kotlin/Main.kt` file, add an HTML input element through an extension function to read user input:



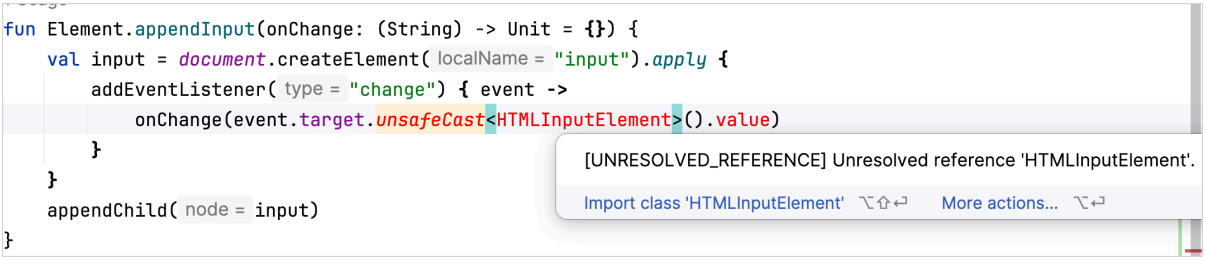
```
// Replace the Element.appendMessage() function
fun Element.appendInput() {
    val input = document.createElement("input")
    appendChild(input)
}
```

2. Call the `appendInput()` function in `main()`. It displays an input element on the page:

```
fun main() {
    // Replace document.body!!.appendMessage(message)
    document.body?.appendInput()
}
```

3. Run the application again.

   Your application looks like this:



Application with an input element

Add an input event handling

1. Add a listener inside the `appendInput()` function to read the input value and react to changes:

```
// Replace the current appendInput() function
fun Element.appendInput(onChange: (String) -> Unit = {}) {
    val input = document.createElement("input").apply {
        addEventListener("change") { event ->
            onChange(event.target.unsafeCast<HTMLInputElement>().value)
        }
    }
    appendChild(input)
}
```

2. Follow the IDE's suggestions to import the `HTMLInputElement` dependency.

Import dependencies

3. Call the `onChange` callback in `main()`. It reads and handles the input value:

```
fun main() {
    // Replace document.body?.appendInput()
    document.body?.appendInput(onChange = { println(it) })
}
```

Add an output element

1. Add a text element to display the output by defining an extension function that creates a paragraph:

```
fun Element.appendTextContainer(): Element {
    return document.createElement("p").also(::appendChild)
}
```

2. Call the `appendTextContainer()` function in `main()`. It creates the output element:

```
fun main() {
    // Creates a text container for our output
    // Replace val message = Message(topic = "Kotlin/JS", content = "Hello!")
    val output = document.body?.appendTextContainer()

    // Reads the input value
    document.body?.appendInput(onChange = { println(it) })
}
```

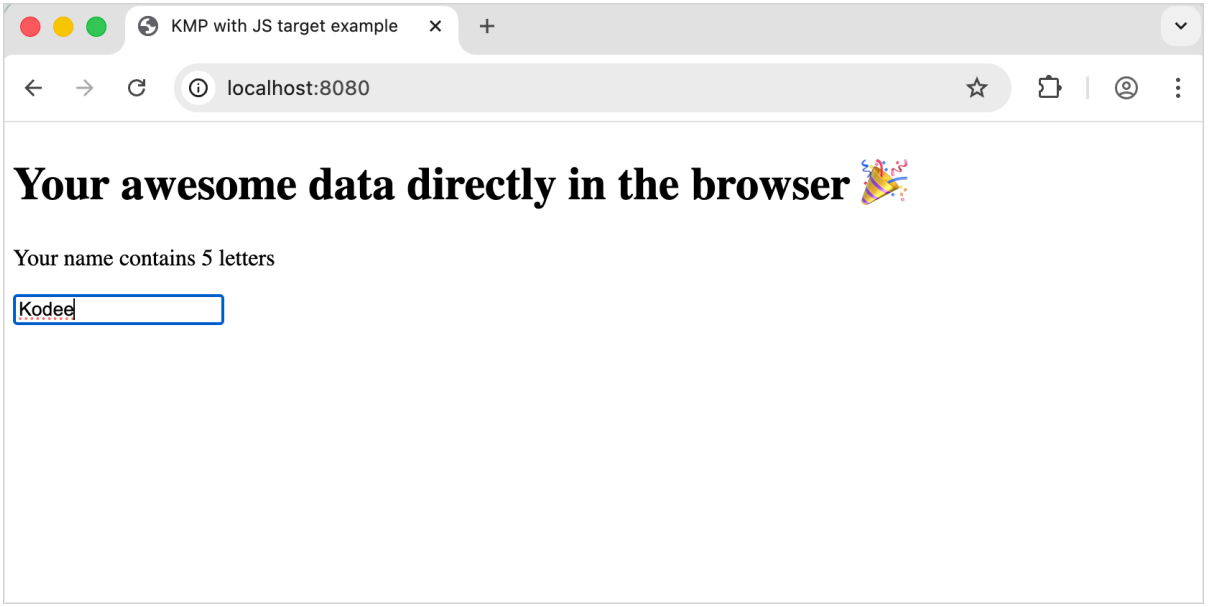
Process the input to count the letters

Process the input by removing whitespace and displaying the output with the number of letters.

Add the following code to the `appendInput()` function within the `main()` function:

```
fun main() {
    // Creates a text container for our output
    val output = document.body?.appendTextContainer()

    // Reads the input value
    // Replace the current appendInput() function
    document.body?.appendInput(onChange = { name →
        name.replace(" ", "").let {
            output?.textContent = "Your name contains ${it.length} letters"
        }
    })
}
```



From the code above:

- The `replace()` function removes the empty spaces in the name.
- The `let{}` scope function runs the function within the object context.
- The string template (`${it.length}`) inserts the word's length into the string by prefixing it with a dollar sign (`$`) and enclosing it in curly braces (`{}`). Whereas `it` is the default name of a lambda parameter.

Run the application

1. Run the application.
2. Enter your name.
3. Press Enter.

You can see the result:

Application output

Process the input to count unique letters

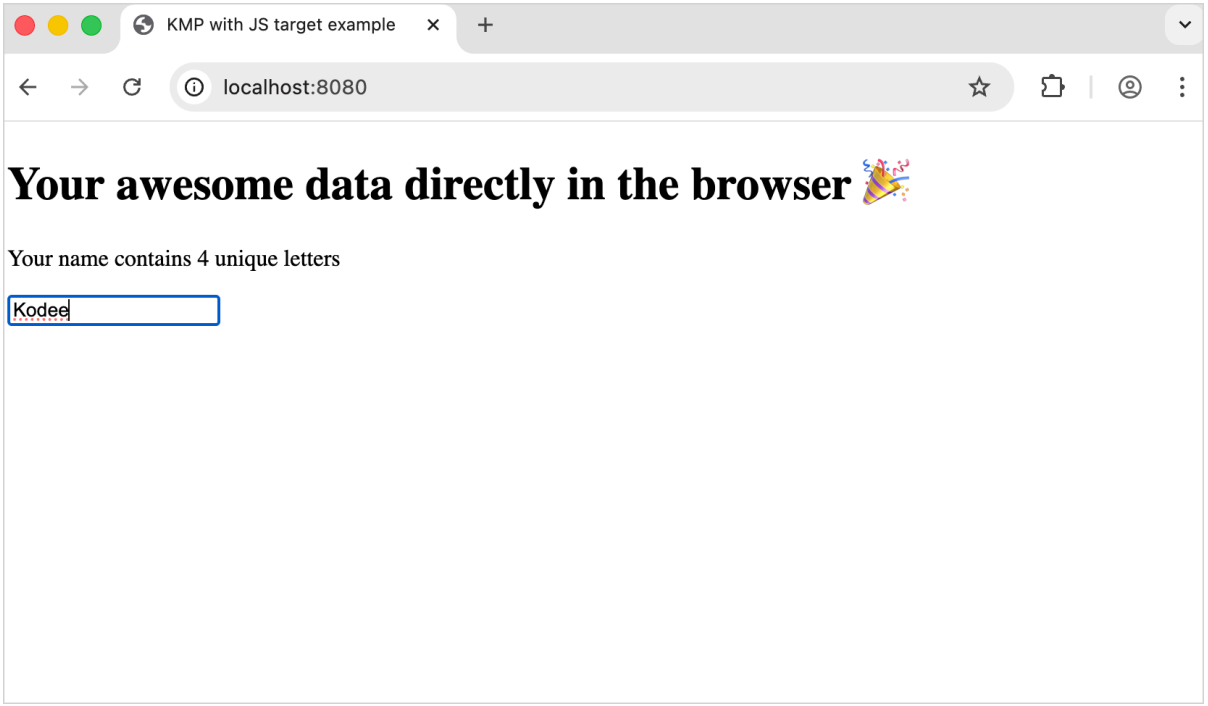
As an additional exercise, let's process the input to calculate and display the number of unique letters in the word:

1. In the `src/jsMain/kotlin/Main.kt` file, add the `.countDistinctCharacters()` extension function for `String`:

   ```
   fun String.countDistinctCharacters() = lowercase().toList().distinct().count()
   ```

   From the code above:

   - The `.lowercase()` function converts the name to lowercase.
   - The `toList()` function converts the input string to a list of characters.
   - The `distinct()` function selects only the distinct characters from the word.
   - The `count()` function counts the distinct characters.



2. Call the `.countDistinctCharacters()` function in `main()`. It counts the unique letters in your name:

   ```
   fun main() {
       // Creates a text container for our output
       val output = document.body?.appendTextContainer()

       // Reads the input value
       document.body?.appendInput(onChange = { name ->
           name.replace(" ", "").let {
               // Prints the number of unique letters
               // Replace output?.textContent = "Your name contains ${it.length} letters"
               output?.textContent = "Your name contains ${it.countDistinctCharacters()} unique
   letters"
           }
       })
   }
   ```

3. Follow the steps to run the application and enter your name.

You can see the result:

Application output

Create your application using Gradle

In this section, you can learn how to manually create a Kotlin/JS application using Gradle.

Gradle is the default build system for Kotlin/JS and Kotlin Multiplatform projects. It is also commonly used in Java, Android, and other ecosystems.

Create project files

1. Make sure you use a Gradle version that is compatible with the Kotlin Gradle plugin (KGP). See the compatibility table for more details.
2. Create an empty directory for your project using your file explorer, the command line, or any tool you prefer.
3. Inside the project directory, create a `build.gradle.kts` file with the following content:

Kotlin

```
// build.gradle.kts
plugins {
    kotlin("multiplatform") version "2.4.20"
}

repositories {
    mavenCentral()
}

kotlin {
    js {
        // Use browser() for running in a browser or nodejs() for running in Node.js
        browser()
        binaries.executable()
    }
}
```

Groovy

```
// build.gradle
plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}

repositories {
    mavenCentral()
}

kotlin {
    js {
        // Use browser() for running in a browser or nodejs() for running in Node.js
        browser()
        binaries.executable()
    }
}
```

You can use different execution environments, such as `browser()` or `nodejs()`. Each environment defines where your code runs and determines how Gradle generates task names in the project.

4. Within the project directory, create an empty `settings.gradle.kts` file.
5. Within the project directory, create a `src/jsMain/kotlin` directory.
6. Inside the `src/jsMain/kotlin` directory, add a `hello.kt` file with the following content:

```
fun main() {
    println("Hello, Kotlin/JS!")
}
```

By convention, all sources are located in the `src/<target name>[Main|Test]/kotlin` directory:

- `Main` is the location for the source code.
- `Test` is the location for tests.

- `<target name>` corresponds to the target platform (`js` in this case).

For the `browser` environment

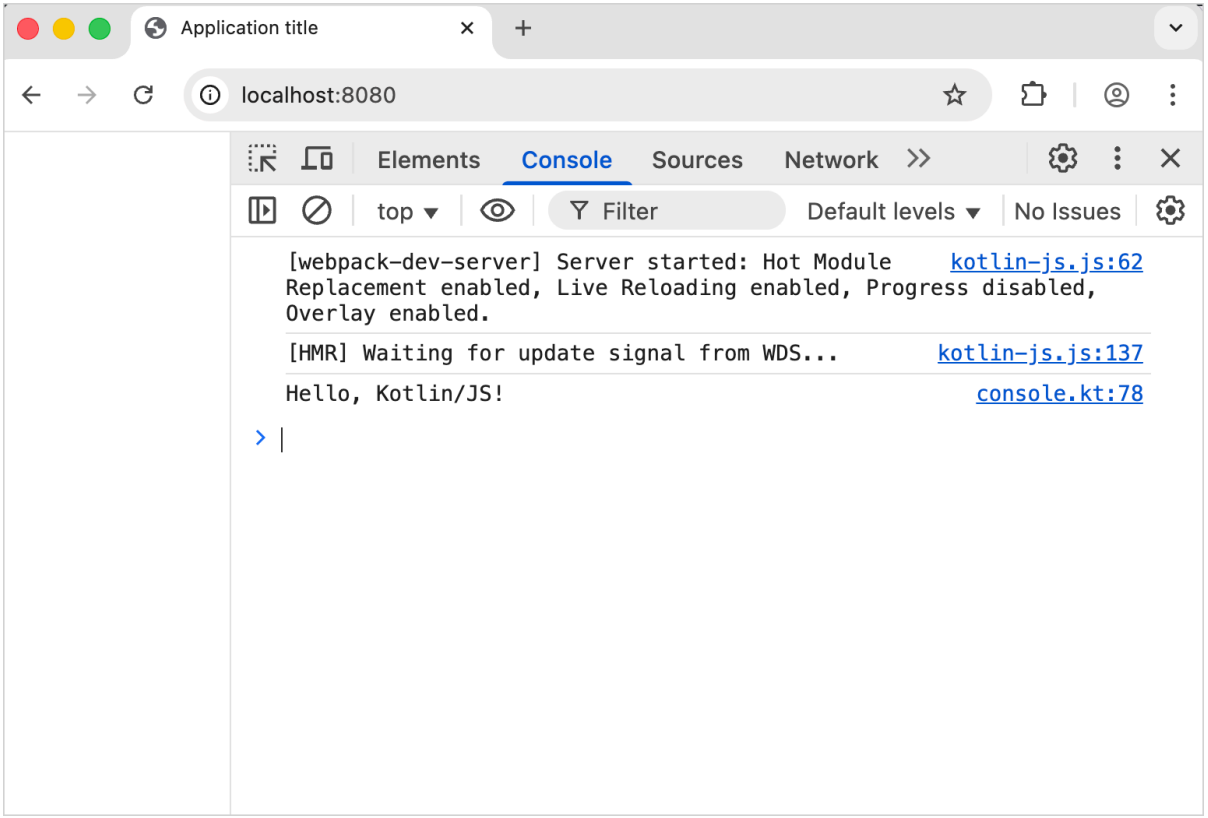
> Follow the next steps if you are working with the `browser` environment. If you are working with the `nodejs` environment, go to the Build and run the project section.

1. Within the project directory, create a `src/jsMain/resources` directory.
2. Inside the `src/jsMain/resources` directory, create an `index.html` file with the following content:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="UTF-8">
    <title>Application title</title>
</head>
<body>
    <script src="$NAME_OF_YOUR_PROJECT_DIRECTORY.js"></script>
</body>
</html>
```

3. Replace the `<$NAME_OF_YOUR_PROJECT_DIRECTORY>` placeholder with the name of your project directory.

Build and run the project



To build the project, run the following command from the root project directory:

```
# For browser
gradle jsBrowserDevelopmentRun

# OR

# For Node.js
gradle jsNodeDevelopmentRun
```

If you are using the `browser` environment, you can see that the browser opens the `index.html` file and prints `"Hello, Kotlin/JS!"` to the browser console. You can open the console using the Ctrl + Shift + J/Cmd + Option + J commands.

Application output

If you are using the `nodejs` environment, you can see that the terminal prints `"Hello, Kotlin/JS!"`.

```
> Task :jsNodeDevelopmentRun
Hello, Kotlin/JS!

BUILD SUCCESSFUL in 12s
17 actionable tasks: 17 executed
```

Application output

Open the project in an IDE

You can open your project in any IDE that supports Gradle.

If you use IntelliJ IDEA:

1. Select **File** | **Open**.
2. Find the project directory.
3. Click **Open**.

IntelliJ IDEA automatically detects if it's a Kotlin/JS project. If you encounter a problem with the project, IntelliJ IDEA displays the error message in the **Build** pane.

What's next?

- Set up your Kotlin/JS project.

- Learn how to debug Kotlin/JS applications.
- Learn how to write and run tests with Kotlin/JS.
- Learn how to write Gradle build scripts for real-life Kotlin/JS projects.
- Read more about the Gradle build system.

Set up a Kotlin/JS project

Kotlin/JS projects use Gradle as a build system. To let developers easily manage their Kotlin/JS projects, we offer the `kotlin.multiplatform` Gradle plugin that provides project configuration tools together with helper tasks for automating routines typical for JavaScript development.

The plugin downloads npm dependencies in the background using the npm or Yarn package managers and builds a JavaScript bundle from a Kotlin project using webpack. Dependency management and configuration adjustments can be done to a large part directly from the Gradle build file, with the option to override automatically generated configurations for full control.

You can apply the `org.jetbrains.kotlin.multiplatform` plugin to a Gradle project manually in the `build.gradle(.kts)` file:

Kotlin

```
plugins {
    kotlin("multiplatform") version "2.4.20"
}
```

Groovy

```
plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}
```

The Kotlin Multiplatform Gradle plugin lets you manage aspects of your project in the `kotlin {}` block of the build script:

```
kotlin {
    // ...
}
```

Inside the `kotlin {}` block, you can manage the following aspects:

- Target execution environment: browser or Node.js
- Support for ES2015 features: classes, modules, and generators
- Configure output granularity
- Generation of TypeScript declaration files
- Project dependencies: Maven and npm
- Run configuration

- Test configuration
- Bundling and CSS support for browser projects
- Target directory and module name
- Project's `package.json` file

Execution environments

Kotlin/JS projects can target two different execution environments:

- Browser for client-side scripting in browsers
- Node.js for running JavaScript code outside a browser, for example, for server-side scripting.

To define the target execution environment for a Kotlin/JS project, add the `js {}` block with `browser {}` or `nodejs {}` inside:

```
kotlin {
    js {
        browser {
        }
        binaries.executable()
    }
}
```

The instruction `binaries.executable()` explicitly instructs the Kotlin compiler to emit executable `.js` files. Omitting `binaries.executable()` will cause the compiler to only generate Kotlin-internal library files, which can be used from other projects but not run on their own.

> This is typically faster than creating executable files, and can be a possible optimization when dealing with non-leaf modules of your project.

The Kotlin Multiplatform plugin automatically configures its tasks for working with the selected environment. This includes downloading and installing the required environment and dependencies for running and testing the application. This allows developers to build, run, and test simple projects without additional configuration. There is also an option to use an existing installation. Learn how to use pre-installed Node.js.

Support for ES2015 features

Kotlin provides support for ES2015 features, including:

- Modules that simplify your codebase and improve maintainability.
- Classes that allow incorporating OOP principles, resulting in cleaner and more intuitive code.
- Generators for compiling suspend functions that improve the final bundle size and help with debugging.
- JavaScript code inlining.

You can enable all the supported ES2015 features at once by adding the `es2015` compilation target to your `build.gradle(.kts)` file:

```
tasks.withType<KotlinJsCompile>().configureEach {
    compilerOptions {
        target = "es2015"
    }
}
```

Learn more about ES2015 (ECMAScript 2015, ES6) in the official documentation.

Configure output granularity

You can choose how the compiler outputs `.js` files in your project:

- **One per module**. By default, the JS compiler outputs separate `.js` files for each project module as a compilation result.
- **One per project**. You can compile the whole project into a single `.js` file by adding the following line to the `gradle.properties` file:

  ```
  kotlin.js.ir.output.granularity=whole-program // 'per-module' is the default
  ```

- **One per file**. You can set up a more granular output that generates one (or two, if the file contains exported declarations) JavaScript file per each Kotlin file. To enable the per-file compilation mode:

  1. Set `es2015` as the compilation target to support ES2015 features in your project.
  2. Add the following line to the `gradle.properties` file:

     ```
     kotlin.js.ir.output.granularity=per-file // 'per-module' is the default
     ```

Experimental

Generation of TypeScript declaration files (`d.ts`)

The Kotlin/JS compiler can generate TypeScript definitions from your Kotlin code. These definitions can be used by JavaScript tools and IDEs when working on hybrid applications to:

- Provide autocompletion
- Support static analyzers
- Simplify the addition of Kotlin code in JavaScript and TypeScript projects

Generating TypeScript definitions is especially valuable for the business logic sharing use cases.

The compiler collects any top-level declarations marked with `@JsExport` and automatically generates TypeScript definitions in a `.d.ts` file.

To generate TypeScript definitions, explicitly configure it in your Gradle build file. Add the `generateTypeScriptDefinitions()` function to your `build.gradle.kts` file in the `js {}` block:

```
kotlin {
    js {
        binaries.executable()
        browser {
        }
        generateTypeScriptDefinitions()
    }
}
```

You can find the definitions in the `build/js/packages/<package_name>/kotlin` directory alongside the corresponding un-webpacked JavaScript code.

Dependencies

To declare a dependency, use the `dependencies {}` block in the `jsMain` source set in your `build.gradle(.kts)` file:

Kotlin

```
kotlin {
    sourceSets {
        jsMain {
            dependencies {
                implementation("org.example.myproject:1.1.0")
            }
        }
    }
}
```

Groovy

```
kotlin {
    sourceSets {
        jsMain {
            dependencies {
                implementation 'org.example.myproject:1.1.0'
            }
        }
    }
}
```

Only libraries that include artifacts for Kotlin/JS can be used as dependencies. To resolve dependencies, declare the repositories where Gradle should look for them in the `repositories {}` block of your `build.gradle(.kts)` file. For example:

```
repositories {
    mavenCentral()
}
```

If the library you are adding has dependencies on packages from npm, Gradle automatically resolves these transitive dependencies as well.

Kotlin standard libraries

The dependencies on the standard library are added automatically. The version of the standard library is the same as the version of the Kotlin Multiplatform plugin.

For multiplatform tests, the `kotlin.test` API is available. When you create a multiplatform project, you can add test dependencies to all the source sets by using a single dependency in `commonTest`:

Kotlin

```
kotlin {
    sourceSets {
        commonTest.dependencies {
            implementation(kotlin("test")) // Brings all the platform dependencies automatically
        }
    }
}
```

Groovy

```
kotlin {
    sourceSets {
        commonTest {
            dependencies {
                implementation kotlin("test") // Brings all the platform dependencies automatically
            }
        }
    }
}
```

npm dependencies

In the JavaScript world, the most common way to manage dependencies is npm. It offers the biggest public repository of JavaScript modules.

The Kotlin Multiplatform Gradle plugin lets you declare npm dependencies in the Gradle build script, just how you declare any other dependencies.

To declare an npm dependency, pass its name and version to the `npm()` function inside a dependency declaration. You can also specify one or multiple version ranges based on npm's semver syntax.

Kotlin

```
kotlin {
    sourceSets {
        jsMain {
            dependencies {
                implementation(npm("core-js", "^3.38.1"))
            }
        }
    }
}
```

Groovy

```
kotlin {
    sourceSets {
        jsMain {
            dependencies {
                implementation npm('core-js', '^3.38.1')
            }
        }
    }
}
```

By default, the plugin uses a separate instance of the Yarn package manager to download and install npm dependencies. It works out of the box without additional configuration, but you can tune it to specific needs.

You can also work with npm dependencies directly using the npm package manager instead. To use npm as your package manager, in your `gradle.properties` file, set the following property:

```
kotlin.js.yarn=false
```

Besides regular dependencies, there are three more types of dependencies that can be used from the Gradle DSL. To learn more about when each type of dependency can best be used, have a look at the official documentation linked from npm:

- devDependencies, via `devNpm(...)`,
- optionalDependencies via `optionalNpm(...)`, and
- peerDependencies via `peerNpm(...)`.

Once an npm dependency is installed, you can use its API in your code as described in Calling JS from Kotlin.

run task

The Kotlin Multiplatform Gradle plugin provides a `jsBrowserDevelopmentRun` task that lets you run pure Kotlin/JS projects without additional configuration.

For running Kotlin/JS projects in the browser, this task is an alias for the `browserDevelopmentRun` task (which is also available in Kotlin multiplatform projects). It uses the webpack-dev-server to serve your JavaScript artifacts. If you want to customize the configuration used by `webpack-dev-server`, for example, adjust the port the server runs on, use the webpack configuration file.

For running Kotlin/JS projects targeting Node.js, use the `jsNodeDevelopmentRun` task that is an alias for the `nodeRun` task.

To run a project, execute the standard lifecycle `jsBrowserDevelopmentRun` task, or the alias to which it corresponds:

```
./gradlew jsBrowserDevelopmentRun
```

To automatically trigger a re-build of your application after making changes to the source files, use the Gradle continuous build feature:

```
./gradlew jsBrowserDevelopmentRun --continuous
```

or

```
./gradlew jsBrowserDevelopmentRun -t
```

Once the build of your project has succeeded, the `webpack-dev-server` will automatically refresh the browser page.

test task

The Kotlin Multiplatform Gradle plugin automatically sets up a test infrastructure for projects. It downloads and installs the required test runners and other dependencies.

For browser projects, you can choose between the Karma test runner and the new DSL for browser testing. For Node.js projects, the Mocha test framework is available.

The plugin also provides useful testing features, for example:

- Source map generation
- Test report generation
- Test run results in the console

Karma

> The Karma project has been deprecated. No new features or bug fixes are expected. As an alternative for browser testing, try out the new DSL for browser testing.

To configure the Karma test runner, add the `useKarma {}` block inside the browser's `testTask` in your `build.gradle(.kts)` file. For example, to run tests against specific browsers, use:

```
kotlin {
    js {
        browser {
            testTask {
                useKarma {
                    useIe()
                    useSafari()
                    useFirefox()
                    useChrome()
                    useChromeCanary()
                    useChromeHeadless()
                    usePhantomJS()
                    useOpera()
                }
            }
        }
        binaries.executable()
        // ...
    }
}
```

Alternatively, you can add test targets for browsers in the `gradle.properties` file:

```
kotlin.js.browser.karma.browsers=firefox,safari
```

This allows you to define a list of browsers for all modules and then add specific browsers in the build files of particular modules.

The Kotlin Multiplatform Gradle plugin automatically generates a Karma configuration file at `build/js/packages/projectName-test/karma.conf.js` at build time. The file includes settings you set in the `useKarma {}` block in your build file.

You can also place additional configuration files inside the `karma.config.d` directory at the root of your project. All `.js` configuration files in this directory are picked up and automatically merged into the generated `karma.conf.js` at build time.

For more information on the Karma configuration, see Karma's documentation.

Experimental

DSL for browser testing

Kotlin offers an experimental DSL for running Kotlin/JS tests in a browser environment. It's designed to be technology-agnostic. The current implementation includes the following tools under the hood:

- Playwright acts as a browser driver and a distribution manager that supports the Chromium, Firefox, and WebKit (Safari) browser engines.
- Mocha acts as a test runner.
- webpack acts as a bundler (will be replaced with Vite in future releases).

To try out the new DSL for browser testing, add the opt-in `test {}` block inside `browser {}` for your Kotlin/JS target:

```
import org.jetbrains.kotlin.gradle.ExperimentalJsTestDsl
import kotlin.time.Duration.Companion.seconds

kotlin {
    js {
        browser {
            @OptIn(ExperimentalJsTestDsl::class)
            test {
                // Configures the default timeout for all runners with kotlin.Duration
                timeout = 30.seconds
                // Configures headless mode using Gradle providers
                headless = providers
                    .environmentVariable("IS_IN_CI")
                    .map { it.toBoolean() }
                    .orElse(false)
                // Enables and configures a custom Chromium runner
                chromium("chromium-no-webgl2") {
                    // Overrides the default timeout for this runner
                    timeout = 10.seconds

                    // Chromium-specific extra launch argument
                    launchArgs.add("--disable-webgl2")
                }
                // Enables the Firefox runner
                firefox()
                // Enable WebKit (Safari) test runner
                webkit()
                // Enables and configures a custom WebKit runner
                webkit("headful") {
                    headless = false
                }
            }
        }
    }
}
```

For more information on the configuration of the new DSL for browser testing, see Run tests in Kotlin/JS.

Node.js

For Node.js projects, the Kotlin Multiplatform Gradle plugin automatically sets up the Mocha test framework.

To specify environment variables used by your Node.js test runners (for example, to pass external information to your tests, or to fine-tune package resolution), use the `environment()` function with a key-value pair inside the `testTask {}` block in your build file:

```
kotlin {
    js {
        nodejs {
            testTask {
                environment("key", "value")
            }
        }
    }
}
```

Run tests

By default, the Kotlin Multiplatform Gradle plugin uses Headless Chrome to run browser tests. No browsers are bundled with the plugin; test runners handle missing browsers differently:

- With Karma, any other browser should already be installed on your machine so that the plugin can use it to run tests. If you are executing Kotlin/JS tests on a continuous integration server, ensure that the browsers you want to test against are installed there as well.
- With the new DSL for browser testing, the plugin installs the necessary browsers on the first run by using the `playwright install` command. Playwright manages the location of these browsers and doesn't use locally installed browsers.

To run tests, execute the standard lifecycle `check` task:

```
./gradlew check
```

If you want to skip tests, disable them in the `testTask {}` block in your build file:

```
kotlin {
    js {
        browser {
            testTask {
                enabled.set(false)
            }
        }
        binaries.executable()
        // ...
    }
}
```

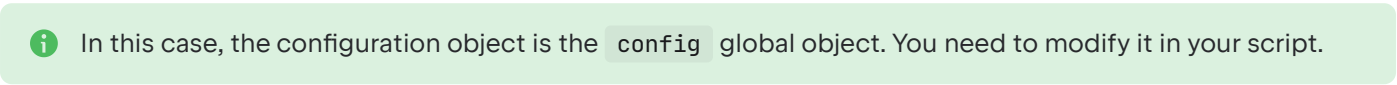
webpack bundling

For browser targets, the Kotlin Multiplatform Gradle plugin uses the widely known webpack module bundler.

webpack task

The most common webpack adjustments can be made directly via the `kotlin.js.browser.webpackTask {}` configuration block in the Gradle build file:

- `mainOutputFileName` - the name of the webpacked output file. It will be generated in `<projectDir>/build/kotlin-webpack/<targetName>/<binaryName>` after an execution of a webpack task. The default value is the project name.
- `output.libraryTarget` - the module system for the webpacked output. Learn more about available module systems for Kotlin/JS projects. The default value is `umd`.



```
webpackTask {
    mainOutputFileName = "mycustomfilename.js"
    output.libraryTarget = "commonjs2"
}
```

You can also configure common webpack settings to use in bundling, running, and testing tasks in the `commonWebpackConfig {}` block.

webpack configuration file

The Kotlin Multiplatform Gradle plugin automatically generates a standard webpack configuration file at the build time. It is located in `build/js/packages/projectName/webpack.config.js`.

If you want to make further adjustments to the webpack configuration, place your additional configuration files inside a directory called `webpack.config.d` in the root of your project. When building your project, all `.js` configuration files will automatically be merged into the `build/js/packages/projectName/webpack.config.js` file. For example, To add a new webpack loader, add the following to a `.js` file inside the `webpack.config.d` directory:

In this case, the configuration object is the `config` global object. You need to modify it in your script.

```
config.module.rules.push({
    test: /\.extension$/,
    loader: 'loader-name'
});
```

All webpack configuration capabilities are well described in its documentation.

Building executables

For building executable JavaScript artifacts through webpack, the Kotlin Multiplatform Gradle plugin contains the `jsBrowserDevelopmentWebpack` and `jsBrowserProductionWebpack` Gradle tasks.

- `jsBrowserDevelopmentWebpack` creates development artifacts, which are larger but take little time to create. As such, use the `jsBrowserDevelopmentWebpack` tasks during active development.
- `jsBrowserProductionWebpack` applies dead code elimination to the generated artifacts and minifies the resulting JavaScript file, which takes more time but generates executables that are smaller. As such, use the `jsBrowserProductionWebpack` task when preparing your project for production use.

Execute either of these tasks to obtain the respective artifacts for development or production. The generated files will be available in `build/kotlin-webpack` unless specified otherwise.

```
./gradlew jsBrowserProductionWebpack
```

Note that these tasks will only be available if your target is configured to generate executable files (via `binaries.executable()`).

To generate the distribution in the `build/dist/<targetName>/<binaryName>` directory, run the `jsBrowserDistribution` task instead:

```
./gradlew jsBrowserDistribution
```

This task generates a ready-to-use distribution that includes the project resources.

CSS

The Kotlin Multiplatform Gradle plugin also provides support for webpack's CSS and style loaders. While all options can be changed by directly modifying the webpack configuration files that are used to build your project, the most commonly used settings are available directly from the `build.gradle(.kts)` file.

To turn on CSS support in your project, set the `cssSupport.enabled` option in the Gradle build file in the `commonWebpackConfig {}` block. This configuration is also enabled by default when creating a new project using the wizard.

Kotlin

```
browser {
    commonWebpackConfig {
        cssSupport {
            enabled.set(true)
        }
    }
}
```

Groovy

```
browser {
    commonWebpackConfig {
        cssSupport {
            it.enabled = true
        }
    }
}
```

Alternatively, you can add CSS support independently for `webpackTask {}`, `runTask {}`, and `testTask {}`:

Kotlin

```
browser {
    webpackTask {
        cssSupport {
            enabled.set(true)
        }
    }
    runTask {
        cssSupport {
            enabled.set(true)
        }
    }
    testTask {
        useKarma {
            // ...
            webpackConfig.cssSupport {
                enabled.set(true)
            }
        }
    }
}
```

Groovy

```
browser {
    webpackTask {
        cssSupport {
            it.enabled = true
        }
    }
    runTask {
        cssSupport {
            it.enabled = true
        }
    }
    testTask {
        useKarma {
            // ...
            webpackConfig.cssSupport {
                it.enabled = true
            }
        }
    }
}
```

Activating CSS support in your project helps prevent common errors that occur when trying to use style sheets from an unconfigured project, such as `Module parse failed: Unexpected character '@' (14:0)`.

You can use `cssSupport.mode` to specify how encountered CSS should be handled. The following values are available:

- `"inline"` (default): styles are added to the global `<style>` tag.
- `"extract"`: styles are extracted into a separate file. They can then be included from an HTML page.
- `"import"`: styles are processed as strings. This can be useful if you need access to the CSS from your code (such as `val styles = require("main.css")`).

To use different modes for the same project, use `cssSupport.rules`. Here, you can specify a list of `KotlinWebpackCssRules`, each of which defines a mode, as well as include and exclude patterns.

Node.js

For Kotlin/JS projects targeting Node.js, the plugin automatically downloads and installs the Node.js environment on the host. You can also use an existing Node.js instance if you have it.

You can configure Node.js settings for each subproject or set them for the project as a whole.

Change Node.js version

The default Node.js version is currently 24.16.0, but you can use a different version for a specific subproject. Add the following lines to your subproject's `build.gradle(.kts)` file. For example:

Kotlin

```
project.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin> {
    project.the<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec>().version = "26.2.0"
}
```

Groovy

```
project.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin) {
    project.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec).version
= "26.2.0"
}
```

To set a version for the entire project, including all subprojects, apply the same code to the `allprojects {}` block. For example:

Kotlin

```
allprojects {
    project.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin> {
        project.the<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec>().version = "26.2.0"
    }
}
```

Groovy

```
allprojects {
    project.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin) {

project.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec).version =
"26.2.0"
    }
}
```

Use pre-installed Node.js

If Node.js is already installed on the host where you build Kotlin/JS projects, you can configure the Kotlin Multiplatform Gradle plugin to use it instead of installing its own Node.js instance.

To use a pre-installed Node.js instance, add the following lines to your `build.gradle(.kts)` file:

Kotlin

```
project.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin> {
    // Set to `true` for default behavior
    project.the<org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec>().download = false
}
```

Groovy

```
project.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsPlugin) {
    // Set to `true` for default behavior
    project.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.nodejs.NodeJsEnvSpec).download
= false
}
```

Yarn

By default, to download and install your declared dependencies at build time, the plugin manages its own instance of the Yarn package manager. It works out of the box without additional configuration, but you can tune it or use Yarn already installed on your host.

Additional Yarn features: .yarnrc

To configure additional Yarn features, place a `.yarnrc` file in the root of your project. At build time, it gets picked up automatically.

For example, to use a custom registry for npm packages, add the following line to a file called `.yarnrc` in the project root:

```
registry "http://my.registry/api/npm/"
```

To learn more about `.yarnrc`, visit the official Yarn documentation.

Use pre-installed Yarn

If Yarn is already installed on the host where you build Kotlin/JS projects, you can configure the Kotlin Multiplatform Gradle plugin to use it instead of installing its own Yarn instance.

To use the pre-installed Yarn instance, add the following lines to `build.gradle(.kts)`:

Kotlin

```
rootProject.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin> {
    rootProject.the<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootEnvSpec>().download = false
    // "true" for default behavior
}
```

Groovy

```
rootProject.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin) {

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootEnvSpec).download
= false
}
```

Version locking via kotlin-js-store

The `kotlin-js-store` directory in the project root is automatically generated by the Kotlin Multiplatform Gradle plugin to hold the `yarn.lock` file, which is necessary for version locking. The lockfile is entirely managed by the Yarn plugin and gets updated during the execution of the `kotlinNpmInstall` Gradle task.

To follow a recommended practice, commit `kotlin-js-store` and its contents to your version control system. It ensures that your application is being built with the exact same dependency tree on all machines.

If needed, you can change both the directory and lockfile names in `build.gradle(.kts)`:

Kotlin

```
rootProject.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin> {
    rootProject.the<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension>().lockFileDirectory
=
        project.rootDir.resolve("my-kotlin-js-store")
    rootProject.the<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension>().lockFileName =
"my-yarn.lock"
}
```

Groovy

```
rootProject.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin) {

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).lockFile
=
        file("my-kotlin-js-store")

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).lockFile
= 'my-yarn.lock'
}
```

Changing the name of the lockfile may cause dependency inspection tools to no longer pick up the file.

To learn more about `yarn.lock`, visit the official Yarn documentation.

Reporting that yarn.lock has been updated

Kotlin/JS provides Gradle settings that could notify you if the `yarn.lock` file has been updated. You can use these settings when you want to be notified if `yarn.lock` has been changed silently during the CI build process:

- `YarnLockMismatchReport`, which specifies how changes to the `yarn.lock` file are reported. You can use one of the following values:
  - `FAIL` fails the corresponding Gradle task. This is the default.
  - `WARNING` writes the information about changes in the warning log.
  - `NONE` disables reporting.
- `reportNewYarnLock`, which reports about the recently created `yarn.lock` file explicitly. By default, this option is disabled: it's a common practice to generate a new `yarn.lock` file at the first start. You can use this option to ensure that the file has been committed to your repository.

- `yarnLockAutoReplace`, which replaces `yarn.lock` automatically every time the Gradle task is run.

To use these options, update `build.gradle(.kts)` as follows:

Kotlin

```
import org.jetbrains.kotlin.gradle.targets.js.yarn.YarnLockMismatchReport
import org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension

rootProject.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin> {
    rootProject.the<YarnRootExtension>().yarnLockMismatchReport =
        YarnLockMismatchReport.WARNING // NONE | FAIL
    rootProject.the<YarnRootExtension>().reportNewYarnLock = false // true
    rootProject.the<YarnRootExtension>().yarnLockAutoReplace = false // true
}
```

Groovy

```
import org.jetbrains.kotlin.gradle.targets.js.yarn.YarnLockMismatchReport
import org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension

rootProject.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin) {

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).yarnLock
=
        YarnLockMismatchReport.WARNING // NONE | FAIL

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).reportNe
= false // true

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).yarnLock
= false // true
}
```

Installing npm dependencies with --ignore-scripts by default

To reduce the likelihood of executing malicious code from compromised npm packages, the Kotlin Multiplatform Gradle plugin prevents the execution of lifecycle scripts during the installation of npm dependencies by default.

You can explicitly enable lifecycle scripts execution by adding the following lines to `build.gradle(.kts)`:

Kotlin

```
rootProject.plugins.withType<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin> {
    rootProject.the<org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension>().ignoreScripts =
false
}
```

Groovy

```
rootProject.plugins.withType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnPlugin) {

rootProject.extensions.getByType(org.jetbrains.kotlin.gradle.targets.js.yarn.YarnRootExtension).ignoreSc
= false
}
```

Distribution target directory

By default, the results of a Kotlin/JS project build reside in the `/build/dist/<targetName>/<binaryName>` directory within the project root.

To set another location for project distribution files, in your build script inside the `browser {}` block, add a `distribution {}` block and assign a value to the `outputDirectory` property by using the `set()` method. Once you run a project build task, Gradle will save the output bundle in this location together with project resources.

Kotlin

```
kotlin {
    js {
        browser {
            distribution {
                outputDirectory.set(projectDir.resolve("output"))
            }
        }
        binaries.executable()
        // ...
    }
}
```

Groovy

```
kotlin {
    js {
        browser {
            distribution {
                outputDirectory = file("$projectDir/output")
            }
        }
        binaries.executable()
        // ...
    }
}
```

Module name

To adjust the name for the JavaScript *module* (which is generated in `build/js/packages/myModuleName`), including the corresponding `.js` and `.d.ts` files, use the `outputModuleName` option:

```
kotlin {
    js {
        outputModuleName = "myModuleName"
    }
}
```

Note that this does not affect the webpacked output in `build/dist`.

package.json customization

The `package.json` file holds the metadata of a JavaScript package. Popular package registries such as npm require all published packages to have such a file. They use it to track and manage package publications.

The Kotlin Multiplatform Gradle plugin automatically generates `package.json` for Kotlin/JS projects during build time. By default, the file contains essential data: name, version, license, dependencies, and some other package attributes.

Aside from basic package attributes, `package.json` can define how a JavaScript project should behave, for example, identifying scripts that are available to run.

You can add custom entries to the project's `package.json` via the Gradle DSL. To add custom fields to your `package.json`, use the `customField()` function in the compilations' `packageJson` block:

```
kotlin {
    js {
        compilations["main"].packageJson {
            customField("hello", mapOf("one" to 1, "two" to 2))
        }
    }
}
```

When you build the project, this code adds the following block to the `package.json` file:

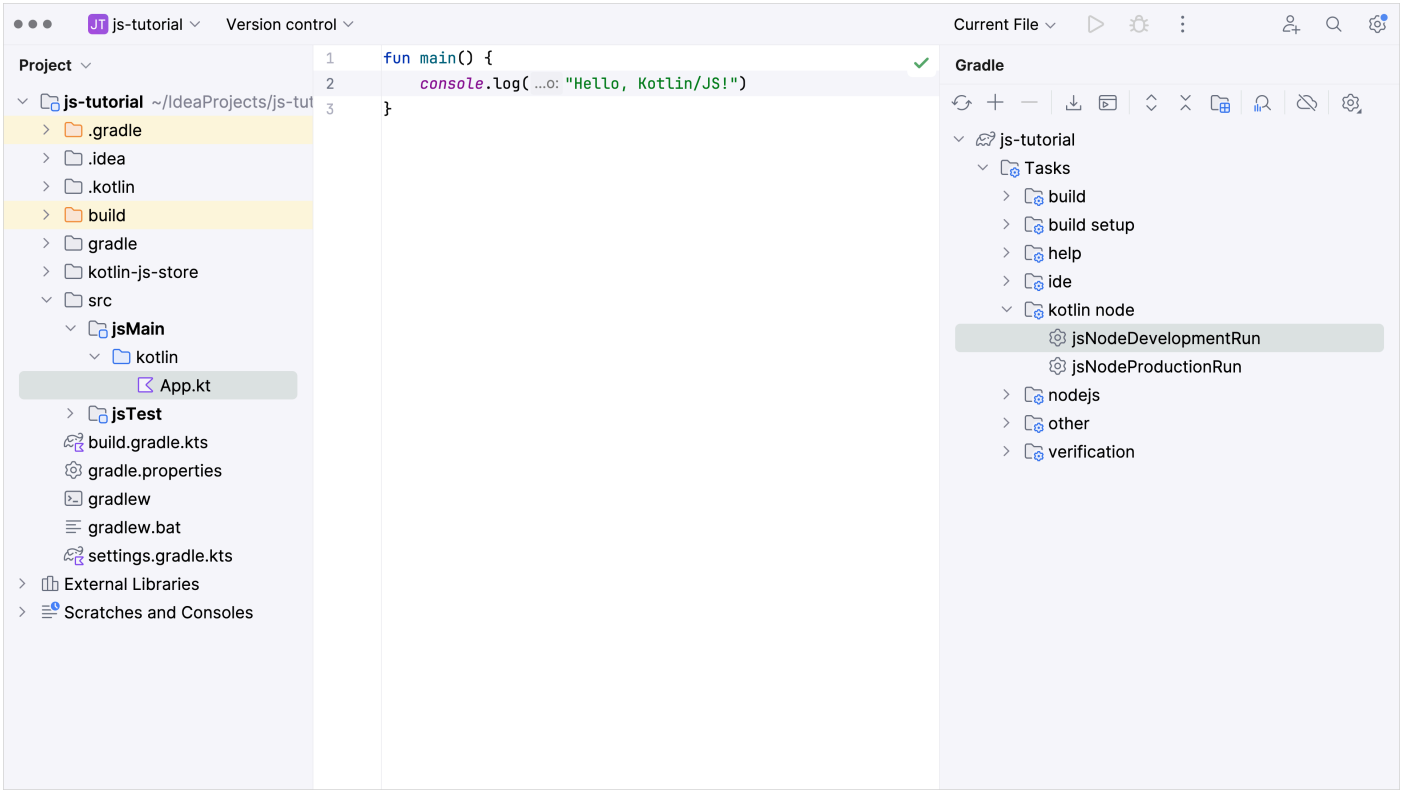
```
"hello": {
    "one": 1,
    "two": 2
}
```

Learn more about writing `package.json` files for the npm registry in the npm docs.

Run Kotlin/JS

Since Kotlin/JS projects are managed with the Kotlin Multiplatform Gradle plugin, you can run your project using the appropriate tasks. If you're starting with a blank project, ensure that you have some sample code to execute. Create the file `src/jsMain/kotlin/App.kt` and fill it with a small "Hello, World"-type code snippet:

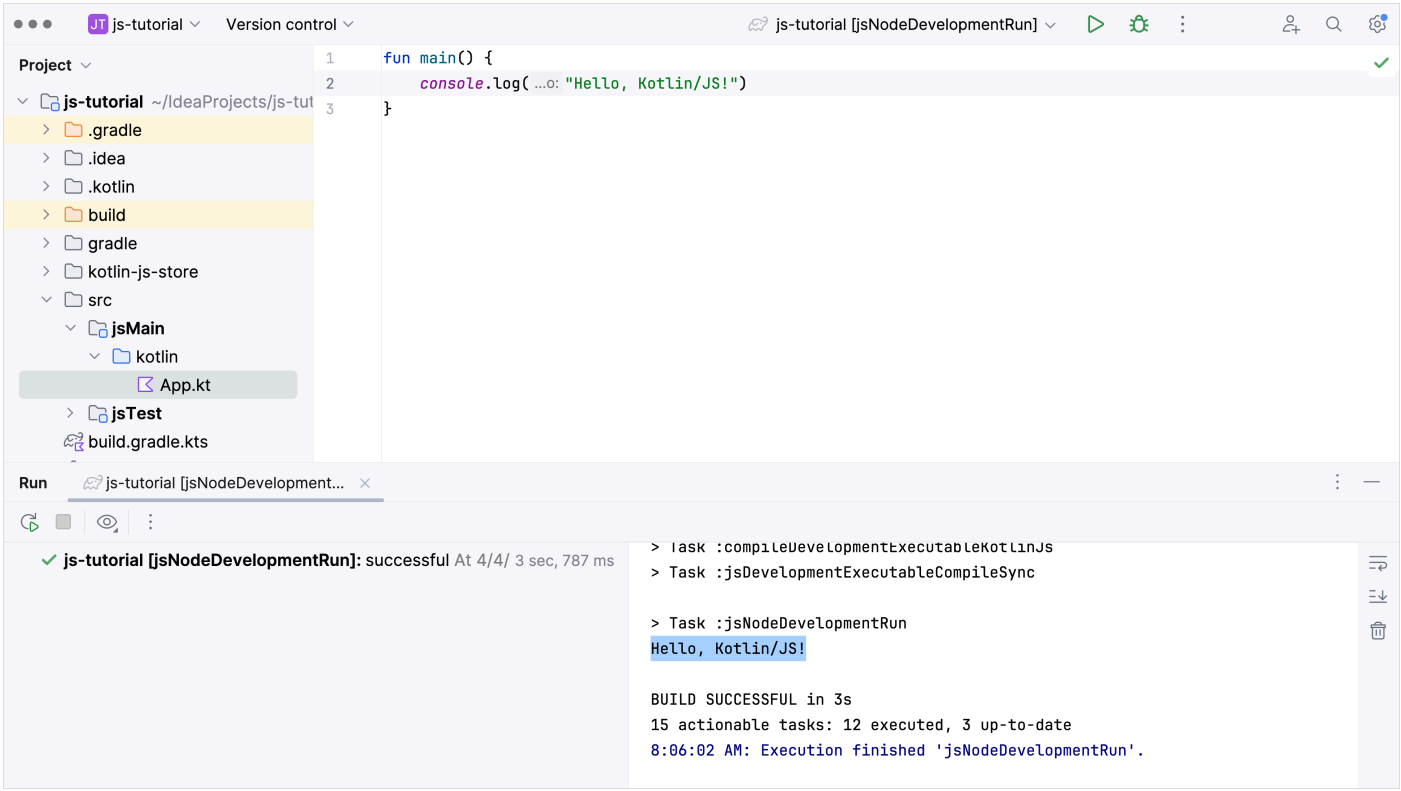
```
fun main() {
    console.log("Hello, Kotlin/JS!")
}
```



Depending on the target platform, some platform-specific extra setup might be required to run your code for the first time.

Run the Node.js target

When targeting Node.js with Kotlin/JS, you can simply execute the `jsNodeDevelopmentRun` Gradle task. This can be done, for example, via the command line, using the Gradle wrapper:



```
./gradlew jsNodeDevelopmentRun
```

If you're using IntelliJ IDEA, you can find the `jsNodeDevelopmentRun` action in the Gradle tool window:

Gradle Run task in IntelliJ IDEA

On first start, the `kotlin.multiplatform` Gradle plugin will download all required dependencies to get you up and running. After the build is completed, the program is executed, and you can see the logging output in the terminal:

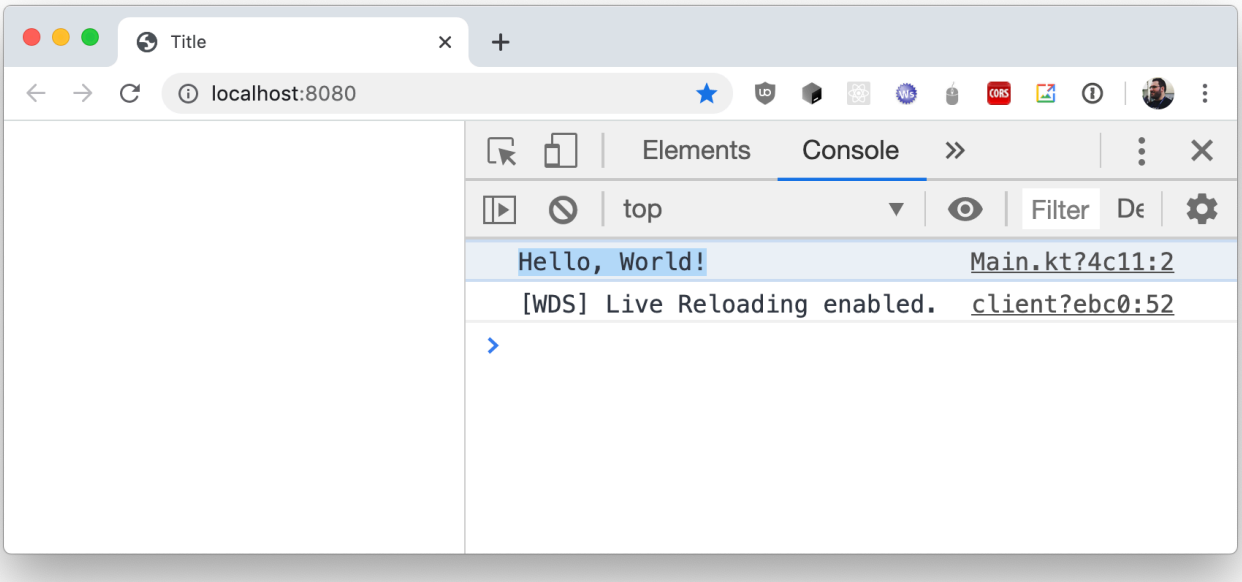
Executing the JS target in a Kotlin Multiplatform project in IntelliJ IDEA

Run the browser target

When targeting the browser, your project is required to have an HTML page. This page will be served by the development server while you are working on your application, and should embed your compiled Kotlin/JS file. Create and fill an HTML file `/src/jsMain/resources/index.html`:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="UTF-8">
    <title>JS Client</title>
</head>
<body>
<script src="js-tutorial.js"></script>
</body>
</html>
```

By default, the name of your project's generated artifact (which is created through webpack) that needs to be referenced is your project name (in this case, `js-tutorial`). If you've named your project `followAlong`, make sure to embed `followAlong.js` instead of `js-tutorial.js`



After making these adjustments, start the integrated development server. You can do this from the command line via the Gradle wrapper:

```
./gradlew jsBrowserDevelopmentRun
```

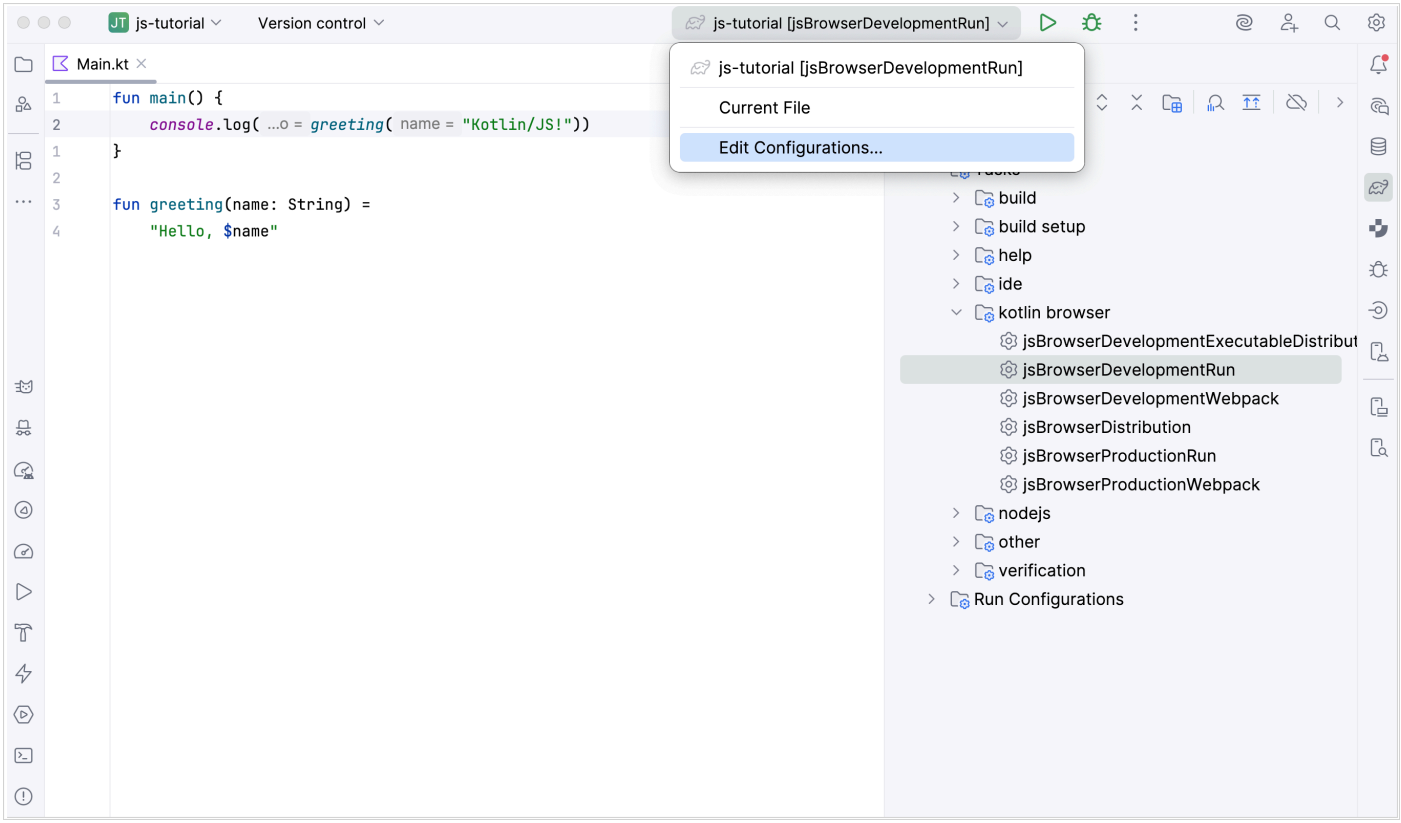
When working from IntelliJ IDEA, you can find the `jsBrowserDevelopmentRun` action in the Gradle tool window.

After the project has been built, the embedded `webpack-dev-server` will start running, and will open a (seemingly empty) browser window pointing to the HTML file you specified previously. To validate that your

program is running correctly, open the developer tools of your browser (for example, by right-clicking and choosing the *Inspect* action). Inside the developer tools, navigate to the console, where you can see the results of the executed JavaScript code:

Console output in browser developer tools

With this setup, you can recompile your project after each code change to see your changes. Kotlin/JS also supports a more convenient way of automatically rebuilding the application while you are developing it. To find out how to set up this *continuous mode*, check out the corresponding tutorial.



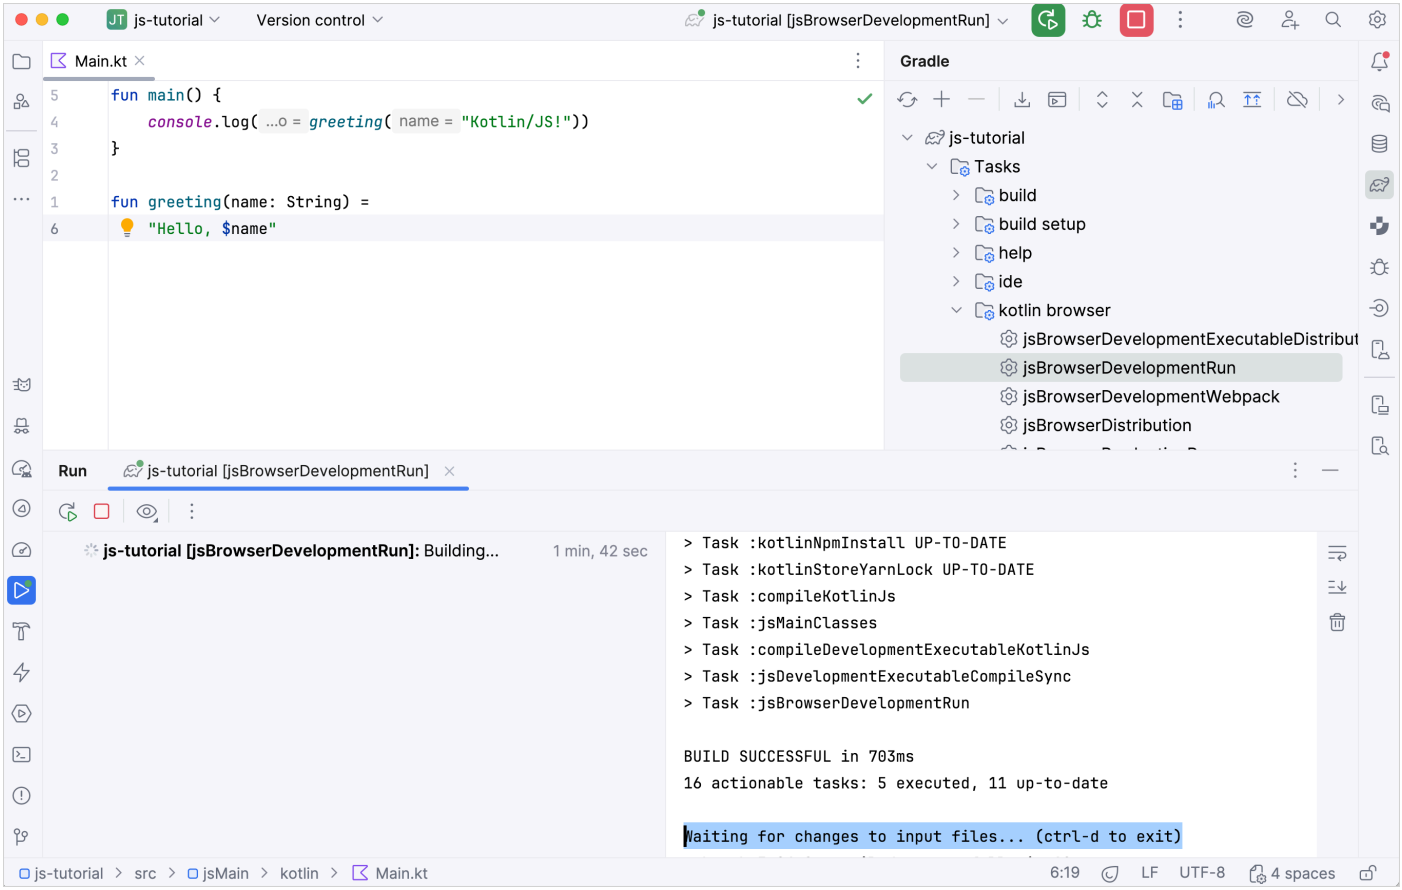
Development server and continuous compilation

Instead of manually compiling and running your Kotlin/JS project each time you want to see the changes you made, you can use the *continuous compilation* mode. Rather than using the regular `jsBrowserDevelopmentRun` (for `browser`) and `jsNodeDevelopmentRun` (for `nodejs`) command, invoke the Gradle wrapper in continuous mode:

```
# For `browser` project
./gradlew jsBrowserDevelopmentRun --continuous

 # For `nodejs` project
./gradlew jsNodeDevelopmentRun --continuous
```

If you are working in IntelliJ IDEA, you can pass the same flag via the list of run configurations. After running the `jsBrowserDevelopmentRun` Gradle task for the first time from the IDE, IntelliJ IDEA automatically generates a run configuration for it, which you can edit at the top toolbar:



Editing run configurations in IntelliJ IDEA

Enable continuous mode via the **Run/Debug Configurations** dialog by adding the `--continuous` flag to the arguments for the run configuration:

Adding the continuous flag to a run configuration in IntelliJ IDEA

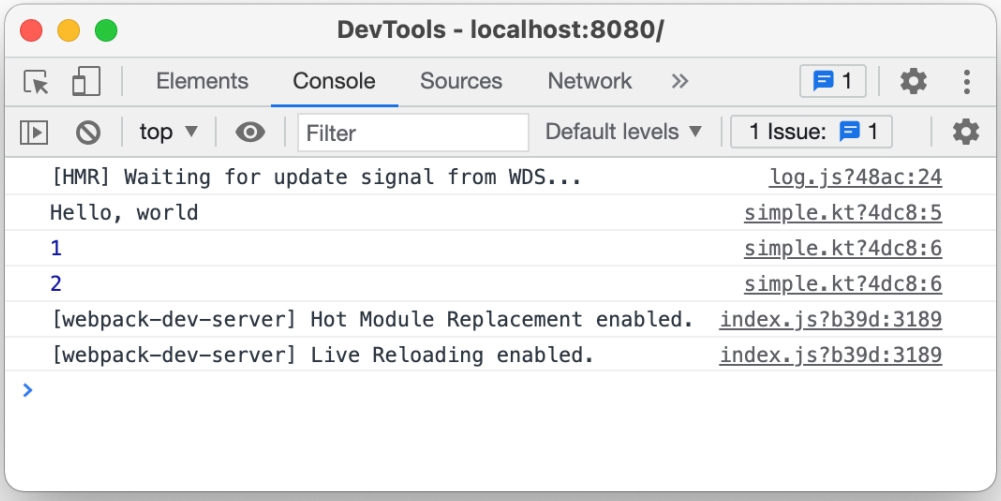
When executing this run configuration, you can note that the Gradle process continues watching for changes to the program:

Gradle waiting for changes

Once a change has been detected, the program is recompiled automatically. If you still have the web page open in the browser, the development server triggers an automatic reload of the page, and the changes become visible. This is thanks to the integrated `webpack-dev-server` that is managed by the Kotlin Multiplatform Gradle plugin.

Debug Kotlin/JS code

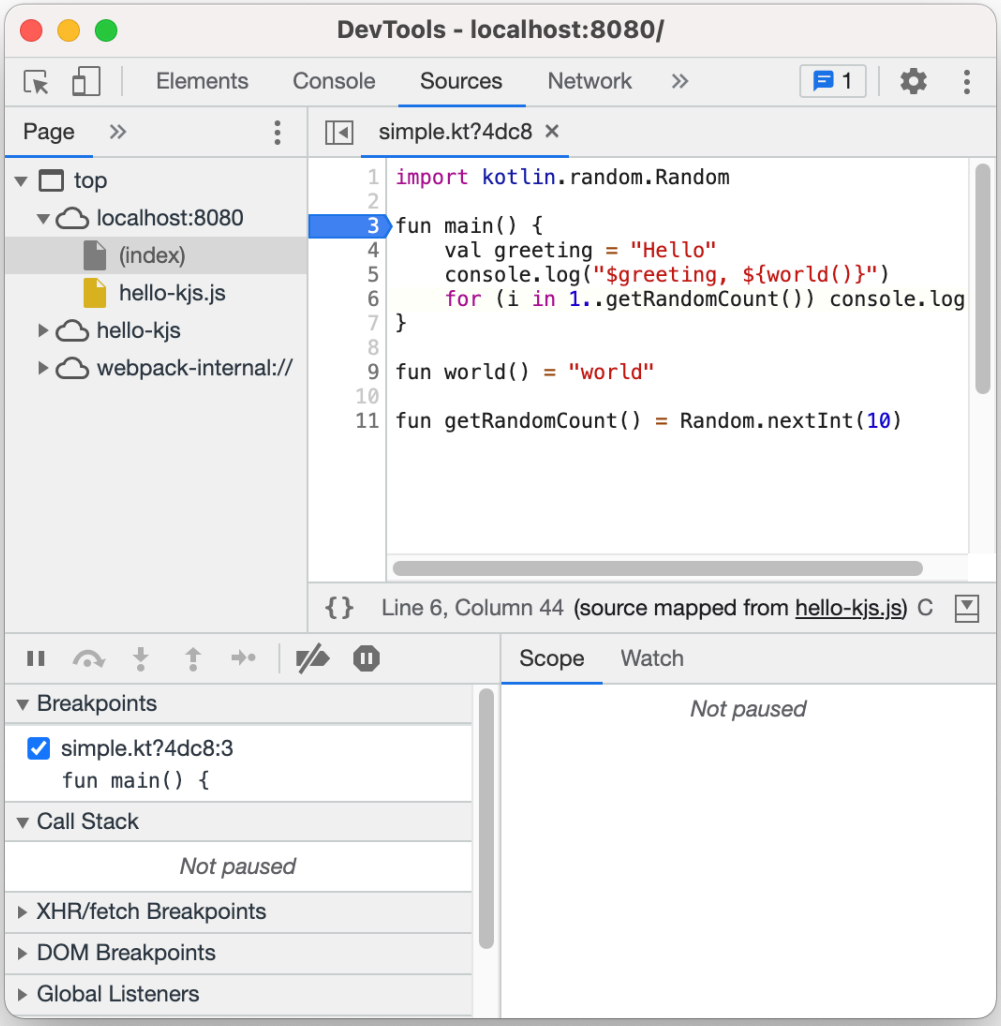
JavaScript source maps provide mappings between the minified code produced by bundlers or minifiers and the actual source code a developer works with. This way, the source maps enable support for debugging the code during its execution.



The Kotlin Multiplatform Gradle plugin automatically generates source maps for the project builds, making them available without any additional configuration.

Debug in browser

Most modern browsers provide tools that allow inspecting the page content and debugging the code that executes on it. Refer to your browser's documentation for more details.



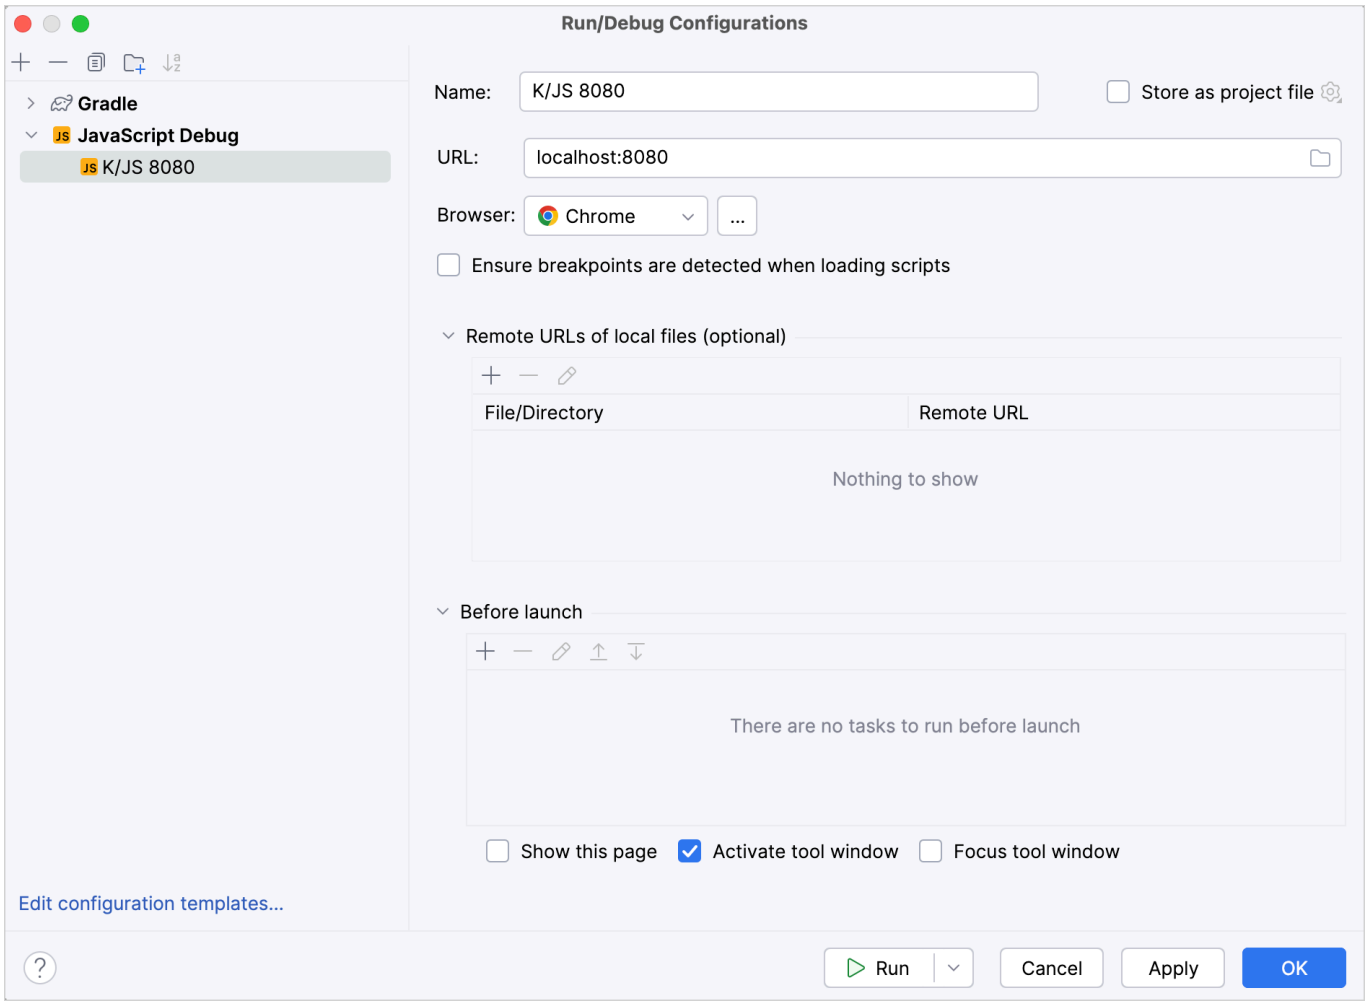
To debug Kotlin/JS in the browser:

1. Run the project by calling one of the available *run* Gradle tasks, for example, `jsBrowserDevelopmentRun`. Learn more about running Kotlin/JS.
2. Navigate to the page in the browser and launch its developer tools (for example, by right-clicking and selecting the **Inspect** action). Learn how to find the developer tools in popular browsers.
3. If your program is logging information to the console, navigate to the **Console** tab to see this output. Depending on your browser, these logs can reference the Kotlin source files and lines they come from:

Chrome DevTools console

4. Click the file reference on the right to navigate to the corresponding line of code. Alternatively, you can manually switch to the **Sources** tab and find the file you need in the file tree. Navigating to the Kotlin file shows you the regular Kotlin code (as opposed to minified JavaScript):

Debugging in Chrome DevTools



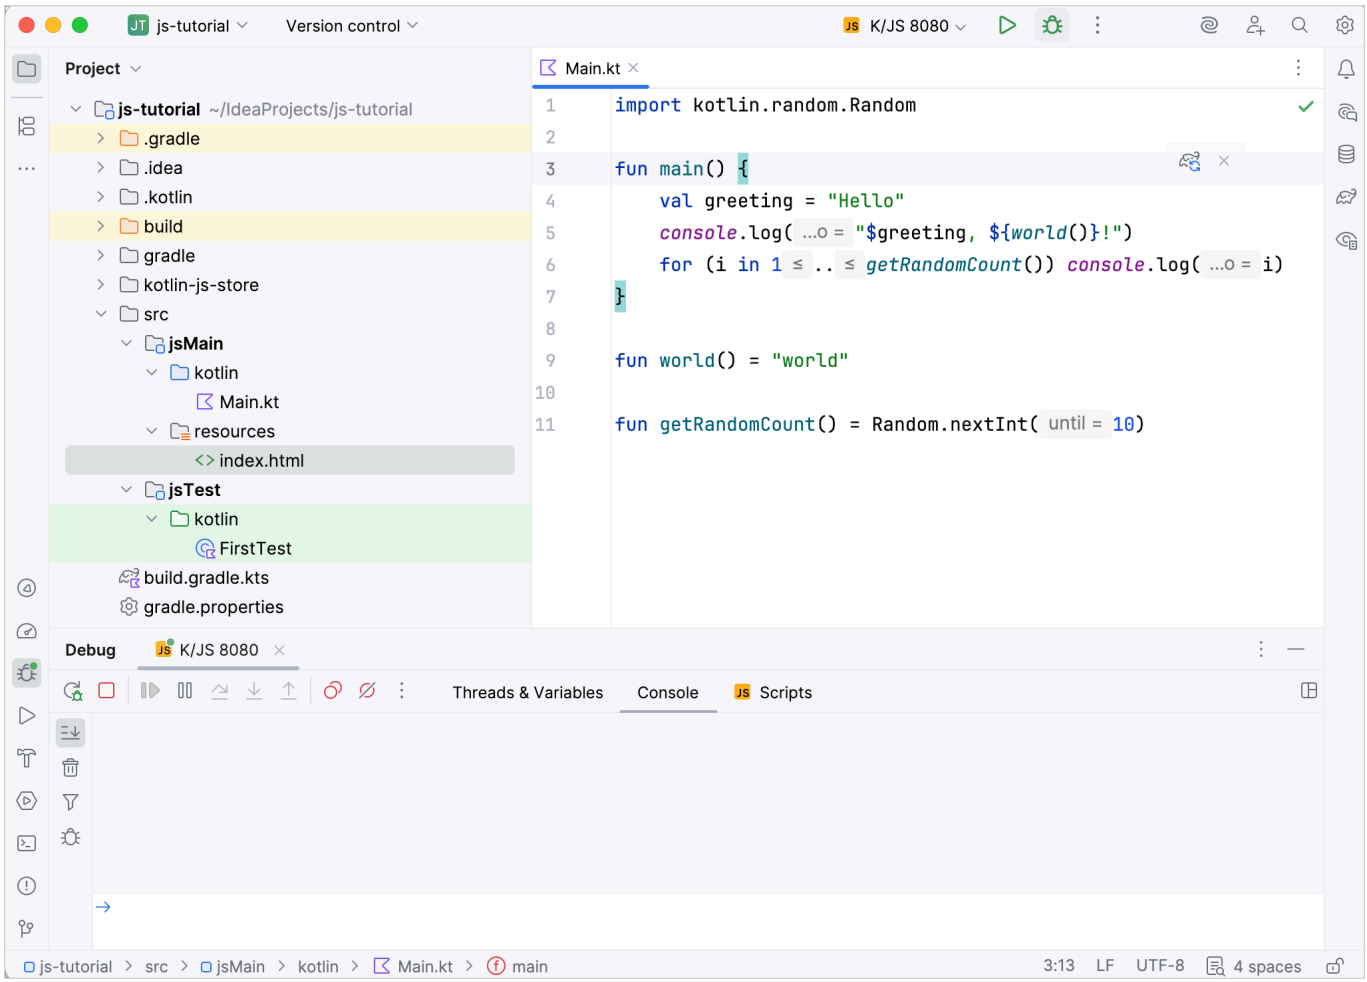
You can now start debugging the program. Set a breakpoint by clicking on one of the line numbers. The developer tools even support setting breakpoints within a statement. As with regular JavaScript code, any set breakpoints will persist across page reloads. This also makes it possible to debug Kotlin's `main()` method which is executed when the script is loaded for the first time.

Debug in the IDE

IntelliJ IDEA with an Ultimate subscription provides a powerful set of tools for debugging code during development.

For debugging Kotlin/JS in IntelliJ IDEA, you'll need a **JavaScript Debug** configuration. To add such a debug configuration:

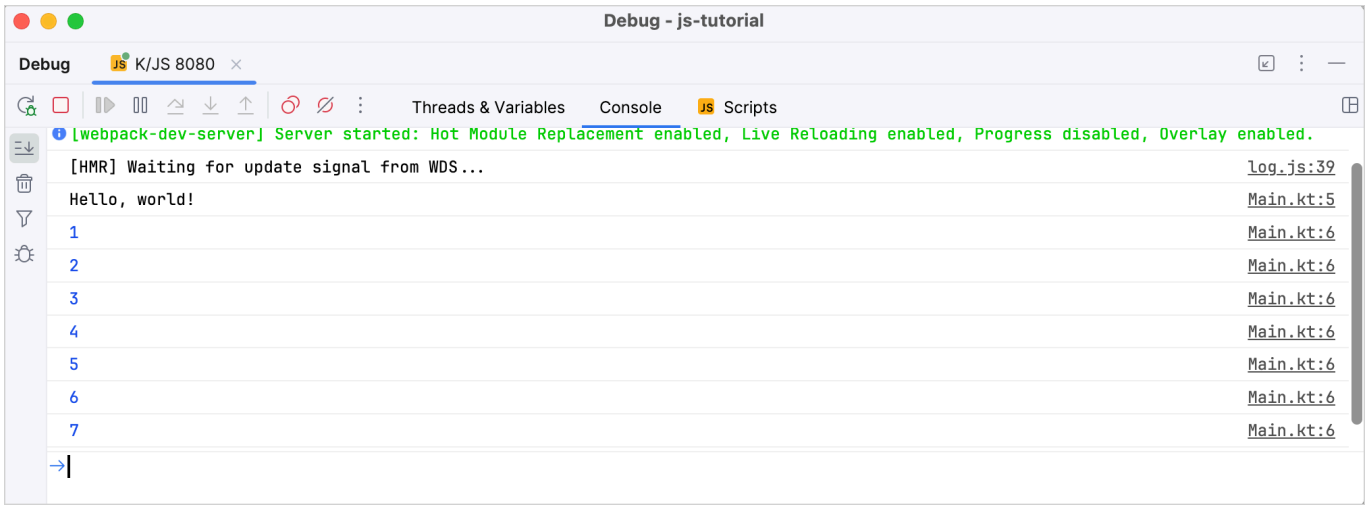
1. Go to **Run | Edit Configurations**.
2. Click **+** and select **JavaScript Debug**.
3. Specify the configuration **Name** and provide the **URL** on which the project runs (`http://localhost:8080` by default).



JavaScript debug configuration

4. Save the configuration.

Learn more about setting up JavaScript debug configurations.



Now you're ready to debug your project!

1. Run the project by calling one of the available *run* Gradle tasks, for example, `jsBrowserDevelopmentRun`. Learn more about running Kotlin/JS.
2. Start the debugging session by running the JavaScript debug configuration you've created previously:

JavaScript debug configuration

3. You can see the console output of your program in the **Debug** window in IntelliJ IDEA. The output items reference the Kotlin source files and lines they come from:

JavaScript debug output in the IDE

4. Click the file reference on the right to navigate to the corresponding line of code.

You can now start debugging the program using the whole set of tools that the IDE offers: breakpoints, stepping, expression evaluation, and more. Learn more about debugging in IntelliJ IDEA.

Because of the limitations of the current JavaScript debugger in IntelliJ IDEA, you may need to rerun the JavaScript debug to make the execution stop on breakpoints.

Debug in Node.js

If your project targets Node.js, you can debug it in this runtime.

To debug a Kotlin/JS application targeting Node.js:

1. Build the project by running the `build` Gradle task.
2. Find the resulting `.js` file for Node.js in the `build/js/packages/your-module/kotlin/` directory inside your project's directory.
3. Debug it in Node.js as described in the Node.js Debugging Guide.

What's next?

Now that you know how to start debug sessions with your Kotlin/JS project, learn to make efficient use of the debugging tools:

- Learn how to debug JavaScript in Google Chrome
- Get familiar with IntelliJ IDEA JavaScript debugger
- Learn how to debug in Node.js.

If you run into any problems

If you face any issues with debugging Kotlin/JS, please report them to our issue tracker, YouTrack

Run tests in Kotlin/JS

The Kotlin Multiplatform Gradle plugin lets you run tests through a variety of test runners that can be specified via the Gradle configuration.

The general workflow for running tests in Kotlin/JS is to add test dependencies, configure the test task in the build file, add tests, and run them.

For browser testing, you can choose between:

- The Karma test runner.
- The new DSL for browser testing.

The Karma project has been deprecated. No new features or bug fixes are expected. As an alternative, try out the new Kotlin DSL for browser testing.

The new DSL for browser testing is currently Experimental. It may be changed at any time. Opt-in is required with the `@OptIn(ExperimentalJsTestDsl::class)` annotation.

Add test dependencies

When you create a multiplatform project, you can add test dependencies to all the source sets, including the JavaScript target, by using a single dependency in `commonTest`:

Kotlin

```
// build.gradle.kts
kotlin {
    sourceSets {
        commonTest.dependencies {
            implementation(kotlin("test")) // Enables test annotations and functionality in JS
        }
    }
}
```

Groovy

```
// build.gradle
kotlin {
    sourceSets {
        commonTest {
            dependencies {
                implementation kotlin("test") // Enables test annotations and functionality in JS
            }
        }
    }
}
```

Configure browsers

You can run tests in Kotlin/JS against specific browsers. To do so, adjust the settings in the `browser {}` configuration block of the Gradle build file.

By default, the plugin uses Headless Chrome to run browser tests. No browsers are bundled with the Kotlin Multiplatform Gradle plugin by default. To enable additional browsers, use the `testTask {}` block for Karma and the `test {}` block for the new DSL for browser testing. See all available options here:

Karma

```
kotlin {
    js {
        browser {
            testTask {
                useKarma {
                    useIe()
                    useSafari()
                    useFirefox()
                    useChrome()
                    useChromeCanary()
                    useChromeHeadless()
                    usePhantomJS()
                    useOpera()
                }
            }
        }
    }
}
```

With Karma, you need to install all necessary browsers on your target system (locally or in CI).

For more information on Karma functionality, see Set up a Kotlin/JS project.

DSL for browser testing

```
import org.jetbrains.kotlin.gradle.ExperimentalJsTestDsl

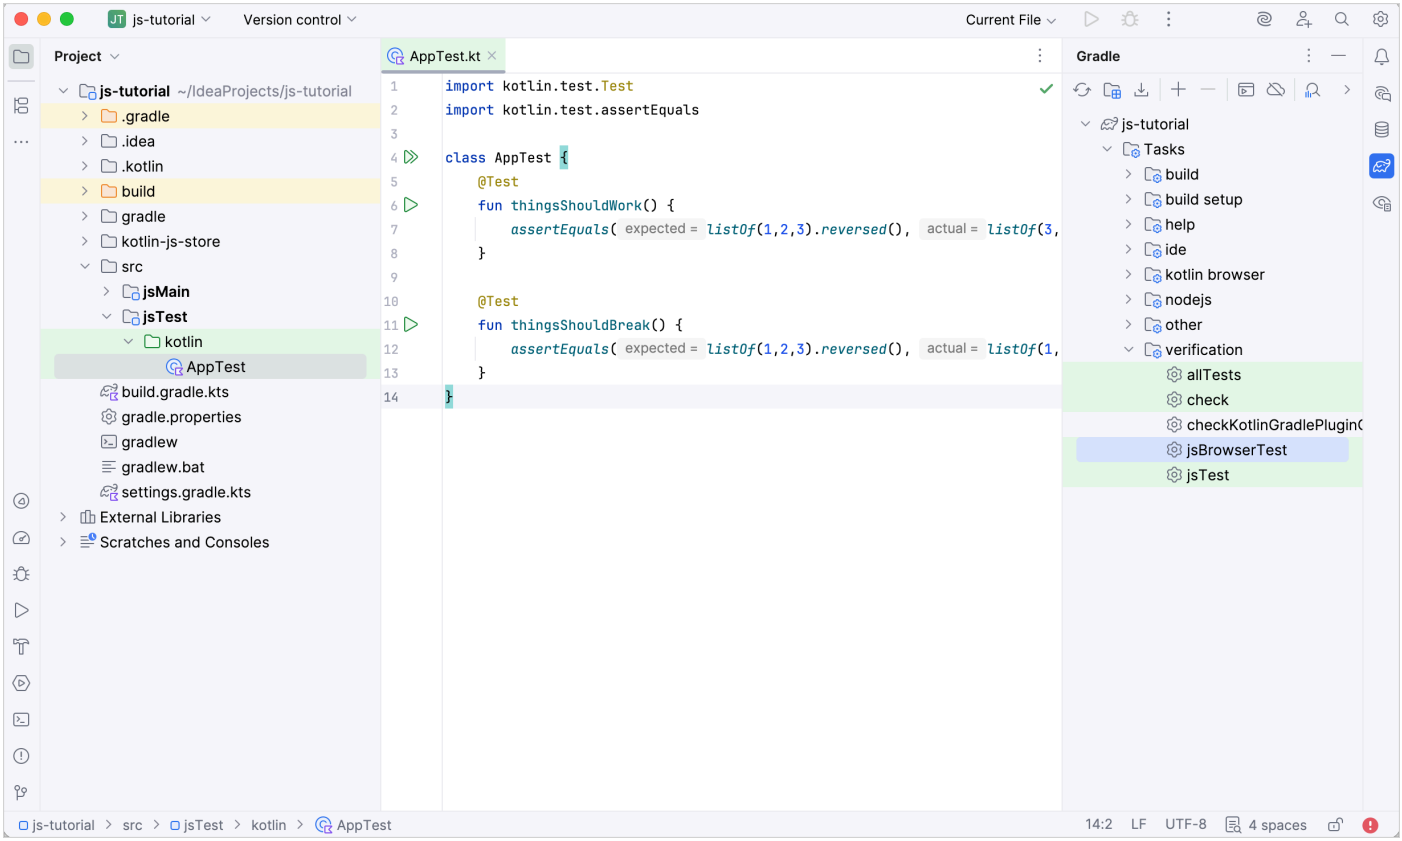
kotlin {
    js {
        browser {
            @OptIn(ExperimentalJsTestDsl::class)
            test {
                chromium()
                firefox()
                webkit() // Safari browser
            }
        }
    }
}
```

With the new DSL for browser testing, the Kotlin Multiplatform Gradle plugin installs the necessary browsers on the first run by using the `playwright install` command. Playwright then manages the location of these browsers and doesn't use locally installed browsers.

For additional settings available in the new DSL for browser testing, see Advanced configuration.

Add a test

To check that tests are executed properly, create a file `src/jsTest/kotlin/AppTest.kt` with the following content:



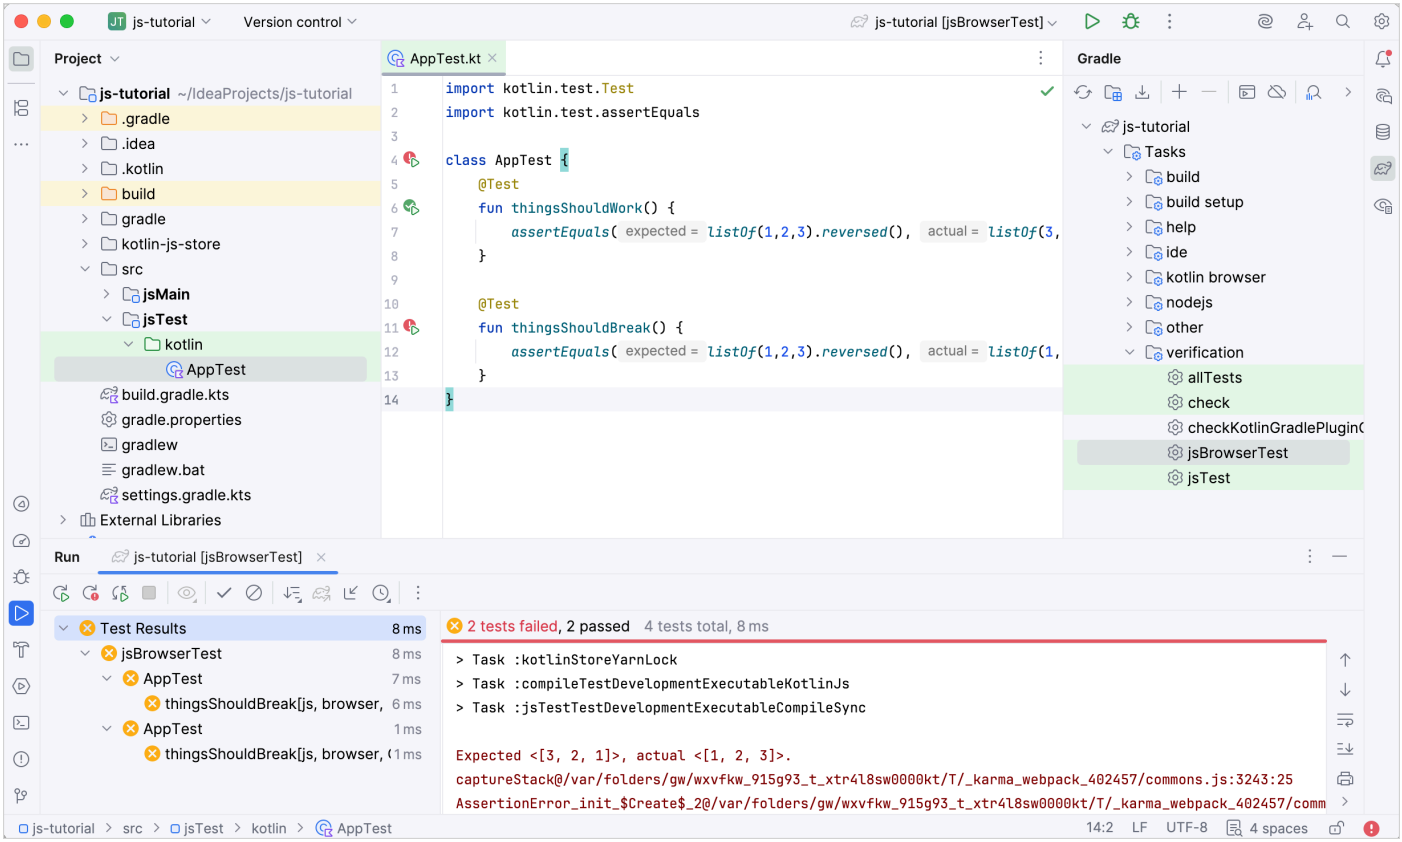
```
import kotlin.test.Test
import kotlin.test.assertEquals

@Test
fun thingsShouldWork() {
    assertEquals(listOf(3,2,1), listOf(1,2,3).reversed())
}

@Test
fun thingsShouldBreak() {
    assertEquals(listOf(1,2,3), listOf(1,2,3).reversed())
}
```

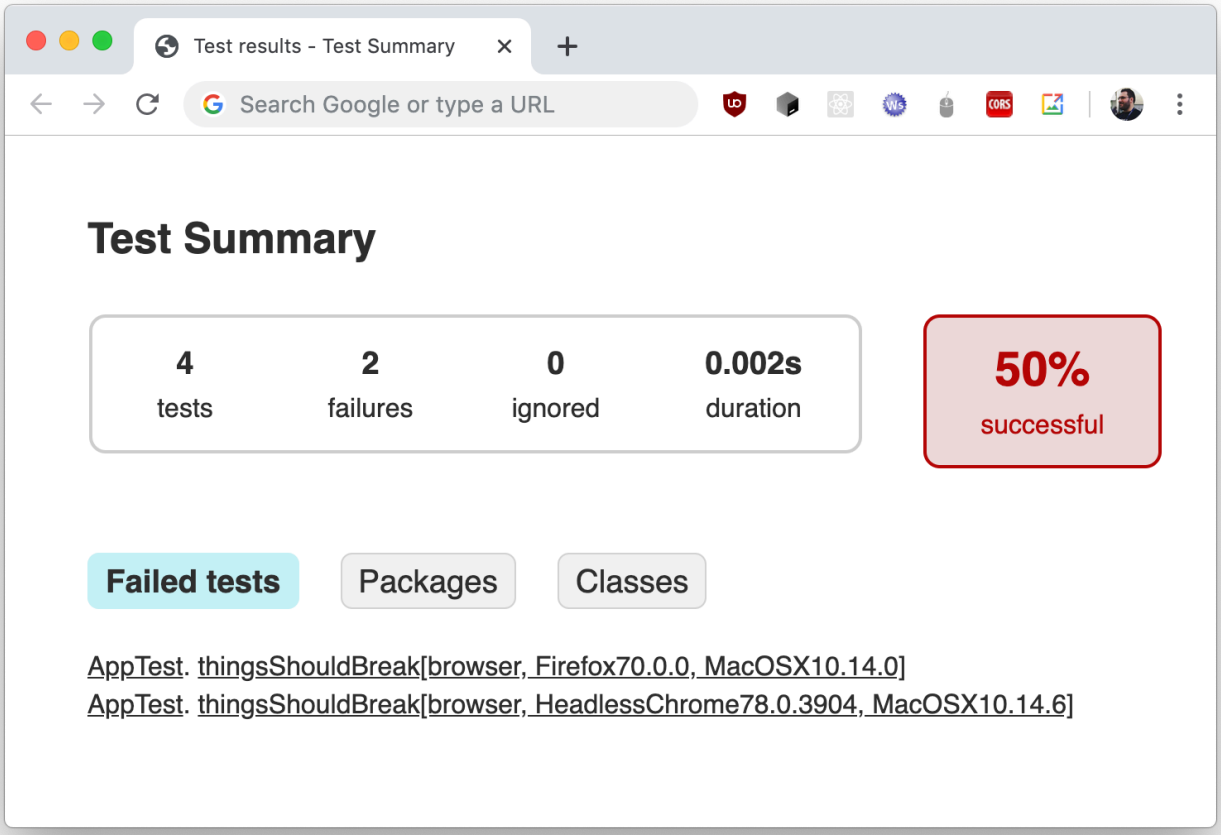
Run tests

To run the tests in the browser, execute the `jsBrowserTest` task or use the gutter icons in IntelliJ IDEA to execute all or individual tests:



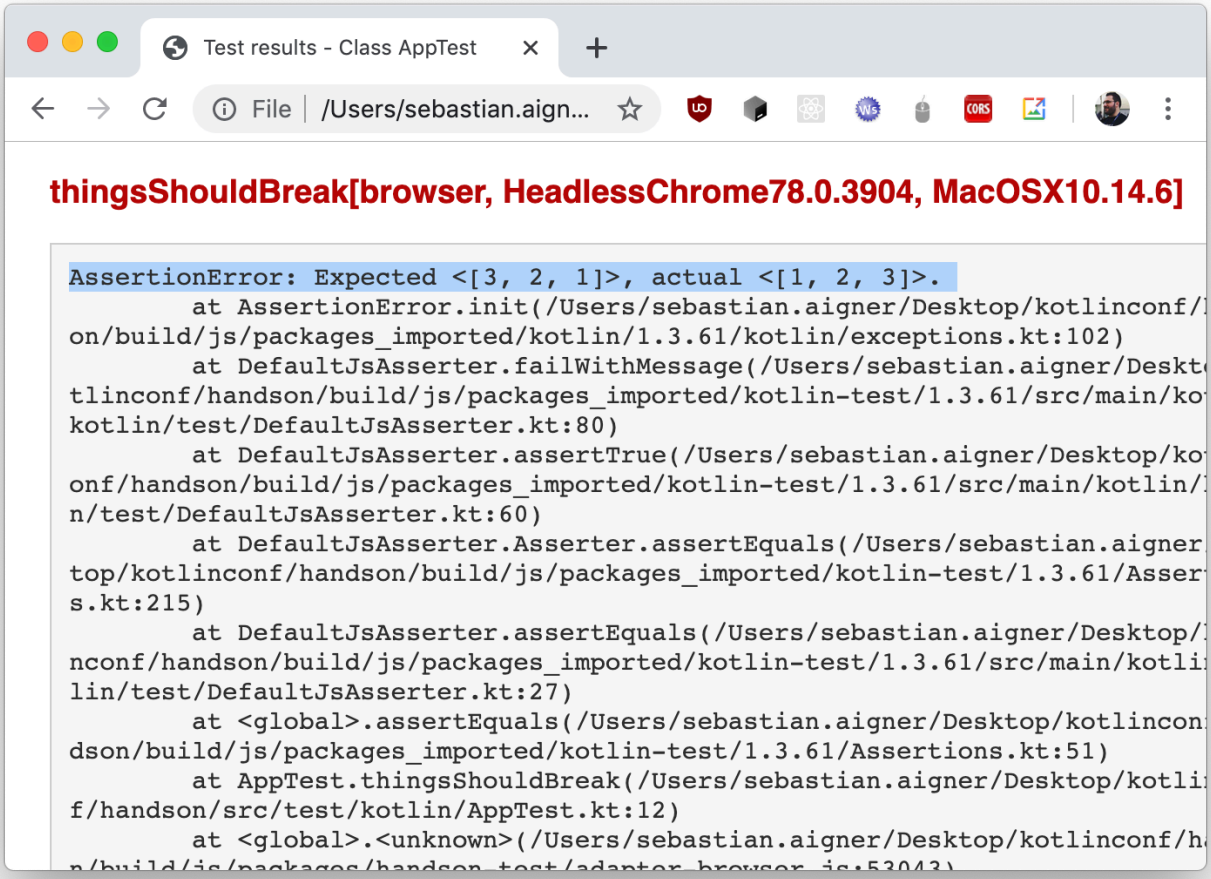
Gradle browserTest task

Alternatively, if you want to run the tests in the command line, use the Gradle wrapper:



```
./gradlew jsBrowserTest
```

After running tests in IntelliJ IDEA, the **Run** tool window shows the test results. You can click failed tests to see their stack trace and navigate to the corresponding test implementation by double-clicking it.



Test results in IntelliJ IDEA

After each test run, regardless of how you executed the test, you can find a properly formatted test report from Gradle in `build/reports/tests/jsBrowserTest/index.html`. Open this file in a browser to see another overview of the test results:

Gradle test summary

If you're using the set of example tests shown in the snippet above, one test passes, and one test fails, resulting in a 50% success rate. To get more information about individual test cases, use the provided links:

Stacktrace of a failed test in the Gradle summary

Experimental

Advanced configuration

This section applies only to the new experimental DSL for browser testing.

The new DSL for browser testing is designed to be minimalistic and tool-agnostic. The current implementation includes:

- Playwright acts as a browser driver and distribution manager that supports the Chromium, Firefox, and WebKit (Safari) browser engines.
- Mocha acts as a test runner.
- webpack acts as a bundler (will be replaced with Vite in future releases).

The DSL exposes timeouts, headless mode, and per-runner options as Gradle properties, so you can share defaults between runners, override them for a specific browser, and compute values lazily with providers:

```
import org.jetbrains.kotlin.gradle.ExperimentalJsTestDsl
import kotlin.time.Duration.Companion.seconds

kotlin {
    js {
        browser {
            @OptIn(ExperimentalJsTestDsl::class)
            test {
                // Configures the default timeout for all runners with kotlin.Duration
                timeout = 30.seconds

                // Configures headless mode using Gradle providers
                headless = providers
                    .environmentVariable("IS_IN_CI")
                    .map { it.toBoolean() }
                    .orElse(false)

                // Enables and configures the Chromium runner with a custom name
                chromium("chromium-no-webgl2") {
                    // Overrides the default timeout for this runner
                    timeout = 10.seconds

                    // Chromium-specific extra launch argument
                    launchArgs.add("--disable-webgl2")
                }

                // Enables the Firefox runner
                firefox()

                // Enables and configures the WebKit runner
                webkit("safari") {
                    timeout = 35.seconds
                }
            }
        }
    }
}
```

You can set the options for all test runners directly in the `test {}` block. To override these common options for a particular runner, use a custom name for it and provide different values inside a runner block. In this example, Chromium and WebKit (Safari) browsers use timeouts of 10 and 35 seconds, respectively, while Firefox uses the common timeout of 30 seconds.

Each runner is registered under its own name, so the test report tells you which browser a particular result comes from.

Experimental

Configuration for plugin authors

This section applies only to the new experimental DSL for browser testing.

If you write a Gradle plugin on top of the Kotlin Multiplatform Gradle plugin, the new DSL for browser testing also gives you access to the browser runners and to the location of the generated test bundle.

Kotlin generates the test bundle for running browser tests using the default test runner page. You can replace it by pointing to a different location in the `testsLocation` property:

```
kotlin {
    js {
        browser {
            @OptIn(ExperimentalJsTestDsl::class)
            test {
                // Implement customJsTestsLocation to modify or replace the default JS test bundle
                @OptIn(DelicateKotlinGradlePluginApi::class)
                testsLocation = customJsTestsLocation(extendFrom = defaultTestsLocationProvider)

                chromium()
            }
        }
    }
}
```

Your custom test bundler can include your own development server, bundler, or test runner. The `defaultTestsLocationProvider` property gives you access to the default location, so you can build on top of it instead of implementing everything from scratch.

Each test location exposes the directory with the generated test bundle (`bundleLocation`), the name of the test page (`testHtmlFileName`), and the URL that the browser opens (`url`) through the `KotlinJsTestsLocation` interface.

With access to these APIs, you can:

- Customize the URL that the browser opens. Each browser runner has its own test location, so you can override it either for all runners in the `test {}` block or for a particular runner.
- Override the bundle location itself, for example, to add extra files to the bundle.
- Post-process the generated test bundle. Register your own task and modify the files there before the browser opens them, for example, to inject your own configuration into `test.html` .

Keep the following limitations in mind when you build plugins using these APIs:

- Configuring `subtarget.test` enables the new test pipeline and disables Karma. There is currently no reliable way to detect which pipeline the user has chosen.
- There is no reliable way to configure a specific browser runner lazily, so the configuration has to happen in `afterEvaluate` . Consider asking your users to set the test location explicitly or exposing decorating functions such as `myPluginChromium()` instead.

Leave feedback

The new DSL for browser testing is in active development. New features, for example debugging, are planned for the next Kotlin releases.

We would appreciate your feedback in YouTrack or in the #javascript Slack channel.

Kotlin/JS frameworks

Take advantage of available Kotlin/JavaScript frameworks that simplify web development. These frameworks provide ready-to-use components, routing, state management, and other tools for building modern web applications.

Here are some Kotlin/JS web frameworks from the community:

Kobweb

Kobweb is a Kotlin framework for creating websites and web applications with Compose HTML. It supports live-reloading for fast development. Inspired by Next.js, Kobweb promotes a standard structure for adding widgets, layouts, and pages.

Out of the box, Kobweb provides page routing, light/dark mode, CSS styling, Markdown support, backend APIs, and more. It also includes Silk, a UI library with a set of versatile widgets for modern UIs.

Kobweb also supports site export by generating page snapshots for SEO and automatic search indexing. Additionally, it enables the creation of DOM-based UIs that efficiently update in response to state changes.

For more information and examples, see the Kobweb documentation.

For updates and discussions about the framework, join the #kobweb and #compose-web channels in Kotlin Slack.

Kilua

Kilua is a composable web framework built on the Compose Runtime and is similar to the compose-html library. Unlike compose-html, Kilua supports both Kotlin/Wasm and Kotlin/JS targets.

Kilua provides a modular API for creating declarative UI components and managing their state. It also includes a set of ready-to-use components for common web application use cases.

Kilua is a successor to the KVision framework. Kilua is designed to be familiar to both Compose users (`@Composable` functions, state management, coroutines/flow integration) and KVision users (a component-based API that allows some imperative interaction with UI components).

For more information and examples, see the Kilua documentation.

For updates and discussions about the framework, join the #kilua channel in Kotlin Slack.

Summon

Summon is a Kotlin Multiplatform frontend framework for building high-performance applications across JVM, Kotlin/JS, and Kotlin/Wasm. It supports component-based UI development, first-class server-side rendering (SSR) with HTML streaming, and modifier-driven styling that compiles to clean CSS.

Summon also focuses on runtime-aware components for accessibility and advanced behavior, while keeping a unified codebase across platforms.

For more information and examples, see the Summon documentation.

Kinetica

Kinetica is a Kotlin UI framework focused on practical outcomes for web apps: fast initial page delivery through server rendering, SEO-friendly HTML output, and a smooth handoff to interactive client-side UI after the page loads. It also supports headless testing, which helps teams test UI behavior quickly and reliably without depending on full browser environments.

Out of the box, Kinetica includes routing, forms, and persistence modules, so teams can ship common app features faster. Its update model applies minimal DOM patches, which helps keep interactions responsive as state changes, and its consistent reactive model is designed to reduce unexpected behavior in larger apps.

For more information and examples, see the Kinetica documentation.

Kotlin React

React is a component-based library, widely used for web and native user interfaces. It offers a large ecosystem of components, learning materials, and an active community.

Kotlin React is a Kotlin wrapper for React that combines the React ecosystem with the type-safety and expressiveness of Kotlin.

For updates and discussions about the library, join the #react and #javascript channels in Kotlin Slack.

KVision

KVision is an object-oriented web framework for building Kotlin/JS applications with ready-to-use UI components. These components can be building blocks for your application's user interface.

With this framework, you can use both reactive and imperative programming models to build your frontend. You can also integrate it with your backend applications by using connectors for Ktor, Spring Boot, and other frameworks. In addition, you can share code using Kotlin Multiplatform.

For more information, tutorials, and examples, see the KVision documentation.

For updates and discussions about the framework, join the #kvision and #javascript channels in Kotlin Slack.

fritz2

fritz2 is a standalone framework for building reactive web user interfaces. It provides its own type-safe DSL for building and rendering HTML elements and uses Kotlin's coroutines and flows to define components and their data bindings.

Out of the box, fritz2 offers state management, validation, routing, and more. It also integrates with Kotlin Multiplatform projects.

For more information, tutorials, and examples, see the fritz2 documentation.

For updates and discussions about the framework, join the #fritz2 and #javascript channels in Kotlin Slack.

Doodle

Doodle is a vector-based UI framework for Kotlin/JS. Doodle applications use the browser's graphics capabilities to draw user interfaces instead of relying on DOM, CSS, or JavaScript. This approach gives you control over the rendering of arbitrary UI elements, vector shapes, gradients, and custom visualizations.

For more information, tutorials, and examples, see the Doodle documentation.

For updates and discussions about the framework, join the #doodle and #javascript channels in Kotlin Slack.

Kotlin/JS compiler features

Kotlin/JS includes compiler features to optimize code for performance, size, and development speed. This works through the compilation process, which transforms Kotlin code into an intermediate representation (IR) before generating the JavaScript code.

Lazy initialization of top-level properties

For better application startup performance, the Kotlin/JS compiler initializes top-level properties lazily. This way, the application loads without initializing all the top-level properties used in its code. It initializes only the ones needed at startup; other properties receive their values later when the code that uses them actually runs.

```
val a = run {
    val result = // intensive computations
    println(result)
    result
} // value is computed upon the first usage
```

If for some reason you need to initialize a property eagerly (upon the application start), mark it with the `@EagerInitialization` annotation.

Incremental compilation for development binaries

The Kotlin/JS compiler provides the *incremental compilation mode for development binaries* that speeds up the development process. In this mode, the compiler caches the results of `compileDevelopmentExecutableKotlinJs` Gradle task on the module level. It uses the cached compilation results for unchanged source files during subsequent compilations, making them complete faster, especially with small changes.

Incremental compilation is enabled by default. To disable incremental compilation for development binaries, add the following line to the project's `gradle.properties` or `local.properties`:

```
kotlin.incremental.js.ir=false // true by default
```

The clean build in the incremental compilation mode is usually slower because of the need to create and populate the caches.

Minification of member names in production

The Kotlin/JS compiler uses its internal information about the relationships of your Kotlin classes and functions to apply more efficient minification, shortening the names of functions, properties, and classes. This reduces the size of resulting bundled applications.

This type of minification is automatically applied when you build your Kotlin/JS application in production mode, and enabled by default. To disable member name minification, use the `-Xir-minimized-member-names` compiler option:

```
kotlin {
    js {
        compilations.all {
            compileTaskProvider.configure {
                compilerOptions.freeCompilerArgs.add("-Xir-minimized-member-names=false")
            }
        }
    }
}
```

Dead code elimination

Dead code elimination (DCE) reduces the size of the resulting JavaScript code by removing unused properties, functions, and classes.

Unused declarations can appear in cases like:

- A function is inlined and never gets called directly (which always happens except for a few cases).
- A module uses a shared library. Without DCE, parts of the library that you don't use are still included in the resulting bundle. For example, the Kotlin standard library contains functions for manipulating lists, arrays, char sequences, adapters for DOM, and so on. All of this functionality would require about 1.3 MB as a JavaScript file. A simple "Hello, world" application only requires console routines, which are only a few kilobytes for the entire file.

In the Kotlin/JS compiler, DCE is handled automatically:

- DCE is disabled in *development* bundling tasks, which correspond to the following Gradle tasks:
  - `jsBrowserDevelopmentRun`
  - `jsBrowserDevelopmentWebpack`
  - `jsNodeDevelopmentRun`
  - `compileDevelopmentExecutableKotlinJs`
  - `compileDevelopmentLibraryKotlinJs`
  - Other Gradle tasks including "development" in their name
- DCE is enabled if you build a *production* bundle, which corresponds to the following Gradle tasks:
  - `jsBrowserProductionRun`
  - `jsBrowserProductionWebpack`
  - `compileProductionExecutableKotlinJs`
  - `compileProductionLibraryKotlinJs`
  - Other Gradle tasks including "production" in their name

With the `@JsExport` annotation, you can specify the declarations you want DCE to treat as roots.

Experimental

JS plain objects compiler plugin

The JavaScript (JS) plain objects compiler plugin (`js-plain-objects`) lets you create and copy plain JS objects in a type-safe way.

Here you can find information about plain JS objects and how to use the `js-plain-objects` compiler plugin for your Kotlin/JS projects.

The `js-plain-objects` plugin only works with the new K2 Kotlin compiler.

Plain JS objects

A plain object is a simple JS object created via an object literal (`{}`) that contains data properties. Many JS APIs accept/return Plain JS objects for configuration or data exchange.

With the `js-plain-objects` plugin, you declare a Kotlin external interface to describe the object shape and annotate it with `@JsPlainObject`. The compiler then generates convenient functions to build and copy such objects while preserving Kotlin type safety.

Enable the plugin

Add the `js-plain-objects` plugin to your project's Gradle configuration file, as the following Kotlin DSL shows:

Kotlin

```
// build.gradle.kts
plugins {
    kotlin("multiplatform") version "2.4.20"
    kotlin("plugin.js-plain-objects") version "2.4.20"
}

kotlin {
    js {
        browser() // or nodejs()
    }
}
```

Groovy

```
// build.gradle
plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
    id 'org.jetbrains.kotlin.plugin.js-plain-objects' version '2.4.20'
}

kotlin {
    js {
        browser() // or nodejs()
    }
}
```

Declare a plain object type

Once you have enabled the `js-plain-objects` plugin, you can declare a plain object type. Annotate an external interface with `@JsPlainObject`. For example:

```
@JsPlainObject
external interface User {
    val name: String
    val age: Int
    // You can use nullable types to declare a property as optional
    val email: String?
}
```

When the plugin processes such an interface, it generates a companion object with two helper functions for creating and copying objects:

```
@JsPlainObject
external interface User {
    val name: String
    val age: Int
    val email: String?

    // Generated by the plugin
    @JsExport.Ignore
    companion object {
        inline operator fun invoke(name: String, age: Int, email: String? = NOTHING): User =
            js("({ name: name, age: age, email: email })")

        inline fun copy(source: User, name: String = NOTHING, age: Int = NOTHING, email: String? =
NOTHING): User =
            js("Object.assign({}, source, { name: name, age: age, email: email })")
    }
}
```

From the previous example:

- `name` and `age` are declared without a nullability mark, so they are required.
- `email` is declared as nullable, so it's optional and can be skipped during creation.
- The operator `invoke` builds a new plain JS object with the provided properties.
- The `copy` function creates a new object by shallow-copying `source` and overriding any specified properties.
- The companion is marked with `@JsExport.Ignore` to avoid leaking these helpers into JS exports.

Use plain objects

Create and copy objects using the generated helpers:

```
fun main() {
    val user = User(name = "Name", age = 10)
    val copy = User.copy(user, age = 11, email = "some@user.com")

    println(JSON.stringify(user))
    // { "name": "Name", "age": 10 }
    println(JSON.stringify(copy))
    // { "name": "Name", "age": 11, "email": "some@user.com" }
}
```

The Kotlin code compiles to JavaScript:

```
function main () {
    var user = { name: "Name", age: 10 };
    var copy = Object.assign({}, user, { age: 11, email: "some@user.com" });

    println(JSON.stringify(user));
    // { "name": "Name", "age": 10 }
    println(JSON.stringify(copy));
    // { "name": "Name", "age": 11, "email": "some@user.com" }
}
```

Any JavaScript objects created with this approach are safe. When you use a wrong property name or value type, you encounter compile-time errors. This approach is also zero-cost since the generated code is inlined as a simple object literal and `Object.assign` calls.

What's next

Learn more about interoperability with JavaScript in the Use JavaScript code from Kotlin and dynamic type documentation.

Beta

Kotlin/Wasm

Kotlin/Wasm has the power to compile your Kotlin code into WebAssembly (Wasm) format. With Kotlin/Wasm, you can create applications that run on different environments and devices, which support Wasm and meet Kotlin's requirements.

Wasm is a binary instruction format for a stack-based virtual machine. This format is platform-independent because it runs on its own virtual machine. Wasm provides Kotlin and other languages with a compilation target.

You can use Kotlin/Wasm in different target environments, such as browsers, for developing web applications built with Compose Multiplatform, or outside the browser in standalone Wasm virtual machines. In the outside-of-browser case, WebAssembly System Interface (WASI) provides access to platform APIs, which you can also utilize.

> To run applications built with Kotlin/Wasm in a browser, your users need a browser version that supports WebAssembly's garbage collection and legacy exception handling proposals. To check the browser support status, see the WebAssembly roadmap.

Kotlin/Wasm and Compose Multiplatform

With Kotlin, you have the power to build applications and reuse mobile and desktop user interfaces (UIs) in your web projects through Compose Multiplatform and Kotlin/Wasm.

Compose Multiplatform is a declarative framework based on Kotlin and Jetpack Compose that allows you to implement the UI once and share it across all the platforms you target.

For web platforms, Compose Multiplatform uses Kotlin/Wasm as its compilation target. Applications built with Kotlin/Wasm and Compose Multiplatform use a `wasm-js` target and run in browsers.

Additionally, you can use the most popular Kotlin libraries in Kotlin/Wasm out of the box. Like in other Kotlin and Multiplatform projects, you can include dependency declarations in the build script. For more information, see Adding dependencies on multiplatform libraries.

Would you like to try it yourself?

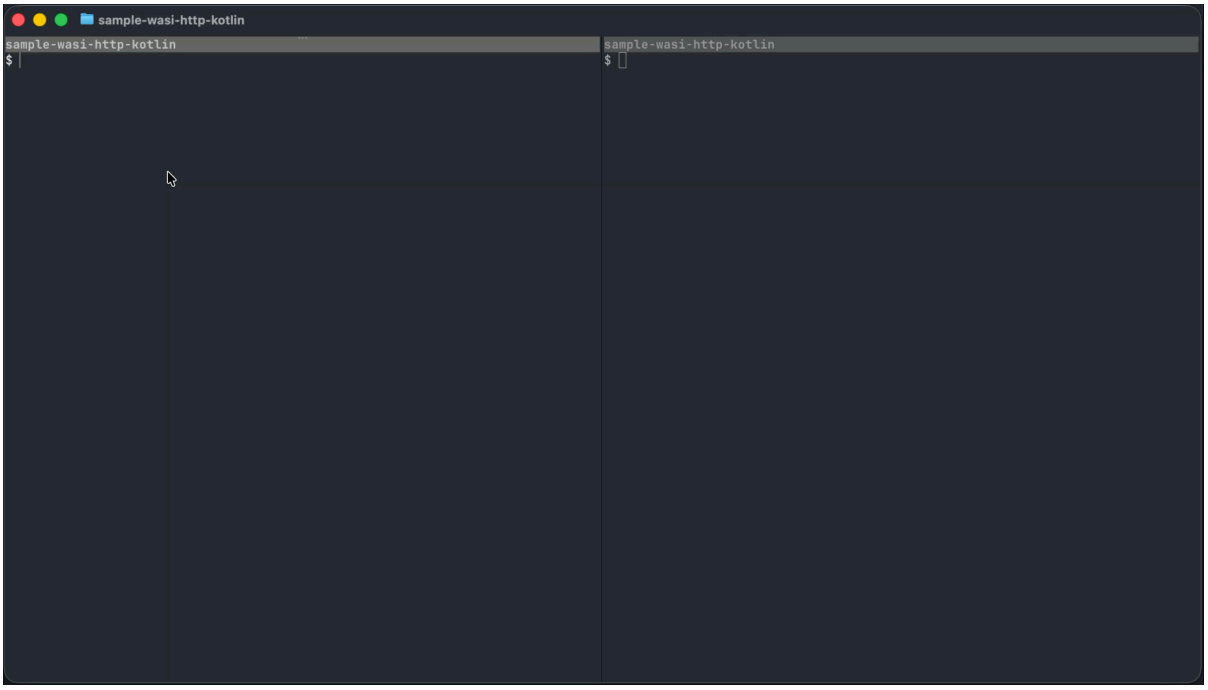
Get started with Kotlin/Wasm

Kotlin/Wasm and WASI

Kotlin/Wasm uses the WebAssembly System Interface (WASI) for backend applications. Applications built with Kotlin/Wasm and WASI use a Wasm-WASI target, allowing you to call the WASI API and run applications outside the browser environment.

Kotlin/Wasm leverages WASI to abstract away platform-specific details, allowing the same Kotlin code to run across diverse platforms. This expands the reach of Kotlin/Wasm beyond web applications without requiring custom handling for each runtime.

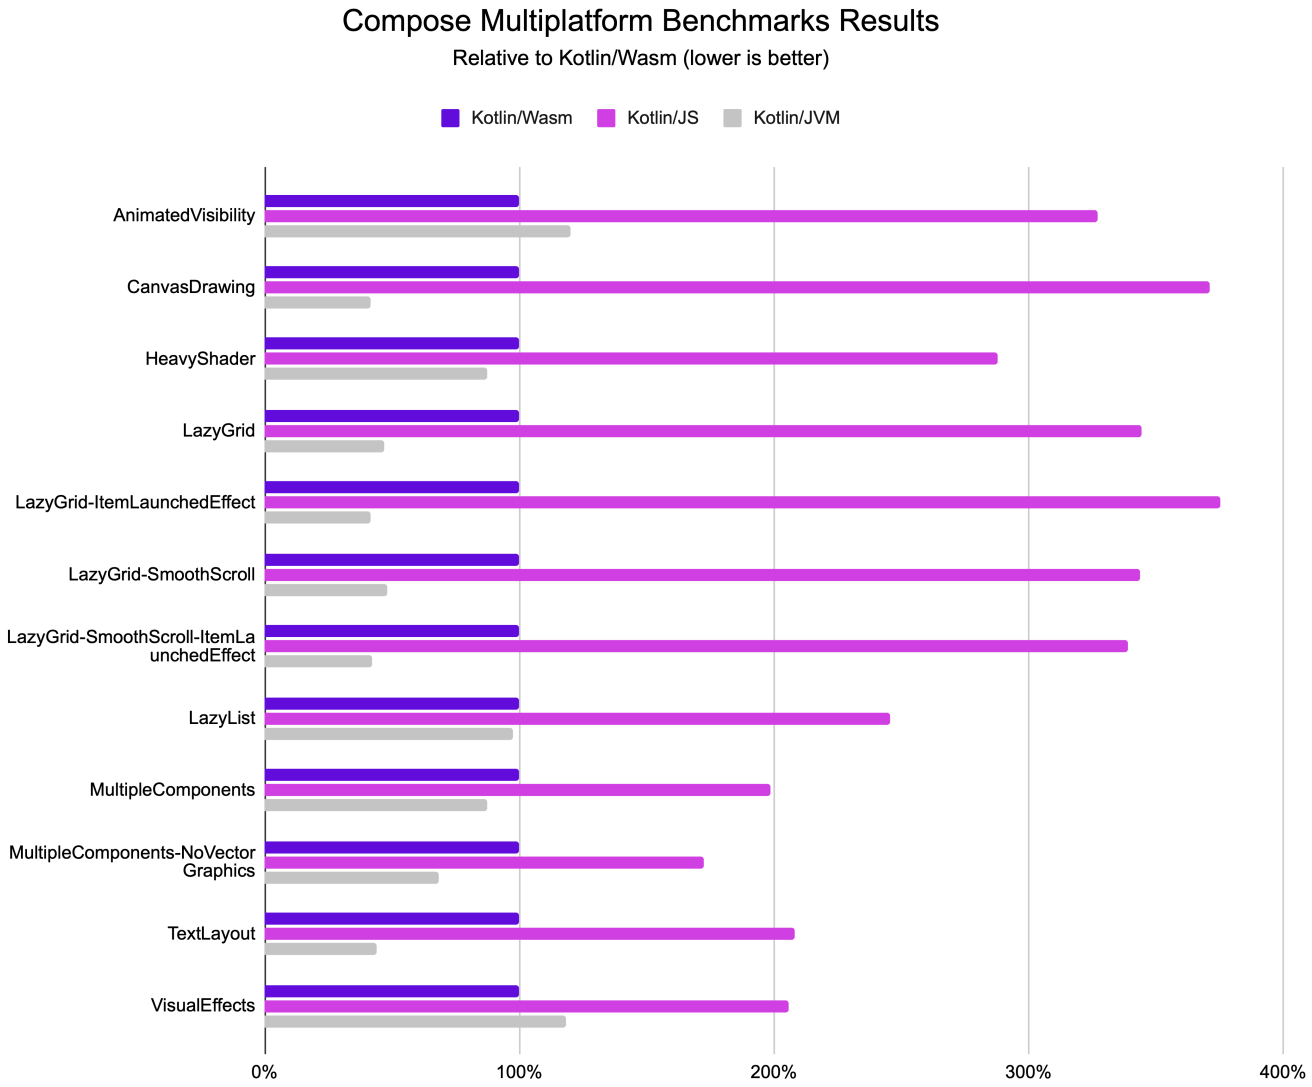
WASI provides a secure, standardized interface for running Kotlin applications compiled to WebAssembly across different environments.



> To see Kotlin/Wasm and WASI in action, check the Get started with Kotlin/Wasm and WASI tutorial.

Experimental

WebAssembly Component Model



WASI 0.2 is built on the WebAssembly Component Model, which defines a way to build components from Wasm modules using standardized interfaces and types. The model lets you define language-agnostic components in applications or libraries. You can also compose Wasm modules and existing components into new components.

To explore what's possible with the WebAssembly Component Model and Kotlin/Wasm, check out this demo of a simple server built with `wasi:http`.

Kotlin/Wasm performance

Although Kotlin/Wasm is still in Beta, Compose Multiplatform running on Kotlin/Wasm already shows encouraging performance traits. You can see that its execution speed outperforms JavaScript and is approaching that of the JVM:

Kotlin/Wasm performance

We regularly run benchmarks on Kotlin/Wasm, and these results come from our testing in a recent version of Google Chrome.

Browser API support

The Kotlin/Wasm standard library provides declarations for browser APIs, including the DOM API. With these declarations, you can directly use the Kotlin API to access and utilize various browser functionalities. For example, in your Kotlin/Wasm applications, you can use manipulation with DOM elements or fetch the API without defining these declarations from scratch. To learn more, see our Kotlin/Wasm browser example.

The declarations for browser API support are defined using JavaScript interoperability capabilities. You can use the same capabilities to define your own declarations. In addition, Kotlin/Wasm–JavaScript interoperability allows you to use Kotlin code from JavaScript. For more information, see Use Kotlin code in JavaScript.

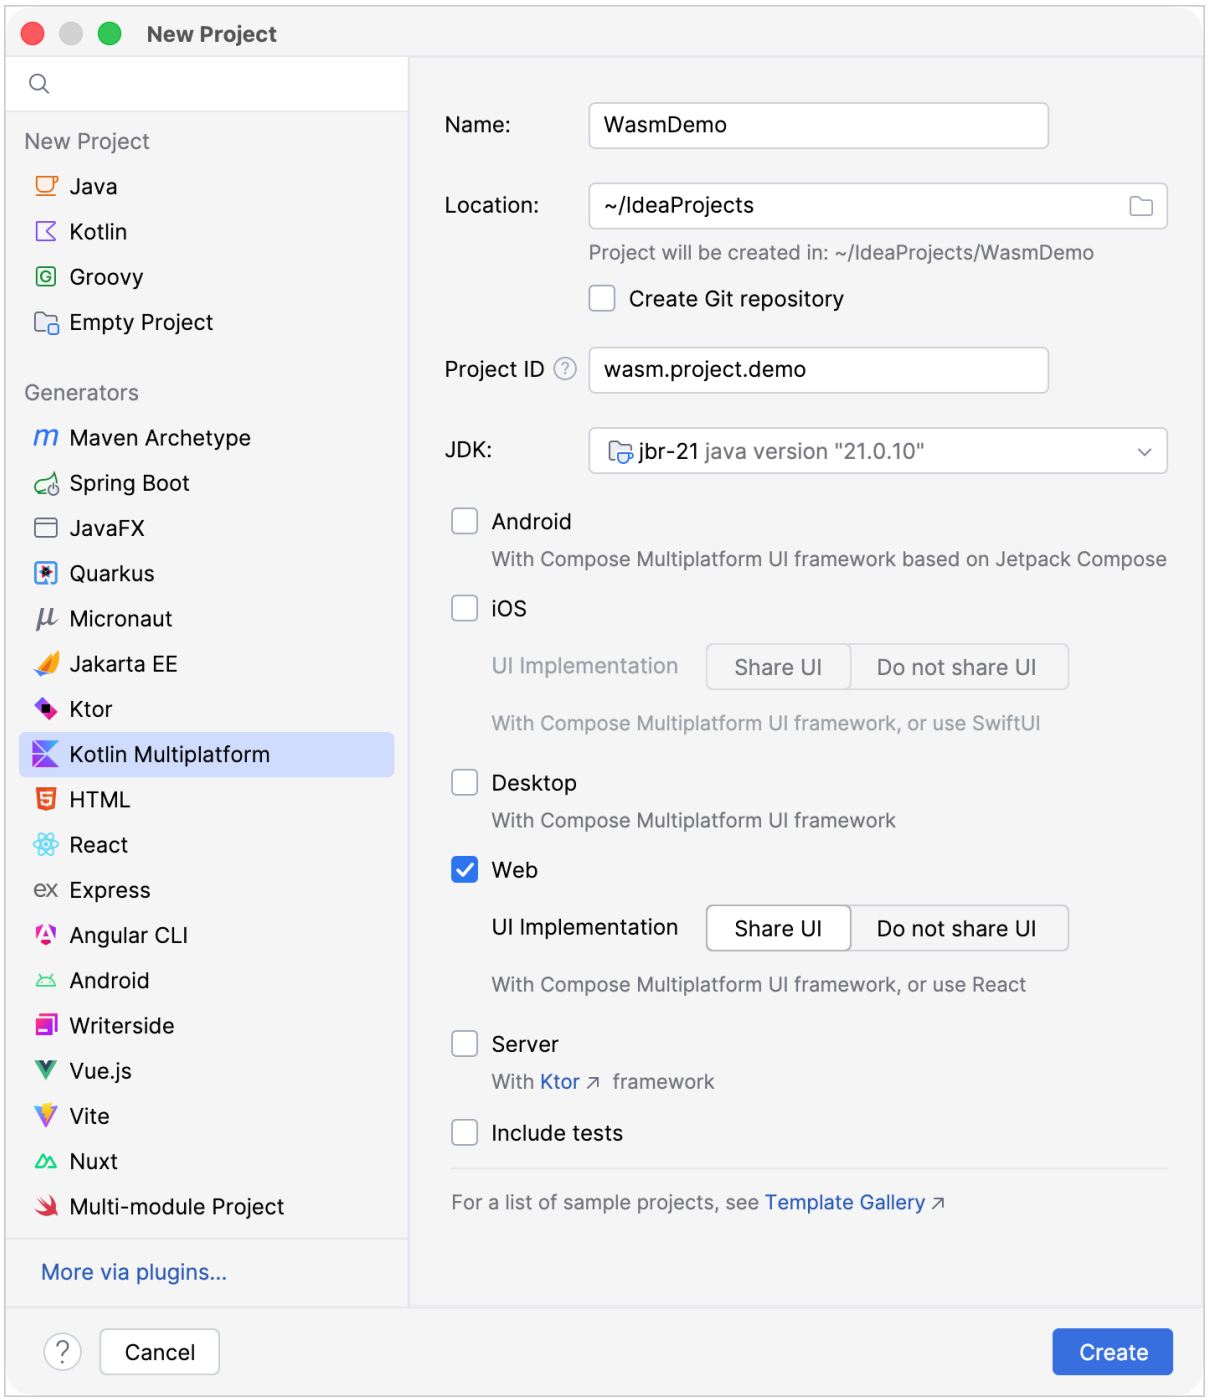
Beta

Get started with Kotlin/Wasm and Compose Multiplatform

This tutorial demonstrates how to run a Compose Multiplatform app with Kotlin/Wasm in IntelliJ IDEA and generate artifacts you can publish as a website.

Create a project

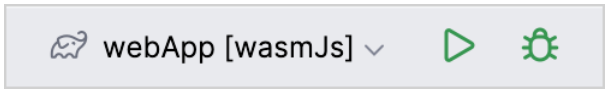


1. Set up your environment for Kotlin Multiplatform development.
2. In IntelliJ IDEA, select **File | New | Project**.
3. In the list of project templates, select **Kotlin Multiplatform**.

   If you're not using the Kotlin Multiplatform IDE plugin, you can generate the same project using the KMP web wizard.

4. Specify the following fields in the **New Project** window:
   - **Name:** WasmDemo
   - **Project ID:** wasm.project.demo

   This tutorial uses `wasm.project.demo` as the Project ID for consistency. However, we recommend keeping your usual group ID, such as `org.example`. Whatever you enter here will be suggested as the default in future projects.

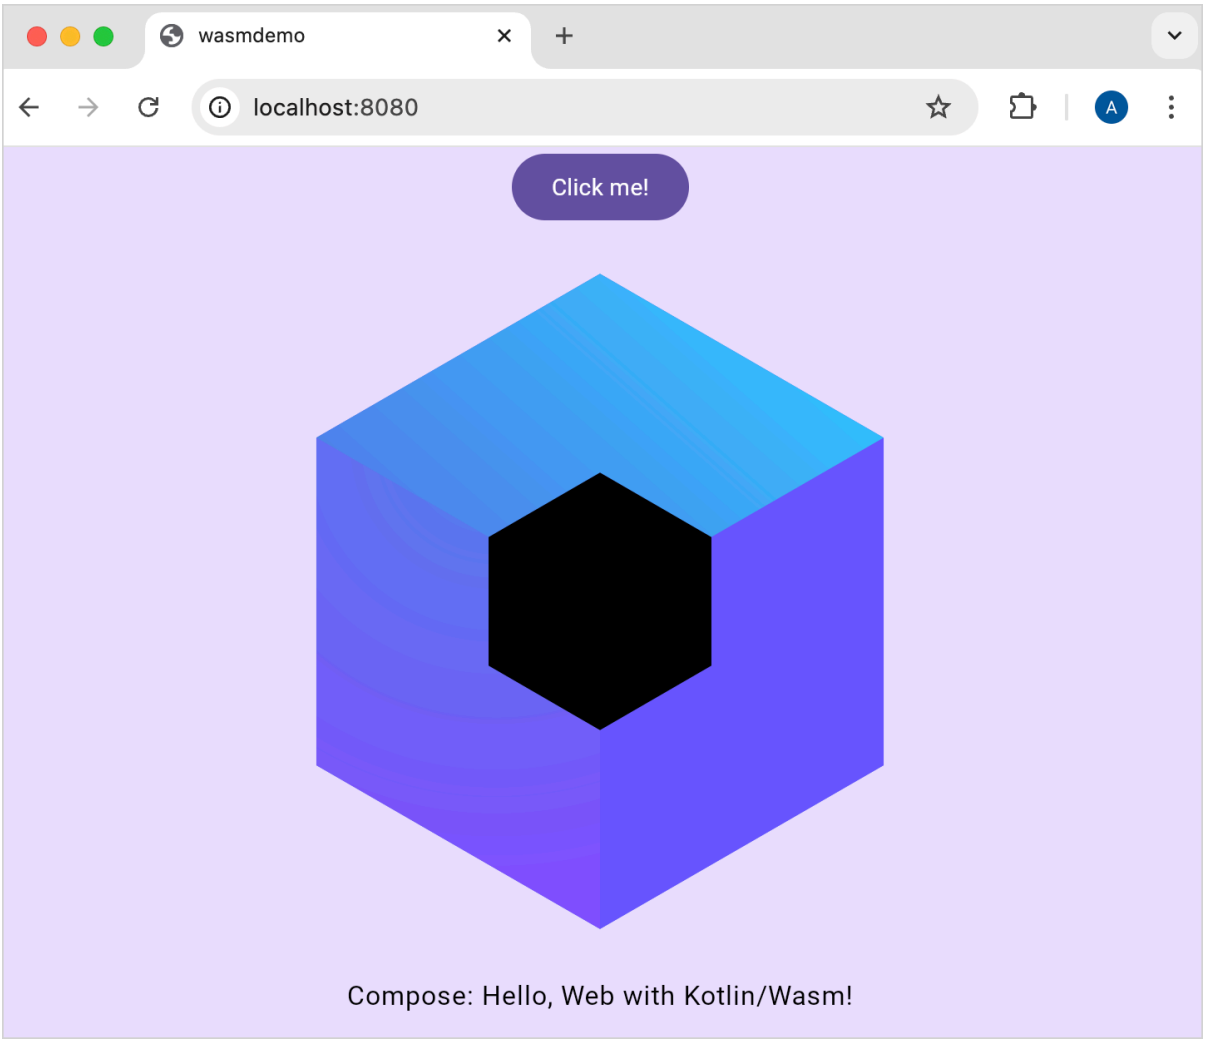


5. Select the **Web** target and the **Share UI** tab. Make sure that no other options are selected.
6. Click **Create**.

Kotlin Multiplatform wizard

Run the application

1. Once the project loads, select **webApp [wasmJs]** in the list of run configurations and click **Run**.



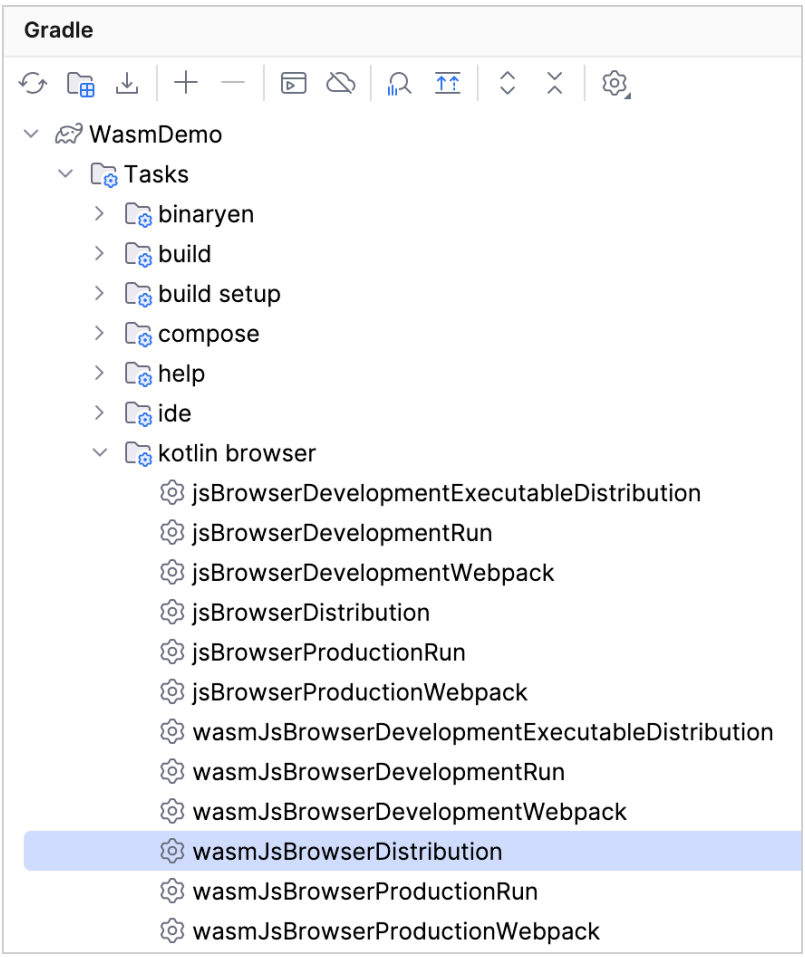
Run the Compose Multiplatform app on web

The web application opens automatically in your browser. Alternatively, once the build finishes, you can open the following URL manually:

```
http://localhost:8080/
```

The port number may vary if port `8080` is already in use. You can find the actual port number in the output of the Gradle build.

2. Click the **Click me!** button. This reveals the Compose Multiplatform logo:



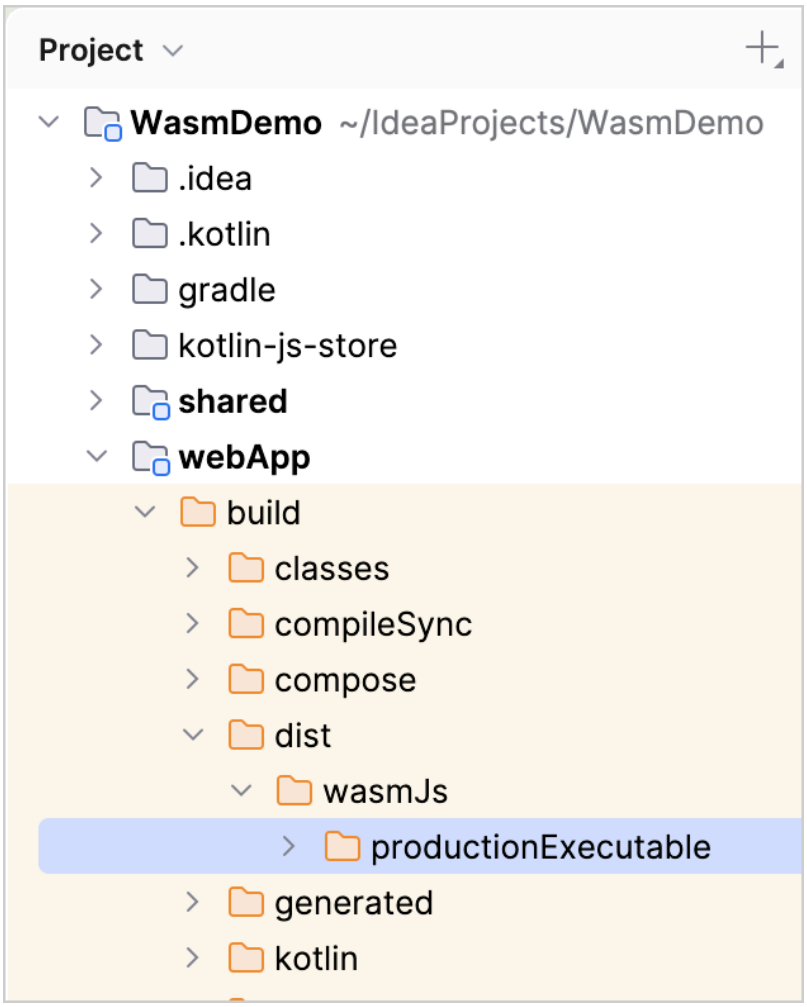
Compose app in browser

Generate artifacts

Generate your project's artifacts to publish on a website:

1. Open the **Gradle** tool window by selecting **View** | **Tool Windows** | **Gradle**.
2. In **WasmDemo** | **Tasks** | **kotlin browser**, select and run the **wasmJsBrowserDistribution** task.

> You need at least Java 11 as your Gradle JVM for the tasks to load successfully. For Compose Multiplatform projects in general, we recommend Java 17 or later.

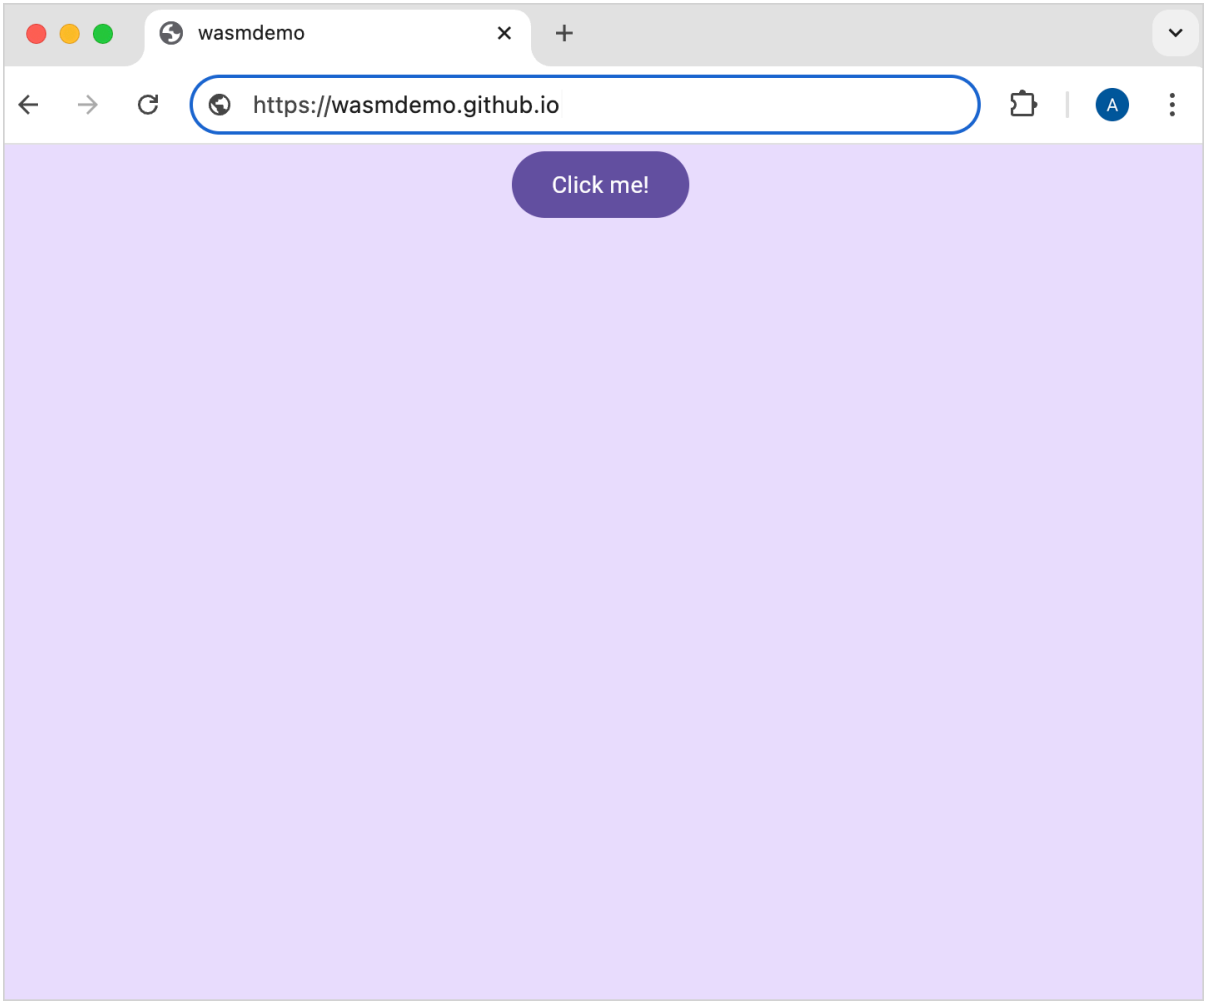


Run the Gradle task

Alternatively, you can run the following command in the terminal from the `WasmDemo` root directory:

```
./gradlew wasmJsBrowserDistribution
```

Once the task completes, you can find the generated artifacts in the `webApp/build/dist/wasmJs/productionExecutable` directory:



Artifacts directory

Publish the application

Use the generated artifacts to deploy your Kotlin/Wasm application. Select a publishing option that you prefer and follow the instructions:

- GitHub pages
- Cloudflare
- Apache HTTP Server

Once your site is created, open the browser and navigate to your platform's page domain. For example, GitHub pages:

Navigate to GitHub pages

Congratulations! You have published your artifacts.

Beta

Get started with Kotlin/Wasm and WASI

This tutorial demonstrates how to run a simple Kotlin/Wasm application using the WebAssembly System Interface (WASI) in various WebAssembly virtual machines.

You can find examples of an application running on Node.js, Wasmtime Deno, and WasmEdge virtual machines. The output is a simple application that uses the standard WASI API.

Currently, Kotlin/Wasm supports WASI 0.1, also known as Preview 1. Support for WASI 0.2 is planned for future releases. Follow this YouTrack issue for updates on WASI 0.2 support.

The `wasmWasi` target uses the new exception handling proposal by default, ensuring better compatibility with modern WebAssembly runtimes.

> The Kotlin/Wasm toolchain provides Node.js tasks (`wasmWasiNode*`) and Wasmtime (`wasmWasiWasmtime*`) out of the box. Other task variants in the project, such as those utilizing Deno or WasmEdge, are included as custom tasks.

Before you start

1. Download and install the latest version of IntelliJ IDEA.
2. Clone the Kotlin/Wasm WASI template repository by selecting **File | New | Project from Version Control** in IntelliJ IDEA.

   You can also clone it from the command line:

   ```
   git clone git@github.com:Kotlin/kotlin-wasm-wasi-template.git
   ```

Run the application

1. Open the **Gradle** tool window by selecting **View** | **Tool Windows** | **Gradle**.

   In the **Gradle** tool window, you can find the Gradle tasks under **kotlin-wasm-wasi-example** once the project loads.

   > You need at least Java 11 as your Gradle JVM for the tasks to load successfully.

2. From **kotlin-wasm-wasi-example** | **Tasks** | **kotlin node**, select and run one of the following Gradle tasks:

   - **wasmWasiNodeDevelopmentRun** to run the application in Node.js.
   - **wasmWasiWasmtimeDevelopmentRun** to run the application in Wasmtime.
   - **wasmWasiDenoDevelopmentRun** to run the application in Deno.
   - **wasmWasiWasmEdgeDevelopmentRun** to run the application in WasmEdge.

   > When using Deno on a Windows platform, ensure `deno.exe` is installed. For more information, see Deno's installation documentation.

Kotlin/Wasm and WASI tasks

Alternatively, run one of the following commands in the terminal from the `kotlin-wasm-wasi-template` root directory:

- To run the application in Node.js:

```
./gradlew wasmWasiNodeDevelopmentRun
```

- To run the application in Wasmtime:

```
./gradlew wasmWasiWasmtimeDevelopmentRun
```

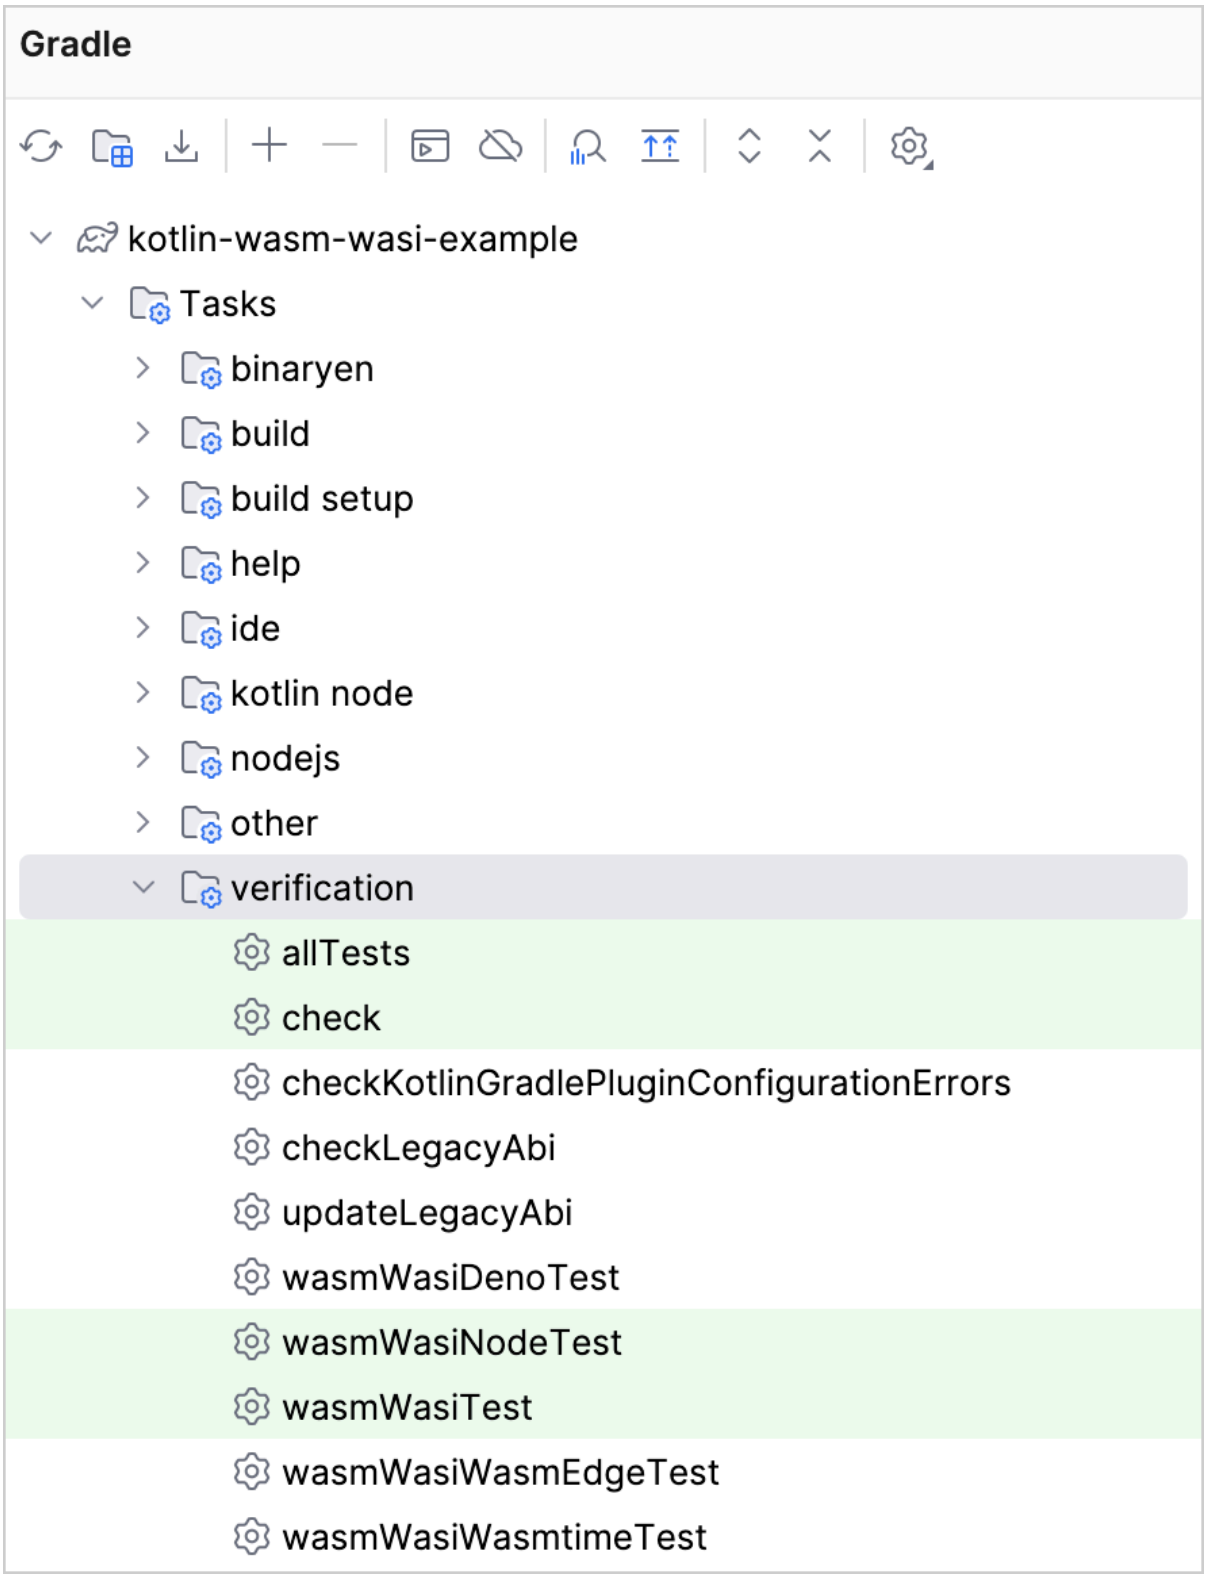
- To run the application in Deno:

```
./gradlew wasmWasiDenoDevelopmentRun
```

- To run the application in WasmEdge:

```
./gradlew wasmWasiWasmEdgeDevelopmentRun
```

The terminal displays a message when your application is built successfully:



Kotlin/Wasm and WASI app

Test the application

You can also test that the Kotlin/Wasm application works correctly across various virtual machines.

In the Gradle tool window, run one of the following Gradle tasks from **kotlin-wasm-wasi-example** | **Tasks** | **verification**:

- **wasmWasiNodeTest** to test the application in Node.js.
- **wasmWasiWasmtimeTest** to test the application in Wasmtime.
- **wasmWasiDenoTest** to test the application in Deno.
- **wasmWasiWasmEdgeTest** to test the application in WasmEdge.

Kotlin/Wasm and WASI test tasks

Alternatively, run one of the following commands in the terminal from the `kotlin-wasm-wasi-template` root directory:

- To test the application in Node.js:

```
./gradlew wasmWasiNodeTest
```

- To test the application in Wasmtime:

```
./gradlew wasmWasiWasmtimeTest
```

- To test the application in Deno:

```
./gradlew wasmWasiDenoTest
```

- To test the application in WasmEdge:

```
./gradlew wasmWasiWasmEdgeTest
```

Beta

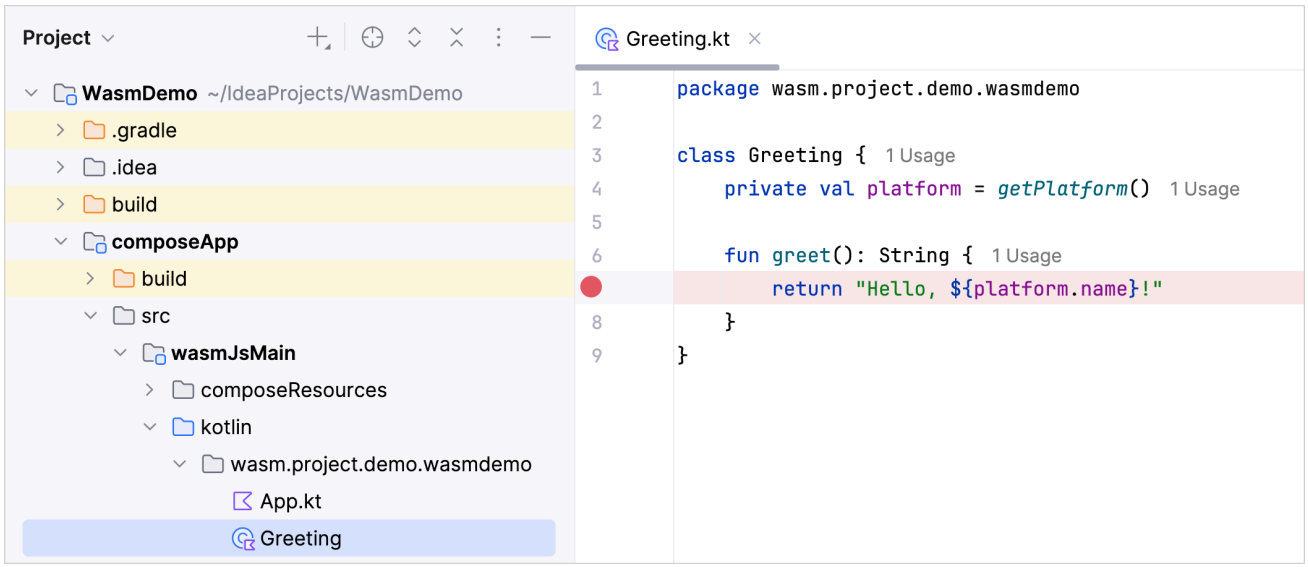
Debug Kotlin/Wasm code

This tutorial demonstrates how to use IntelliJ IDEA and the browser to debug your Compose Multiplatform application built with Kotlin/Wasm.

Before you start

1. Set up your environment for Kotlin Multiplatform development.
2. Follow the instructions to create a Kotlin Multiplatform project targeting Kotlin/Wasm.

- Debugging Kotlin/Wasm code in IntelliJ IDEA is available starting from version 2025.3 of the IDE, currently in the Early Access Program (EAP) and on the way to becoming stable. If you created the `WasmDemo` project in a different version of IntelliJ IDEA, switch to version 2025.3 and open the project there to continue this tutorial.
- To debug Kotlin/Wasm code in IntelliJ IDEA, you must have the JavaScript Debugger plugin installed. See more information about the plugin and how to install it.



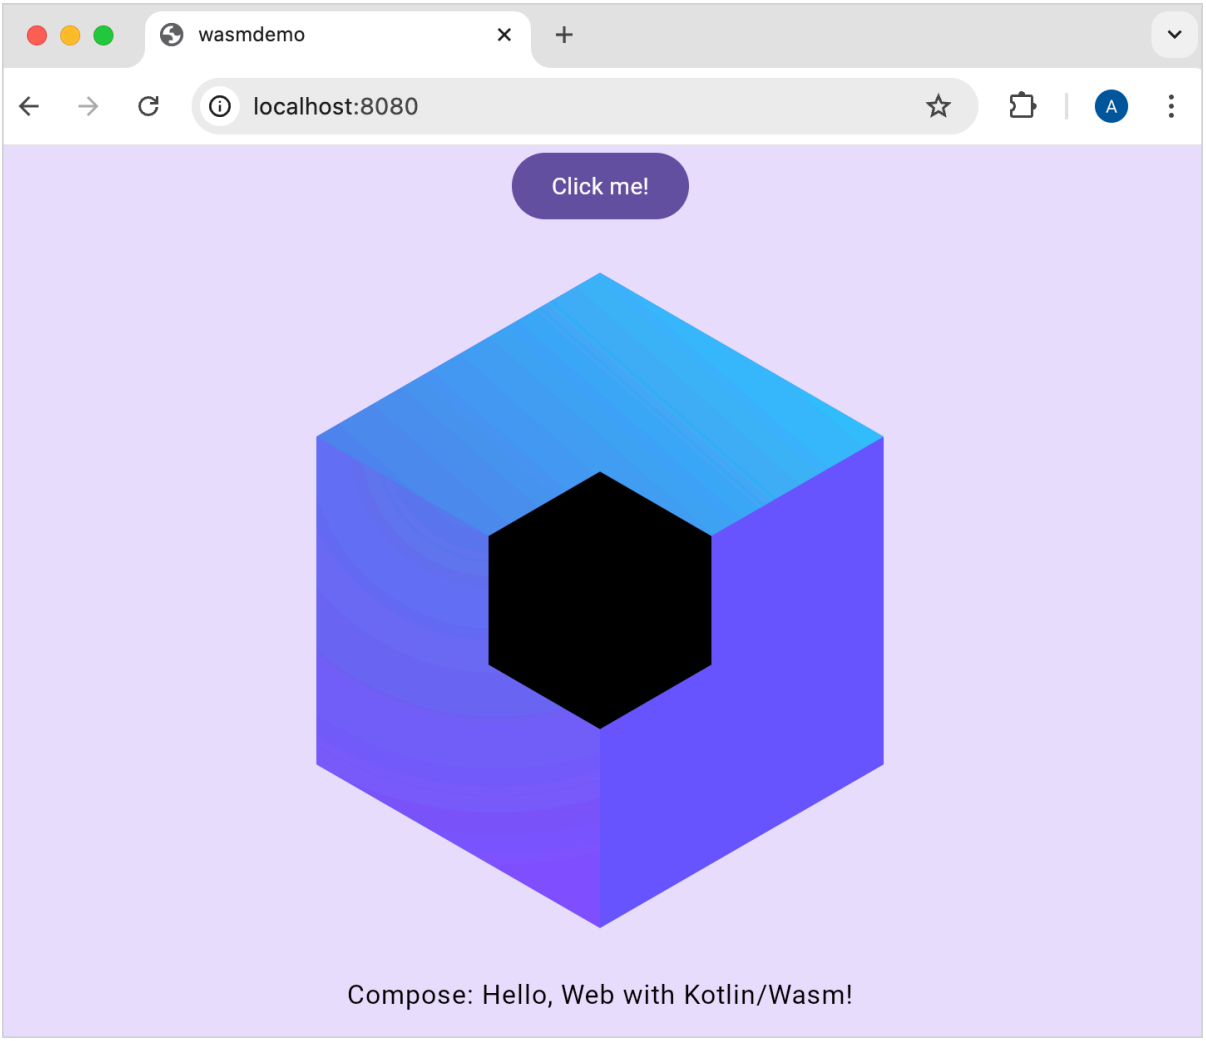
Debug in IntelliJ IDEA

The Kotlin Multiplatform project you created contains a Compose Multiplatform application powered by Kotlin/Wasm. You can debug this application in IntelliJ IDEA out of the box, without additional configuration.

1. In IntelliJ IDEA, open the Kotlin file to debug. In this tutorial, we'll work with the `Greeting.kt` file from the following directory of the Kotlin Multiplatform project:

   `WasmDemo/composeApp/src/wasmJsMain/kotlin/wasm.project.demo.wasmdemo`

2. Click on the line numbers to set breakpoints on the code that you want to inspect.



Set breakpoints

3. In the list of run configurations, select **composeApp[wasmJs]**.
4. Run the code in debug mode by clicking the debug icon at the top of the screen.

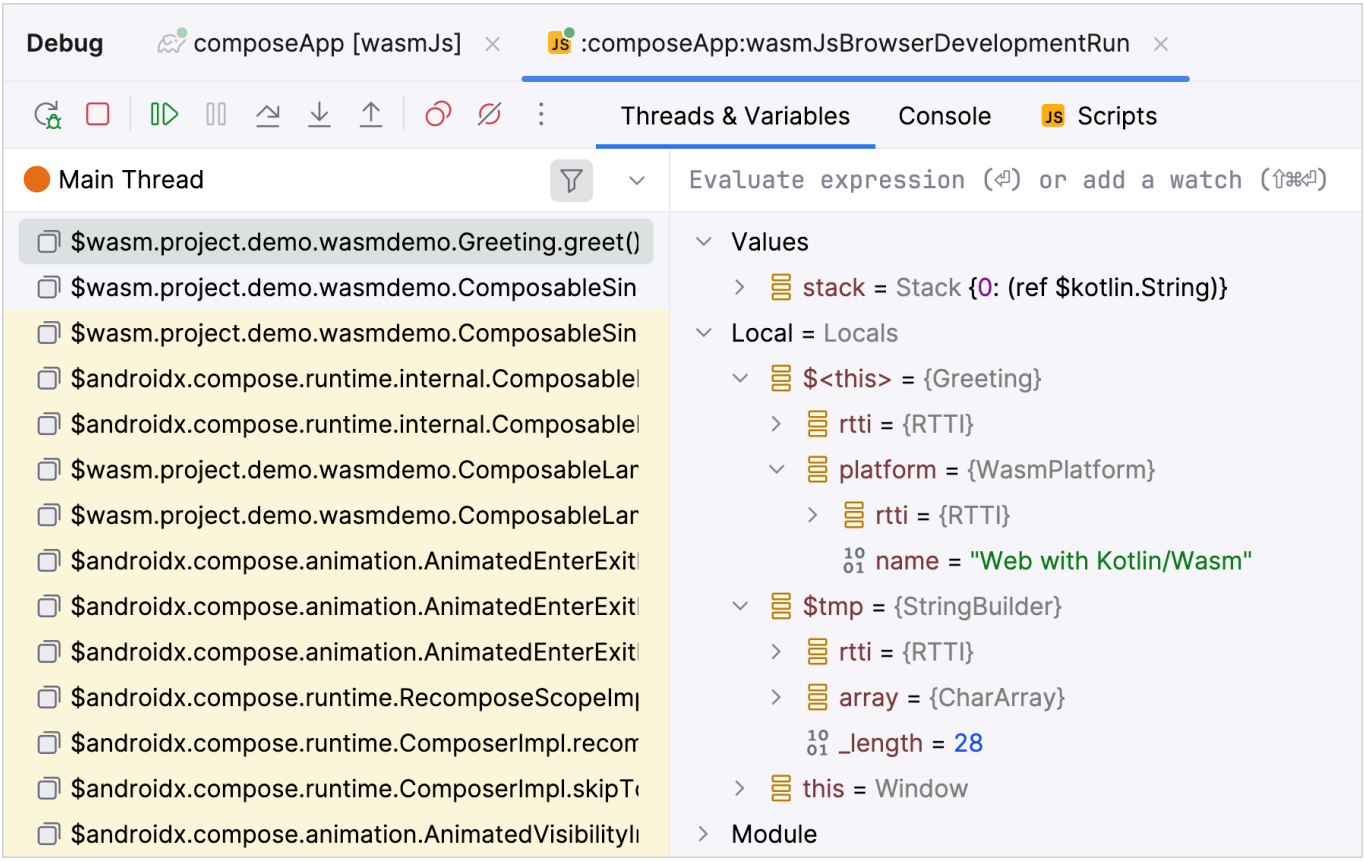
Run in debug mode

Once the application starts, it opens in a new browser window.

Compose app in browser

Also, the **Debug** panel opens automatically in IntelliJ IDEA.

Compose app debugger



Inspect your application

If you're debugging in your browser, you can follow the same steps for inspecting your application.

1. In the application's browser window, click on the **Click me!** button to interact with the application. This action triggers the execution of the code, and the debugger pauses when the execution reaches a breakpoint.
2. In the debugging pane, use the debugging control buttons to inspect variables and code execution at the breakpoints:
   - Step over to execute the current line and pause on the next line.
   - Step into to investigate a function more deeply.

- Step out to execute the code until it exits the current function.

3. Check the **Threads & Variables** pane. It helps you trace the sequence of function calls and pinpoint the location of any errors.

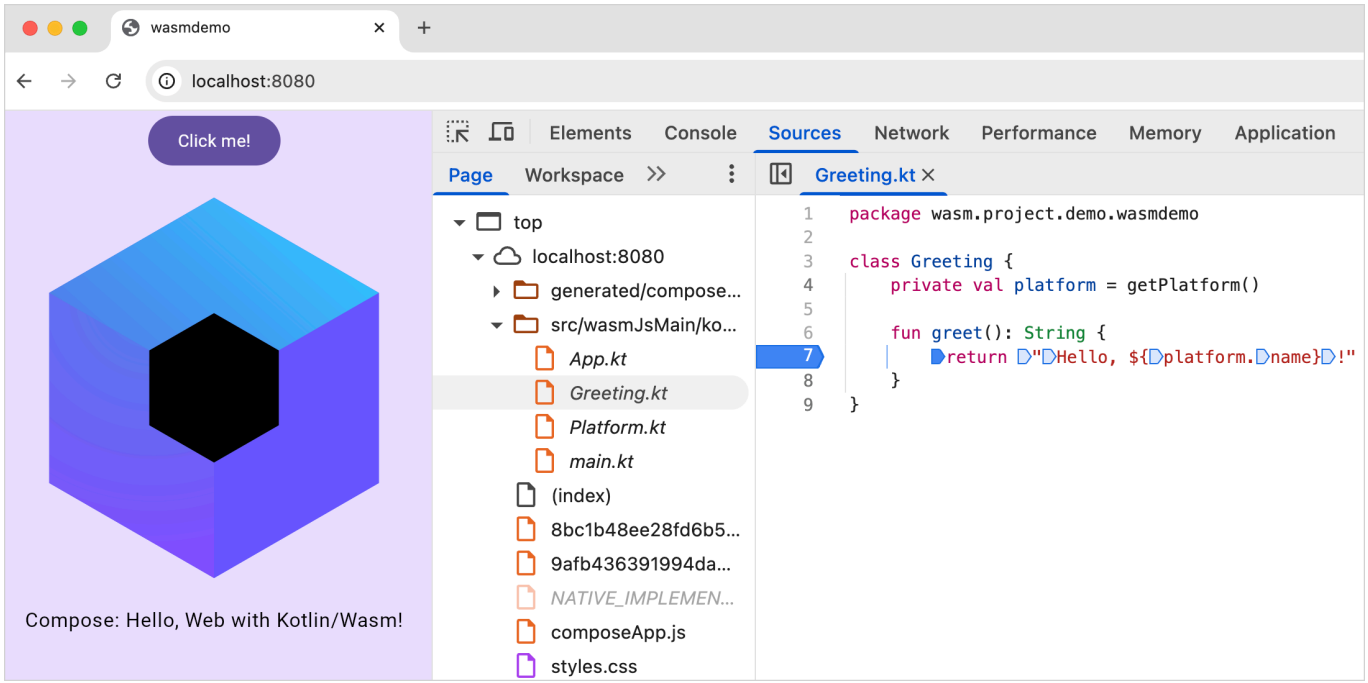
Check Threads & Variables

4. Make changes to your code and run the application again to verify how it works.
5. When you're done debugging, click on the line numbers with breakpoints to remove the breakpoints.

Debug in your browser

You can also debug this Compose Multiplatform application in your browser without additional configuration.

When you run development Gradle tasks (`*DevRun`), Kotlin automatically serves the source files to the browser, allowing you to set breakpoints, inspect variables, and step through Kotlin code.

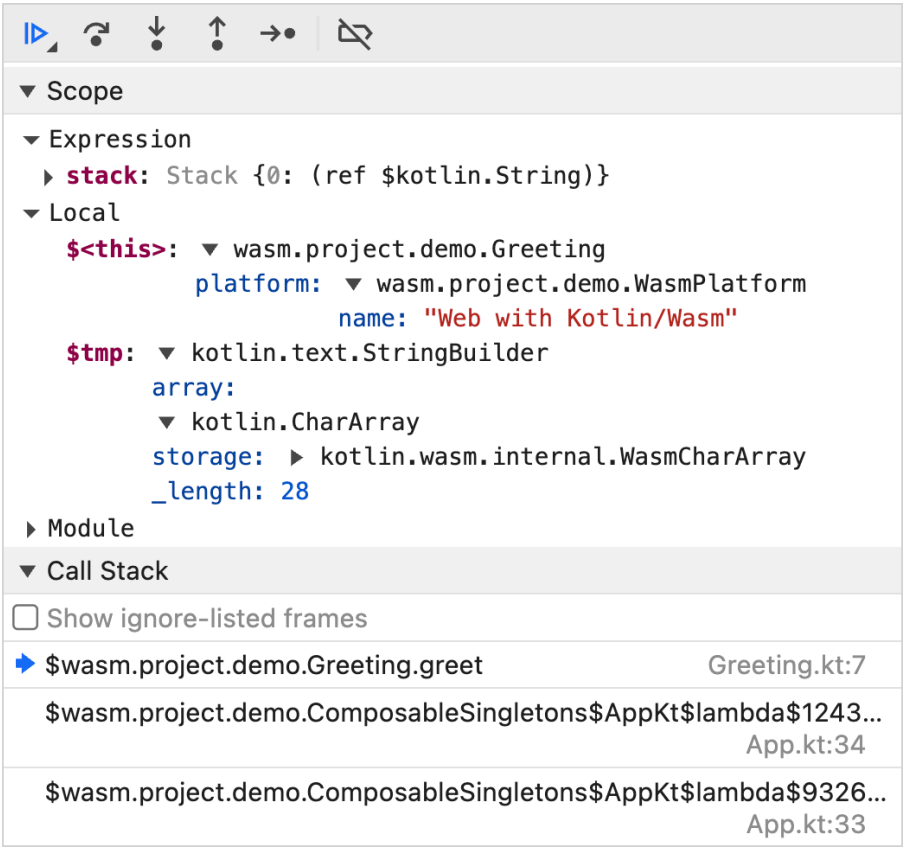


The configuration to serve the Kotlin/Wasm project sources in the browser is now included in the Kotlin Gradle plugin. If you previously added this configuration to your `build.gradle.kts` file, you should remove it to avoid conflicts.

> This tutorial uses the Chrome browser, but you should be able to follow these steps with other browsers. For more information, see Browser versions.

1. Follow the instructions to run the Compose Multiplatform application.
2. In the application's browser window, right-click and select the **Inspect** action to access developer tools. Alternatively, you can use the **F12** shortcut or select **View** | **Developer** | **Developer Tools**.

3. Switch to the **Sources** tab and select the Kotlin file to debug. In this tutorial, we'll work with the `Greeting.kt` file.

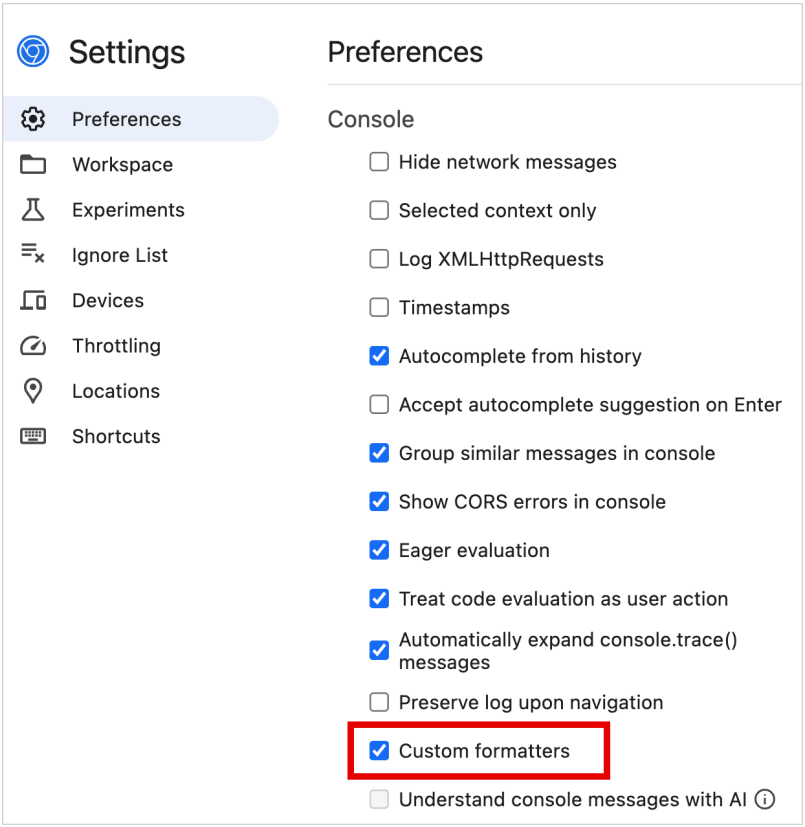


4. Click on the line numbers to set breakpoints on the code that you want to inspect. Only the lines with darker numbers can have breakpoints — in this example, 4, 7, 8, and 9.

Set breakpoints

5. Inspect your application similar to debugging in IntelliJ IDEA.

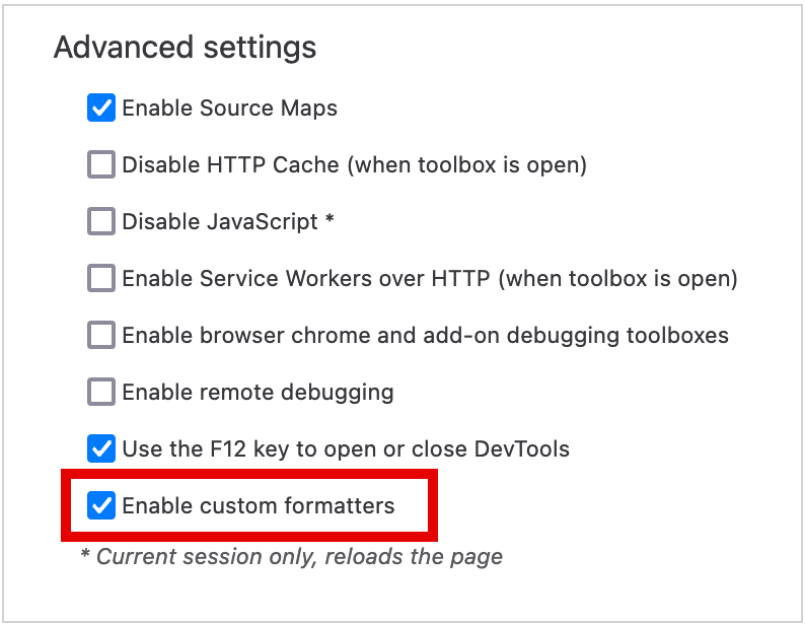
   When debugging in your browser, the panes to trace the sequence of function calls and pinpoint any errors are **Scope** and **Call Stack**.



Check the call stack

Use custom formatters

Custom formatters help display and locate variable values in a more user-friendly and comprehensible manner when debugging Kotlin/Wasm code in your browser.



Custom formatters are enabled by default in Kotlin/Wasm development builds, but you still need to ensure that custom formatters are enabled in your browser's developer tools:

- In Chrome DevTools, find the **Custom formatters** checkbox in **Settings | Preferences | Console**:

Enable custom formatters in Chrome

- In Firefox DevTools, find the **Enable custom formatters** checkbox in **Settings | Advanced settings**:

Enable custom formatters in Firefox

This feature uses the custom formatters API, and is supported in Firefox and Chromium-based browsers.

Given that custom formatters work by default only for Kotlin/Wasm development builds, you need to adjust your Gradle configuration if you want to use them for production builds. Add the following compiler option to the `wasmJs {}` block:

```
// build.gradle.kts
kotlin {
    wasmJs {
        // ...

        compilerOptions {
            freeCompilerArgs.add("-Xwasm-debugger-custom-formatters")
        }
    }
}
```

Leave feedback

We would appreciate any feedback you may have on your debugging experience!

- Slack: get a Slack invite and provide your feedback directly to the developers in our #webassembly channel.
- Provide your feedback in YouTrack.

  - WASI example
  - Compose example

Beta

Interoperability with JavaScript

Kotlin/Wasm allows you to use both JavaScript code in Kotlin and Kotlin code in JavaScript.

As with Kotlin/JS, the Kotlin/Wasm compiler also has interoperability with JavaScript. If you are familiar with Kotlin/JS interoperability, you can notice that Kotlin/Wasm interoperability is similar. However, there are key differences to consider.

Kotlin/Wasm is Beta. It may be changed at any time. Use it in scenarios before production. We would appreciate your feedback in YouTrack.

Use JavaScript code in Kotlin

Learn how to use JavaScript code in Kotlin by using `external` declarations, functions with JavaScript code snippets, and the `@JsModule` annotation.

External declarations

External JavaScript code is not visible in Kotlin by default. To use JavaScript code in Kotlin, you can describe its API with `external` declarations.

JavaScript functions

Consider this JavaScript function:

```
function greet (name) {
    console.log("Hello, " + name + "!");
}
```

You can declare it in Kotlin as an `external` function:

```
external fun greet(name: String)
```

External functions don't have bodies, and you can call it as a regular Kotlin function:

```
fun main() {
    greet("Alice")
}
```

JavaScript properties

Consider this global JavaScript variable:

```
let globalCounter = 0;
```

You can declare it in Kotlin using external `var` or `val` properties:

```
external var globalCounter: Int
```

These properties are initialized externally. The properties can't have `= value` initializers in Kotlin code.

JavaScript classes

Consider this JavaScript class:

```
class Rectangle {
    constructor (height, width) {
        this.height = height;
        this.width = width;
    }

    area () {
        return this.height * this.width;
    }
}
```

You can use it in Kotlin as an external class:

```
external class Rectangle(height: Double, width: Double) : JsAny {
    val height: Double
    val width: Double
    fun area(): Double
}
```

All declarations inside the `external` class are implicitly considered external.

External interfaces

You can describe the shape of a JavaScript object in Kotlin. Consider this JavaScript function and what it returns:

```
function createUser (name, age) {
    return { name: name, age: age };
}
```

See how its shape can be described in Kotlin with an `external interface User` type:

```
external interface User : JsAny {
    val name: String
    val age: Int
}

external fun createUser(name: String, age: Int): User
```

External interfaces don't have runtime type information and are a compile-time-only concept. Therefore, external interfaces have some restrictions compared to regular interfaces:

- You can't use them on the right-hand side of `is` checks.
- You can't use them in class literal expressions (such as `User::class`).
- You can't pass them as reified type arguments.
- Casting with `as` to external interfaces always succeeds.

External objects

Consider these JavaScript variables holding an object:

```
let Counter = {
    value: 0,
    step: 1,
    increment () {
        this.value += this.step;
    }
};
```

You can use them in Kotlin as an external object:

```
external object Counter : JsAny {
    fun increment()
    val value: Int
    var step: Int
}
```

External type hierarchy

Similar to regular classes and interfaces, you can declare external declarations to extend other external classes and implement external interfaces. However, you can't mix external and non-external declarations in the same type hierarchy.

Experimental

Callable JavaScript objects with `@nativeInvoke`

You can use the `@nativeInvoke` annotation on a Kotlin member function of an `external` declaration (a class or an interface) to make it callable as a JavaScript function.

With this annotation, each call to that function in Kotlin translates to a direct call to the JavaScript object:

```
import kotlin.js.nativeInvoke

@OptIn(ExperimentalWasmJsInterop::class)
external class JsAction {
    @nativeInvoke
    operator fun invoke(data: String)
}

fun main() {
    val action = JsAction()
    action("Run task")
}
```

The `@nativeInvoke` annotation is a temporary solution until there's a design for stable interoperability. Currently, when you use `@nativeInvoke`, the compiler reports a warning.

Kotlin functions with JavaScript code

You can add a JavaScript snippet to Kotlin/Wasm code by defining a function with `= js("code")` body:

```
fun getCurrentURL(): String =
    js("window.location.href")
```

If you want to run a block of JavaScript statements, surround your code inside the string with curly brackets `{}`:

```
fun setLocalSettings(value: String): Unit = js(
    """{
        localStorage.setItem('settings', value);
}"""
)
```

If you want to return an object, surround the curly brackets `{}` with parentheses `()`:

```
fun createJsUser(name: String, age: Int): JsAny =
    js("({ name: name, age: age })")
```

Kotlin/Wasm treats calls to the `js()` function in a special way, and the implementation has some restrictions:

- A `js()` function call must be provided with a string literal argument.
- A `js()` function call must be the only expression in the function body.

- The `js()` function is only allowed to be called from package-level functions.
- The function return type must be provided explicitly.
- Types are restricted, similar to `external fun`.

The Kotlin compiler puts the code string into a function in the generated JavaScript file and imports it into WebAssembly format. The Kotlin compiler doesn't verify these JavaScript snippets. If there are JavaScript syntax errors, they are reported when you run your JavaScript code.

The `@JsFun` annotation has similar functionality and will likely be deprecated.

JavaScript modules

By default, external declarations correspond to the JavaScript global scope. If you annotate a Kotlin file with the `@JsModule` annotation, then all external declarations within it are imported from the specified module.

Consider this JavaScript code sample:

```
// users.mjs
export let maxUsers = 10;

export class User {
    constructor (username) {
        this.username = username;
    }
}
```

Use this JavaScript code in Kotlin with the `@JsModule` annotation:

```
// Kotlin
@file:JsModule("./users.mjs")

external val maxUsers: Int

external class User : JsAny {
    constructor(username: String)

    val username: String
}
```

Array interoperability

You can copy JavaScript's `JsArray<T>` into Kotlin's native `Array` or `List` types; likewise, you can copy these Kotlin types to `JsArray<T>`.

To convert `JsArray<T>` to `Array<T>` or the other way around, use one of the available adapter functions.

Here's an example of conversion between generic types:

```
val list: List<JsString> =
    listOf("Kotlin", "Wasm").map { it.toJsString() }

// Uses .toJsArray() to convert List or Array to JsArray
val jsArray: JsArray<JsString> = list.toJsArray()

// Uses .toArray() and .toList() to convert it back to Kotlin types
val kotlinArray: Array<JsString> = jsArray.toArray()
val kotlinList: List<JsString> = jsArray.toList()
```

Similar adapter functions are available for converting typed arrays to their Kotlin equivalents (for example, `IntArray` and `Int32Array`). For detailed information and implementation, see the `kotlinx-browser` repository.

Here's an example of conversion between typed arrays:

```
import org.khronos.webgl.*

    // ...

    val intArray: IntArray = intArrayOf(1, 2, 3)

    // Uses .toInt32Array() to convert Kotlin IntArray to JavaScript Int32Array
    val jsInt32Array: Int32Array = intArray.toInt32Array()

    // Uses toIntArray() to convert JavaScript Int32Array back to Kotlin IntArray
    val kotlinIntArray: IntArray = jsInt32Array.toIntArray()
```

Use Kotlin code in JavaScript

Learn how to use your Kotlin code in JavaScript by using the `@JsExport` annotation.

Functions with the @JsExport annotation

To make a Kotlin/Wasm function available to JavaScript code, use the `@JsExport` annotation:

```
// Kotlin/Wasm

@JsExport
fun addOne(x: Int): Int = x + 1
```

Kotlin/Wasm functions marked with the `@JsExport` annotation are visible as properties on a `default` export of the generated `.mjs` module. You can then use this function in JavaScript:

```
// JavaScript

import exports from "./module.mjs"

exports.addOne(10)
```

The Kotlin/Wasm compiler is capable of generating TypeScript definitions from any `@JsExport` declarations in your Kotlin code. These definitions can be used by IDEs and JavaScript tools to provide code autocompletion, help with type-checks, and make it easier to consume Kotlin code from JavaScript and TypeScript.

The Kotlin/Wasm compiler collects any top-level functions marked with the `@JsExport` annotation and automatically generates TypeScript definitions in a `.d.ts` file.

To generate TypeScript definitions, in your `build.gradle.kts` file in the `wasmJs{}` block, add the `generateTypeScriptDefinitions()` function:

```
kotlin {
    wasmJs {
        binaries.executable()
        browser {
        }
        generateTypeScriptDefinitions()
    }
}
```

Generating TypeScript declaration files in Kotlin/Wasm is Experimental. It may be dropped or changed at any time.

Type correspondence

Kotlin/Wasm allows only certain types in signatures of JavaScript interop declarations. These limitations apply uniformly to declarations with `external`, `= js("code")` or `@JsExport`.

See how Kotlin types correspond to JavaScript types:

Kotlin	JavaScript
`Byte`, `Short`, `Int`, `Char`, `UByte`, `UShort`, `UInt`,	`Number`
`Float`, `Double`,	`Number`
`Long`, `ULong`,	`BigInt`
`Boolean`,	`Boolean`
`String`,	`String`
`Unit` in return position	`undefined`
Function type, for example `(String) -> Int`	Function
`JsAny` and subtypes	Any JavaScript value
`JsReference`	Opaque reference to Kotlin object
Other types	Not supported

You can use nullable versions of these types as well.

JsAny type

JavaScript values are represented in Kotlin using the `JsAny` type and its subtypes.

The Kotlin/Wasm standard library provides representation for some of these types:

- Package `kotlin.js`:
  - `JsAny`
  - `JsBoolean`, `JsNumber`, `JsString`
  - `JsArray`
  - `Promise`

You can also create custom `JsAny` subtypes by declaring an `external` interface or class.

JsReference type

Kotlin values can be passed to JavaScript as opaque references using the `JsReference` type.

For example, if you want to expose this Kotlin class `User` to JavaScript:

```
class User(var name: String)
```

You can use the `toJsReference()` function to create `JsReference<User>` and return it to JavaScript:

```
@JsExport
fun createUser(name: String): JsReference<User> {
    return User(name).toJsReference()
}
```

These references aren't directly available in JavaScript and behave like empty frozen JavaScript objects. To operate on these objects, you need to export more functions to JavaScript using the `get()` method where you unwrap the reference value:

```
@JsExport
fun setUserName(user: JsReference<User>, name: String) {
    user.get().name = name
}
```

You can create a class and change its name from JavaScript:

```
import UserLib from "./userlib.mjs"

let user = UserLib.createUser("Bob");
UserLib.setUserName(user, "Alice");
```

Type parameters

JavaScript interop declarations can have type parameters if they have an upper bound of `JsAny` or its subtypes. For example:

```
external fun <T : JsAny> processData(data: JsArray<T>): T
```

Exception handling

You can use Kotlin `try-catch` expressions to catch JavaScript exceptions in Kotlin/Wasm code. Exception handling works as follows:

- Exceptions thrown from JavaScript: detailed information is available on the Kotlin side. If such an exception propagates back to JavaScript, it's no longer wrapped into WebAssembly.
- Exceptions thrown from Kotlin: they can be caught on JavaScript's side as regular JS errors.

Here's an example that demonstrates catching a JavaScript exception on the Kotlin side:

```
external object JSON {
    fun <T: JsAny> parse(json: String): T
}

fun main() {
    try {
        JSON.parse("an invalid JSON")
    } catch (e: JsException) {
        println("Thrown value is: ${e.thrownValue}")
        // SyntaxError: Unexpected token 'a', "an invalid JSON" is not valid JSON

        println("Message: ${e.message}")
        // Message: Unexpected token 'a', "an invalid JSON" is not valid JSON

        println("Stacktrace:")
        // Stacktrace:

        // Prints the full JavaScript stack trace
        e.printStackTrace()
    }
}
```

This exception handling works automatically in modern browsers that support the `WebAssembly.JSTag` feature:

- Chrome 115+
- Firefox 129+
- Safari 18.4+

Kotlin/Wasm and Kotlin/JS interoperability differences

Although Kotlin/Wasm interoperability shares similarities with Kotlin/JS interoperability, there are key differences to consider:

	Kotlin/Wasm	Kotlin/JS
External enums	Doesn't support external enum classes.	Supports external enum classes.
Type extensions	Doesn't support non-external types to extend external types.	Supports non-external types.

	Kotlin/Wasm	Kotlin/JS
`JsName` annotation	Only has an effect when annotating external declarations.	Can be used to change names of regular non-external declarations.
`js()` function	`js("code")` function calls are allowed as a single expression body of package-level functions.	The `js("code")` function can be called in any context and returns a `dynamic` value.
Module systems	Supports ES modules only. There is no analog of the `@JsNonModule` annotation. Provides its exports as properties on the `default` object. Allows exporting package-level functions only.	Supports ES modules and legacy module systems. Provides named ESM exports. Allows exporting classes and objects.
Types	Applies stricter type restrictions uniformly to all interop declarations `external`, `= js("code")`, and `@JsExport`. Allows a select number of built-in Kotlin types and `JsAny` subtypes.	Allows all types in `external` declarations. Restricts types that can be used in `@JsExport`.
Long	Type corresponds to JavaScript `BigInt`.	Visible as a custom class in JavaScript.
Arrays	Not supported in interop directly yet. You can use the new `JsArray` type instead.	Implemented as JavaScript arrays.
Other types	Requires `JsReference<>` to pass Kotlin objects to JavaScript.	Allows the use of non-external Kotlin class types in external declarations.
Exception handling	You can catch any JavaScript exception with the `JsException` and `Throwable` types.	Can catch JavaScript `Error` using the `Throwable` type. It can catch any JavaScript exception using the `dynamic` type.
Dynamic types	Does not support the `dynamic` type. Use `JsAny` instead (see sample code below).	Supports the `dynamic` type.

Kotlin/JS dynamic type for interoperability with untyped or loosely typed objects is not supported in Kotlin/Wasm. Instead of the `dynamic` type, you can use the `JsAny` type:

```
// Kotlin/JS
fun processUser(user: dynamic, age: Int) {
    // ...
    user.profile.updateAge(age)
    // ...
}

// Kotlin/Wasm
private fun updateUserAge(user: JsAny, age: Int): Unit =
    js("{ user.profile.updateAge(age); }")

fun processUser(user: JsAny, age: Int) {
    // ...
    updateUserAge(user, age)
    // ...
}
```

Web-related browser APIs

The `kotlinx-browser` library is a standalone library that provides JavaScript browser APIs, including:

- Package `org.khronos.webgl`:
  - Typed arrays, like `Int8Array`.
  - WebGL types.
- Packages `org.w3c.dom.*`:
  - DOM API types.
- Package `kotlinx.browser`:
  - DOM API global objects, like `window` and `document`.

To use the declarations from the `kotlinx-browser` library, add it as a dependency in your project's build configuration file:

```
val wasmJsMain by getting {
    dependencies {
        implementation("org.jetbrains.kotlinx:kotlinx-browser:0.3")
    }
}
```

Beta

Supported versions and configuration

This page provides details about the WebAssembly proposals, supported browsers, and configuration recommendations for efficient development with Kotlin/Wasm.

Browser versions

Kotlin/Wasm relies on the latest WebAssembly proposals, such as garbage collection (WasmGC) and exception handling, to introduce improvements and new features within WebAssembly.

To make sure these features work properly, provide an environment that supports the latest proposals. Check if your browser version supports the new WasmGC by default or if you need to make changes to the environment.

Chrome

- **For version 119 or later:**

  Works by default.

- **For older versions:**

  > To run applications in an older browser, you need a Kotlin version older than 1.9.20.

  1. In your browser, go to `chrome://flags/#enable-webassembly-garbage-collection`.
  2. Enable **WebAssembly Garbage Collection**.
  3. Relaunch your browser.

Chromium-based

Including Chromium-based browsers such as Edge, Brave, Opera, or Samsung Internet.

- **For version 119 or later:**

  Works by default.

- **For older versions:**

  > To run applications in an older browser, you need a Kotlin version older than 1.9.20.

  Run the application with the `--js-flags=--experimental-wasm-gc` command line argument.

Firefox

- **For version 120 or later:**

  Works by default.

- **For version 119:**

  1. In your browser, go to `about:config`.
  2. Enable `javascript.options.wasm_gc` option.
  3. Refresh the page.

Safari/WebKit

- **For version 18.2 or later:**

  Works by default.

- **For older versions:**

  Not supported.

> Safari 18.2 is available for iOS 18.2, iPadOS 18.2, visionOS 2.2, macOS 15.2, macOS Sonoma, and macOS Ventura. On iOS and iPadOS, Safari 18.2 is bundled with the operating system. To get it, update your device to version 18.2 or later.
>
> For more information, see the Safari release notes.

Wasm proposals support

Kotlin/Wasm improvements are based on WebAssembly proposals. Here you can find details about the support for WebAssembly's garbage collection and (legacy) exception handling proposals.

Garbage collection proposal

Since Kotlin 1.9.20, the Kotlin toolchain uses the latest version of the Wasm garbage collection (WasmGC) proposal.

For this reason, we strongly recommend that you update your Wasm projects to the latest version of Kotlin. We also recommend you use the latest versions of browsers with the Wasm environment.

Exception handling proposal

The Kotlin toolchain supports both the legacy and the new versions of the exception handling proposal. This allows Kotlin-produced Wasm binaries to run in a wider range of environments.

The `wasmJs` target uses the legacy exception handling proposal by default. To enable the new exception handling proposal for the `wasmJs` target, use the `-Xwasm-use-new-exception-proposal` compiler option.

By contrast, the `wasmWasi` target uses the new proposal by default, ensuring better compatibility with modern WebAssembly runtimes. To switch to the legacy proposal, use the `-Xwasm-use-new-exception-proposal=false` compiler option.

For the `wasmWasi` target, it is safe to adopt the new exception handling proposal. Applications targeting this environment usually run in a less diverse runtime environment (often running on a single specific VM) that is typically controlled by the user, reducing the risk of compatibility issues.

> Learn more about setting up projects, using dependencies, and other tasks with our Kotlin/Wasm examples.

Use default import

Importing Kotlin/Wasm code into Javascript has shifted to named exports, moving away from default exports.

If you still want to use a default import, generate a new JavaScript wrapper module. Create a `.mjs` file with the following snippet:

```
// Specifies the path to the main .mjs file
import * as moduleExports from "./wasm-test.mjs";

export { moduleExports as default };
```

You can place your new `.mjs` file in the resources folder, and it will automatically be placed next to the main `.mjs` file during the build process.

You can also place your `.mjs` file in a custom location. In this case, you need to either manually move it next to the main `.mjs` file or adjust the path in the import statement to match its location.

Kotlin/Wasm incremental compilation

Kotlin/Wasm targets support incremental compilation, which allows the compiler to recompile only the files affected by recent changes. This helps reduce compilation time.

Incremental compilation for the Wasm targets is enabled by default. To disable it, add the following line to your project's `local.properties` or `gradle.properties` file:

```
kotlin.incremental.wasm=false
```

Diagnostics in fully qualified class names

On Kotlin/Wasm, the compiler does not store fully qualified names (FQNs) of classes in the generated binary by default, to avoid increasing the application size.

For this reason, the compiler reports an error when you call the `KClass::qualifiedName` property in Kotlin/Wasm projects, unless you explicitly enable the qualified names feature.

This diagnostic is enabled by default, and errors are reported automatically. To disable the diagnostic and allow `qualifiedName` in Kotlin/Wasm, instruct the compiler to store fully qualified names for all classes by adding the following option to your `build.gradle.kts` file:

```
// build.gradle.kts
kotlin {
   wasmJs {
       ...
       compilerOptions {
           freeCompilerArgs.add("-Xwasm-kclass-fqn")
       }
   }
}
```

Keep in mind that enabling this option increases the application size.

Fully qualified names

On Kotlin/Wasm targets, fully qualified names (FQNs) are available at runtime without any additional configuration. This means that the `KClass.qualifiedName` property is enabled by default.

Using FQNs improves code portability from JVM to Wasm targets and makes runtime errors more informative by showing the full qualified name.

Array out-of-bounds access and traps

In Kotlin/Wasm, accessing an array with an index outside its bounds triggers a WebAssembly trap instead of a regular Kotlin exception. The trap immediately stops the current stack of execution.

When running in a JavaScript environment, these traps appear as `WebAssembly.RuntimeError` and can be caught on the JavaScript side.

You can avoid such traps in Kotlin/Wasm environments by using the following compiler option in the command line when linking an executable:

```
-Xwasm-enable-array-range-checks
```

Or add it to the `compilerOptions {}` block of your Gradle build file:

```
// build.gradle.kts
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-Xwasm-enable-array-range-checks")
    }
}
```

With the compiler option enabled, an `IndexOutOfBoundsException` is thrown instead of a trap.

See more details and share your feedback in this YouTrack issue.

Experimental annotations

Kotlin/Wasm provides several experimental annotations for general WebAssembly interoperability.

`@WasmImport` and `@WasmExport` let you call functions defined outside a Kotlin/Wasm module and expose Kotlin functions to the host or other Wasm modules, respectively.

Because these mechanisms are still evolving, all annotations are marked as experimental. You must explicitly opt in to use them, and their design or behavior may change in future Kotlin versions.

Reloads during debugging

Debugging your applications in modern browsers works out of the box. When you run development Gradle tasks (`*DevRun`), Kotlin automatically serves the source files to the browser.

However, serving sources by default may cause repeated reloads of the application in the browser before Kotlin compilation and bundling are complete. As a workaround, adjust your webpack configuration to ignore Kotlin source files and disable watching for served static files. Add a `.js` file with the following content into the `webpack.config.d` directory at the root of your project:

```
config.watchOptions = config.watchOptions || {
    ignored: ["**/*.kt", "**/node_modules"]
}

if (config.devServer) {
    config.devServer.static = config.devServer.static.map(file => {
        if (typeof file === "string") {
            return {
                directory: file,
                watch: false,
            }
        } else {
            return file
        }
    })
}
```

Kotlin/Native

Kotlin/Native is a technology for compiling Kotlin code to native binaries that can run without a virtual machine. Kotlin/Native includes an LLVM-based backend for the Kotlin compiler and a native implementation of the Kotlin standard library.

Why Kotlin/Native?

Kotlin/Native is primarily designed to allow compilation for platforms on which *virtual machines* are not desirable or possible, such as embedded devices or iOS. It's ideal for situations when you need to produce a self-contained program that doesn't require an additional runtime or a virtual machine.

It's easy to include compiled Kotlin code in existing projects written in C, C++, Swift, Objective-C, and other languages. You can also use existing native code, static or dynamic C libraries, Swift/Objective-C frameworks, graphical engines, and anything else directly from Kotlin/Native.

Get started with Kotlin/Native

Target platforms

Kotlin/Native supports the following platforms:

- Linux
- Windows (through MinGW)
- Android NDK
- Apple targets for macOS, iOS, tvOS, and watchOS

> To compile Apple targets, you need to install Xcode and its command-line tools.

See the full list of supported targets and hosts.

Interoperability

Kotlin/Native supports two-way interoperability with native programming languages for different operating systems. The compiler can create executables for many platforms, static or dynamic C libraries, and Swift/Objective-C frameworks.

Interoperability with C

Kotlin/Native provides interoperability with C. You can use existing C libraries directly from Kotlin code.

To learn more, complete the following tutorials:

- Create a dynamic library with C headers for C/C++ projects
- Learn how C types are mapped into Kotlin
- Create a native HTTP client using C interop and libcurl

Interoperability with Swift/Objective-C

Kotlin/Native provides interoperability with Swift through Objective-C. You can use Kotlin code directly from Swift/Objective-C applications on macOS and iOS.

To learn more, complete the Kotlin/Native as an Apple framework tutorial.

Sharing code between platforms

Kotlin/Native includes a set of prebuilt platform libraries that help share Kotlin code between projects. POSIX, gzip, OpenGL, Metal, Foundation, and many other popular libraries and Apple frameworks are pre-imported and included as Kotlin/Native libraries in the compiler package.

Kotlin/Native is a part of the Kotlin Multiplatform technology that helps share common code across multiple platforms, including Android, iOS, JVM, web, and native. Multiplatform libraries provide the necessary APIs for common Kotlin code and allow writing shared parts of projects in Kotlin all in one place.

Memory manager

Kotlin/Native uses an automatic memory manager that is similar to the JVM and Go. It has its own tracing garbage collector, which is also integrated with Swift/Objective-C's ARC.

The memory consumption is controlled by a custom memory allocator. It optimizes memory usage and helps prevent sudden surges in memory allocation.

Get started with Kotlin/Native

In this tutorial, you'll learn how to create a Kotlin/Native application. Choose the tool that works best for you and create your app using:

- The IDE. Here, you can clone the project template from a version control system and use it in IntelliJ IDEA.
- The Gradle build system. To better understand how things work under the hood, create build files for your project manually.

- The command line tool. You can use the Kotlin/Native compiler, which is shipped as a part of the standard Kotlin distribution, and create the app directly in the command line tool.

  Console compilation may seem easy and straightforward, but it doesn't scale well for larger projects with hundreds of files and libraries. For such projects, we recommend using an IDE or a build system.

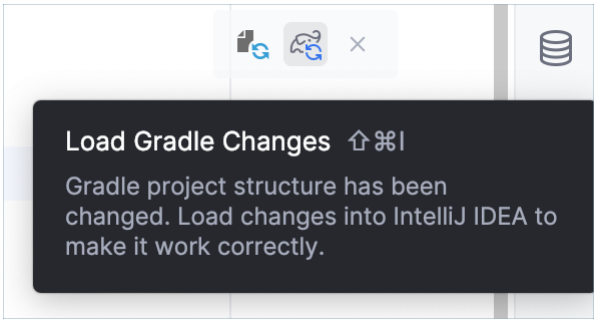
With Kotlin/Native, you can compile for different targets, including Linux, macOS, and Windows. While cross-platform compilation is possible, which means using one platform to compile for a different one, in this tutorial, you'll be targeting the same platform you're compiling on.

> If you use a Mac and want to create and run applications for macOS or other Apple targets, you also need to install Xcode Command Line Tools, launch it, and accept the license terms first.

In IDE

In this section, you'll learn how to use IntelliJ IDEA to create a Kotlin/Native application.

Create the project



1. Download and install the latest version of IntelliJ IDEA.
2. Clone the project template by selecting **File** | **New** | **Project from Version Control** in IntelliJ IDEA and using this URL:

   ```
   https://github.com/Kotlin/kmp-native-wizard
   ```

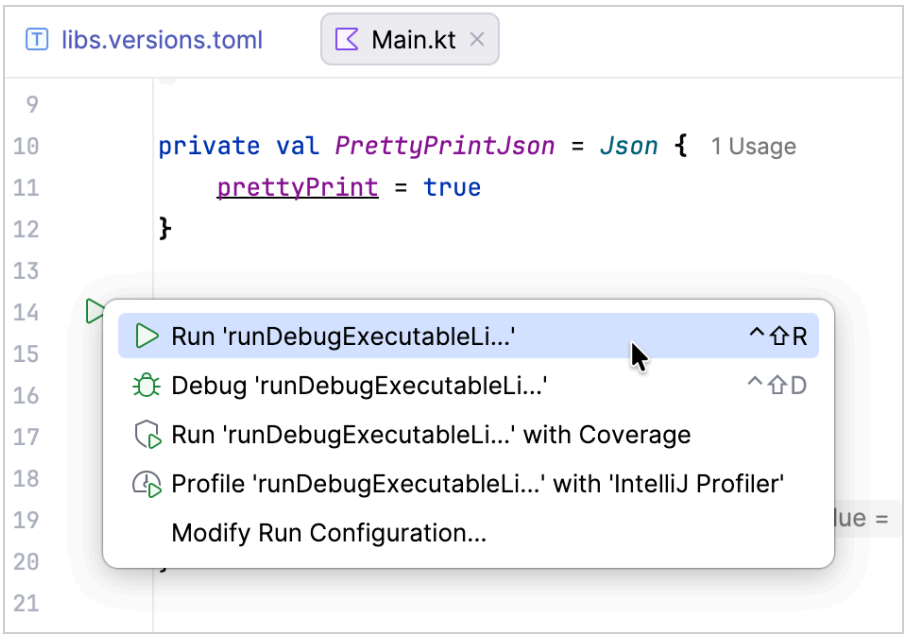
3. Open the `gradle/libs.versions.toml` file, which is the version catalog for project dependencies. To create Kotlin/Native applications, you need the Kotlin Multiplatform Gradle plugin, which has the same version as Kotlin. Ensure that you use the latest Kotlin version:

   ```
   [versions]
   kotlin = "2.4.20"
   ```

4. Follow the suggestion to reload Gradle files:

Load Gradle changes button

For more information about these settings, see the Multiplatform Gradle DSL reference.



Build and run the application

Open the `Main.kt` file in the `src/nativeMain/kotlin/` directory:

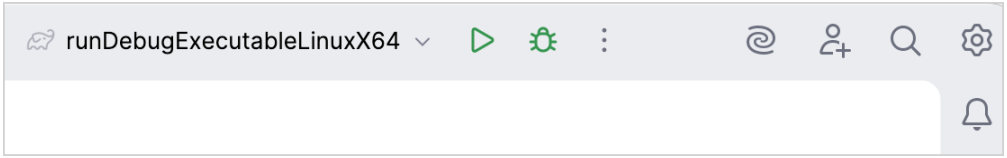
- The `src` directory contains Kotlin source files.

- The `Main.kt` file includes code that prints "Hello, Kotlin/Native!" using the `println()` function.

Press the green icon in the gutter to run the code:

Run the application

IntelliJ IDEA runs the code using the Gradle task and outputs the result in the **Run** tab:



```
> Task :runDebugExecutableMacosArm64
{
    "topic": "Kotlin/Native",
    "content": "Hello!"
}

> Task :compileKotlinMingwX64 UP-TO-DATE
> Task :linkDebugExecutableMingwX64 UP-TO-DATE
> Task :runDebugExecutableMingwX64 SKIPPED

BUILD SUCCESSFUL in 1s
```

Application output

After the first run, the IDE creates the corresponding run configuration at the top:

Gradle run configuration

IntelliJ IDEA users with an Ultimate subscription can install the Native Debugging Support plugin that allows debugging compiled native executables and also automatically creates run configurations for imported Kotlin/Native projects.

You can configure IntelliJ IDEA to build your project automatically:

1. Go to **Settings | Build, Execution, Deployment | Compiler**.
2. On the **Compiler** page, select **Build project automatically**.
3. Apply the changes.

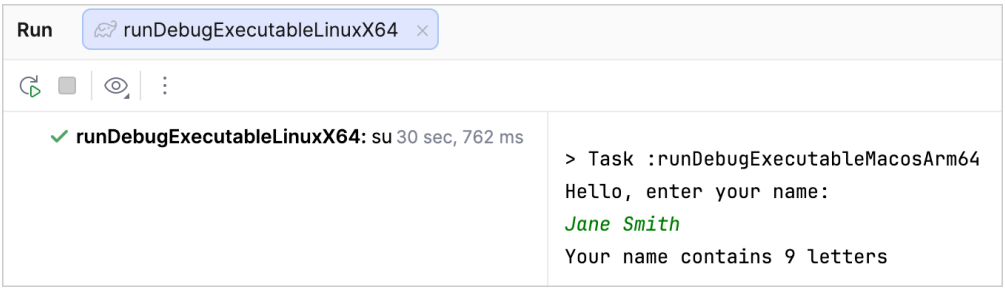
Now, when you make changes in the class files or save the file (Ctrl + S/Cmd + S), IntelliJ IDEA automatically performs an incremental build of the project.

Update the application

Let's add a feature to your application so it can count the number of letters in your name:

1. In the `Main.kt` file, add code to read the input. Use the `readln()` function to read the input value and assign it to the `name` variable:

```
fun main() {
    // Read the input value.
    println("Hello, enter your name:")
    val name = readln()
}
```



2. To run this app using Gradle, specify `System.in` as the input to use in the `build.gradle.kts` file and load the Gradle changes:

```
kotlin {
    // ...
    targets.withType<KotlinNativeTarget>().configureEach {
        binaries {
            executable {
                entryPoint = "main"
                runTaskProvider?.configure { standardInput = System.`in` }
            }
        }
    }
    // ...
}
```

3. Eliminate the whitespaces and count the letters:
   - Use the `replace()` function to remove the empty spaces in the name.
   - Use the scope function `let` to run the function within the object context.
   - Use a string template to insert your name length into the string by adding a dollar sign `$` and enclosing it in curly braces – `${it.length}`. `it` is the default name of a lambda parameter.

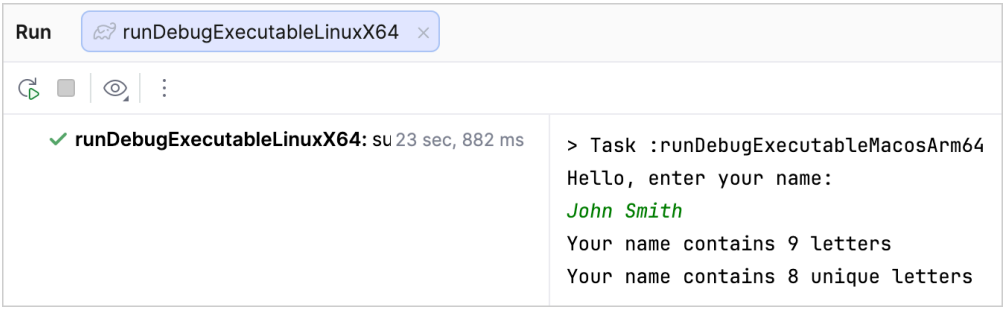
```
fun main() {
    // Read the input value.
    println("Hello, enter your name:")
    val name = readln()
    // Count the letters in the name.
    name.replace(" ", "").let {
        println("Your name contains ${it.length} letters")
    }
}
```

4. Run the application.
5. Enter your name and enjoy the result:

Application output

Now let's count only the unique letters in your name:

1. In the `Main.kt` file, declare the new extension function `.countDistinctCharacters()` for `String`:
   - Convert the name to lowercase using the `.lowercase()` function.
   - Convert the input string to a list of characters using the `toList()` function.
   - Select only the distinct characters in your name using the `distinct()` function.
   - Count the distinct characters using the `count()` function.



```
fun String.countDistinctCharacters() = lowercase().toList().distinct().count()
```

2. Use the `.countDistinctCharacters()` function to count the unique letters in your name:

```
fun String.countDistinctCharacters() = lowercase().toList().distinct().count()

fun main() {
    // Read the input value.
    println("Hello, enter your name:")
    val name = readln()
    // Count the letters in the name.
    name.replace(" ", "").let {
        println("Your name contains ${it.length} letters")
        // Print the number of unique letters.
        println("Your name contains ${it.countDistinctCharacters()} unique letters")
    }
}
```

3. Run the application.
4. Enter your name and see the result:

Application output

Using Gradle

In this section, you'll learn how to manually create a Kotlin/Native application using Gradle. It's the default build system for Kotlin/Native and Kotlin Multiplatform projects, which is also commonly used in Java, Android, and other ecosystems.

When building Kotlin/Native projects, the Kotlin Gradle plugin downloads the following artifacts:

- The main Kotlin/Native bundle, which includes different tools like `konanc`, `cinterop`, and `jsinterop`. By default, the Kotlin/Native bundle is downloaded from the Maven Central repository as a simple Gradle dependency.
- Dependencies required for `konanc` itself, like `llvm`. They are downloaded from the JetBrains CDN using custom logic.

You can change the source for the main bundle download in the `repositories {}` block in your Gradle build script.

Create project files

1. To get started, install a compatible version of Gradle. See the compatibility table to check the Kotlin Gradle plugin (KGP) compatibility with available Gradle versions.
2. Create an empty project directory. Inside it, create a `build.gradle(.kts)` file with the following content:

Kotlin

```kotlin
// build.gradle.kts
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    kotlin("multiplatform") version "2.4.20"
}

repositories {
    // Specify the source to download the main bundle
    // Maven Central is used by default
    mavenCentral()
}

kotlin {
    macosArm64()    // on macOS
    // linuxArm64() // on Linux
    // mingwX64()   // on Windows

    targets.withType<KotlinNativeTarget>().configureEach {
        binaries {
            executable()
        }
    }
}

tasks.withType<Wrapper> {
    gradleVersion = "9.7.0"
    distributionType = Wrapper.DistributionType.BIN
}
```

Groovy

```
// build.gradle
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}

repositories {
    // Specify the source to download the main bundle
    // Maven Central is used by default
    mavenCentral()
}

kotlin {
    macosArm64()    // on macOS
    // linuxArm64() // on Linux
    // mingwX64()   // on Windows

    targets.withType(KotlinNativeTarget).configureEach {
        binaries {
            executable()
        }
    }
}

wrapper {
    gradleVersion = '9.7.0'
    distributionType = 'BIN'
}
```

You can use different target names, such as `macosArm64`, `iosArm64` `linuxArm64`, and `mingwX64` to define the targets for which you are compiling your code. The target name is used to generate the source paths and task names in the project.

3. Create an empty `settings.gradle(.kts)` file in the project directory.
4. Create a `src/nativeMain/kotlin` directory and place a `hello.kt` file inside with the following content:

```
fun main() {
    println("Hello, Kotlin/Native!")
}
```

By convention, all sources are located in the `src/<platform name>[Main|Test]/kotlin` directories, where `Main` is for the source code and `Test` is for tests. In this case, `<platform name>` is `native`.

Build and run the project

1. From the root project directory, run the `<yourTargetName>Binaries` build command for your target, for example:

```
./gradlew macosArm64Binaries
```

This command creates the `build/bin/<yourTargetName>` directory with two directories inside: `debugExecutable` and `releaseExecutable`. They contain the corresponding binary files.

By default, the name of the binary file is the same as the project directory.

2. To run the project, execute the `build/bin/<yourTargetName>/debugExecutable/<project_name>.kexe` command for your target, for example:

```
build/bin/macosArm64/DebugExecutable/hello.kexe
```

The terminal prints "Hello, Kotlin/Native!".

Open the project in IDE

Now, you can open your project in any IDE that supports Gradle. If you use IntelliJ IDEA:

1. Select **File** | **Open**.
2. Select the project directory and click **Open**. IntelliJ IDEA automatically detects if it's a Kotlin/Native project.

If you encounter a problem with the project, IntelliJ IDEA displays the error message in the **Build** tab.

Using the command-line compiler

In this section, you'll learn how to create a Kotlin/Native application using the Kotlin compiler in the command line tool.

Download and install the compiler

To install the compiler:

1. Go to the Kotlin's GitHub releases page and scroll down to the **Assets** section.
2. Look for a file with `kotlin-native` in the name and download one that is suitable for your operating system, for example `kotlin-native-prebuilt-linux-x86_64-2.4.20.tar.gz`.
3. Unpack the archive to a directory of your choice.
4. Open your shell profile and add the path to the compiler's `/bin` directory to the `PATH` environment variable:

```
export PATH="/<path to the compiler>/kotlin-native/bin:$PATH"
```

Although the compiler output has no dependencies or virtual machine requirements, the compiler itself requires Java 1.8 or higher runtime. It's supported by JDK 8 (JAVA SE 8) or later versions.

Create the program

Choose a working directory and create a file named `hello.kt`. Update it with the following code:

```
fun main() {
    println("Hello, Kotlin/Native!")
}
```

Compile the code from the console

To compile the application, execute the following command with the downloaded compiler:

```
kotlinc-native hello.kt -o hello
```

The value of the `-o` option specifies the name of the output file, so this call generates the `hello.kexe` binary file on macOS and Linux (and `hello.exe` on Windows).

For the full list of available options, see Kotlin compiler options.

Run the program

To run the program, in your command line tool, navigate to the directory containing the binary file and run the following command:

macOS and Linux

```
./hello.kexe
```

Windows

```
./hello.exe
```

The application prints "Hello, Kotlin/Native" to the standard output.

What's next?

- Complete the Create an app using C interop and libcurl tutorial that explains how to create a native HTTP client and interoperate with C libraries.
- Learn how to write Gradle build scripts for real-life Kotlin/Native projects.
- Read more about the Gradle build system in the documentation.

Kotlin/Native libraries

Library compilation

You can use your project's build file or the Kotlin/Native compiler to produce a `*.klib` artifact for your library.

Using Gradle build file

You can compile a `*.klib` library artifact by specifying a Kotlin/Native target in your Gradle build file:

1. In your `build.gradle(.kts)` file, declare at least one Kotlin/Native target. For example:

```
// build.gradle.kts
plugins {
    kotlin("multiplatform") version "2.4.20"
}

kotlin {
    macosArm64()    // on macOS
    // linuxArm64() // on Linux
    // mingwX64()   // on Windows
}
```

2. Run the `<target>Klib` task. For example:

```
./gradlew macosArm64Klib
```

Gradle automatically compiles source files for that target and produces the `.klib` artifact in the project's `build/libs` directory.

Using Kotlin/Native compiler

To produce a library with the Kotlin/Native compiler:

1. Download and install the Kotlin/Native compiler.
2. To compile a Kotlin/Native source file into a library, use the `-produce library` or `-p library` option:

   ```
   kotlinc-native foo.kt -p library -o bar
   ```

   This command compiles the contents of the `foo.kt` file into a library with the name `bar`, producing a `bar.klib` artifact.
3. To link another file to a library, use the `-library <name>` or `-l <name>` option. For example:

   ```
   kotlinc-native qux.kt -l bar
   ```

   This command compiles the contents of the `qux.kt` source file and the `bar.klib` library and produces the `program.kexe` final executable binary.

klib utility

The **klib** library management utility allows you to inspect libraries using the following syntax:

```
klib <command> <library path> [<option>]
```

The following commands are currently available:

Command	Description
`info`	General information about the library.

Command	Description
`dump-abi`	Dump the ABI snapshot of the library. Each line in the snapshot corresponds to one declaration. In case an ABI-incompatible change happens to a declaration, it'll be visible in the corresponding line of the snapshot.
`dump-ir`	Dump the intermediate representation (IR) of library declarations to the output. Use it only for debugging.
`dump-ir-signatures`	Dump IR signatures of all non-private library declarations and all non-private declarations consumed by this library (as two separate lists). This command relies purely on the data in IR.
`dump-ir-inlinable-functions`	Dump the IR of inlinable functions in the library to the output. Use it only for debugging.
`dump-metadata`	Dump the metadata of all library declarations to the output. Use it only for debugging.
`dump-metadata-signatures`	Dump IR signatures of all non-private library declarations based on the library metadata. In most cases, the output is the same as for the `dump-ir-signatures` command, which renders signatures based on IR. However, if IR-transforming compiler plugins (such as Compose) are used during compilation, patched declarations may have different signatures.

All the above dumping commands accept an additional `-signature-version {N}` argument that instructs the klib utility which IR signature version to render when dumping signatures. If not provided, it uses the most up-to-date version supported by the library. For example:

```
klib dump-metadata-signatures mylib.klib -signature-version 1
```

In addition, the `dump-metadata` command accepts the `-print-signatures {true|false}` argument that instructs the klib utility to print the IR signatures for every declaration in the output.

Creating and using a library

1. Create a library by placing the source code into `kotlinizer.kt`:

   ```
   package kotlinizer

   val String.kotlinized
       get() = "Kotlin $this"
   ```

2. Compile the library into a `.klib`:

   ```
   kotlinc-native kotlinizer.kt -p library -o kotlinizer
   ```

3. Check the current directory for the created library:

```
ls kotlinizer.klib
```

4. Check out general information about the library:

```
klib info kotlinizer.klib
```

5. Create a short program in the `use.kt` file:

```
import kotlinizer.*

fun main(args: Array<String>) {
    println("Hello, ${"world".kotlinized}!")
}
```

6. Compile the program, linking the `use.kt` source file to your library:

```
kotlinc-native use.kt -l kotlinizer -o kohello
```

7. Run the program:

```
./kohello.kexe
```

You should see `Hello, Kotlin world!` in the output.

Library search sequence

> The library search mechanism will change soon. Expect updates to this section and avoid relying on deprecated flags.

When given a `-library foo` option, the compiler searches the `foo` library in the following order:

1. Current compilation directory or an absolute path.
2. Libraries installed in the default repository.

> The default repository is `~/.konan`. You can change it by setting the `konan.data.dir` Gradle property.
>
> Alternatively, you can use the `-Xkonan-data-dir` compiler option to configure your custom path to the directory via the `cinterop` and `konanc` tools.

3. Libraries installed in the `$installation/klib` directory.

Library format

Kotlin/Native libraries are zip files containing a predefined directory structure, with the following layout:

`foo.klib` when unpacked as `foo/` gives us:

```
- foo/
  - $component_name/
    - ir/
      - Serialized Kotlin IR.
    - targets/
      - $platform/
        - kotlin/
          - Kotlin compiled to LLVM bitcode.
        - native/
          - Bitcode files of additional native objects.
      - $another_platform/
        - There can be several platform specific kotlin and native pairs.
    - linkdata/
      - A set of ProtoBuf files with serialized linkage metadata.
    - resources/
      - General resources such as images. (Not used yet).
    - manifest - A file in the java property format describing the library.
```

You can find an example layout in the `klib/common/stdlib` directory of your Kotlin/Native compiler installation.

Using relative paths in klibs

A serialized IR representation of source files is a part of a `klib` library. It includes paths of files for generating proper debug information. By default, stored paths are absolute.

With the `-Xklib-relative-path-base` compiler option, you can change the format and use only relative paths in the artifact. To make it work, pass one or multiple base paths of source files as an argument:

Kotlin

```kotlin
import org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask
// ...

tasks.named<KotlinCompilationTask<*>>("compileKotlin").configure {
    // $base is a base path of source files
    compilerOptions.freeCompilerArgs.add("-Xklib-relative-path-base=$base")
}
```

Groovy

```groovy
import org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask
// ...

tasks.named('compileKotlin', KotlinCompilationTask) {
    compilerOptions {
        // $base is a base path of source files
        freeCompilerArgs.add("-Xklib-relative-path-base=$base")
    }
}
```

What's next?

Learn how to use the cinterop tool to produce `*.klib` artifacts

Platform libraries

To provide access to native services of operating systems, the Kotlin/Native distribution includes a set of prebuilt libraries specific to each target. These are called *platform libraries*.

The packages from platform libraries are available by default. You don't need to specify additional link options to use them. The Kotlin/Native compiler automatically detects which platform libraries are accessed and links the necessary ones.

However, platform libraries in the compiler distribution are merely wrappers and bindings to the native libraries. That means you need to install native libraries themselves (`.so` , `.a` , `.dylib` , `.dll` , and so on) on your local machine.

POSIX bindings

Kotlin provides the POSIX platform library for all UNIX- and Windows-based targets, including Android and iOS. These platform libraries contain bindings to the platform's implementation, which follows the POSIX standard.

To use the library, import it into your project:

```
import platform.posix.*
```

The `platform.posix` contents differ across platforms because of variations in POSIX implementations.

You can explore the contents of the `posix.def` file for each supported platform here:

- iOS
- macOS
- tvOS
- watchOS
- Linux
- Windows (MinGW)
- Android

The POSIX platform library is not available for the WebAssembly target.

Popular native libraries

Kotlin/Native provides bindings for various popular native libraries that are commonly used on different platforms, such as OpenGL, zlib, and Foundation.

On Apple platforms, the `objc` library is included to enable interoperability with Objective-C APIs.

You can explore the native libraries available for Kotlin/Native targets in your compiler distribution, depending on your setup:

- If you installed a standalone Kotlin/Native compiler:
  1. Go to the unpacked archive with the compiler distribution, for example, `kotlin-native-prebuilt-macos-aarch64-2.1.0` .

2. Navigate to the `klib/platform` directory.
3. Choose the folder with the corresponding target.

- If you use the Kotlin plugin in your IDE (bundled with IntelliJ IDEA and Android Studio):
  1. In your command line tool, run the following to navigate to the `.konan` folder:

     macOS and Linux

     ```
     ~/.konan/
     ```

     Windows

     ```
     %USERPROFILE%\.konan
     ```

  2. Open the Kotlin/Native compiler distribution, for example, `kotlin-native-prebuilt-macos-aarch64-2.1.0`.
  3. Navigate to the `klib/platform` directory.
  4. Choose the folder with the corresponding target.

> If you'd like to explore the definition file for each supported platform library: in the compiler distribution folder, navigate to the `konan/platformDef` directory and choose the necessary target.

Learn more about interoperability with Swift/Objective-C

Kotlin/Native memory management

Kotlin/Native uses a modern memory manager that is similar to the JVM, Go, and other mainstream technologies, including the following features:

- Objects are stored in a shared heap and can be accessed from any thread.
- Tracing garbage collection is performed periodically to collect objects that are not reachable from the "roots", like local and global variables.

Garbage collector

Kotlin/Native's garbage collector (GC) algorithm is constantly evolving. Currently, it functions as a concurrent mark and sweep (CMS) collector that does not separate the heap into generations.

The GC is executed on a separate thread and started based on the memory pressure heuristics or by a timer. Alternatively, it can be called manually.

The GC processes the mark queue on several threads in parallel, including application threads, the GC thread, and optional marker threads. Application threads and at least one GC thread participate in the marking process. By

default, the marking phase runs concurrently with application threads, which reduces the GC pause time. You can monitor GC performance through the GC logs.

> You can disable the parallelization of the mark phase with the `kotlin.native.binary.gcMarkSingleThreaded=true` compiler option. However, this may increase the garbage collector's pause time on large heaps.

When the marking phase is completed, the GC processes weak references and nullifies reference points to an unmarked object. By default, weak references are processed concurrently to decrease the GC pause time.

If you encounter problems with CMS, switch back to the parallel mark concurrent sweep (PMCS) setup. To do that, set the following binary option in your `gradle.properties` file:

```
kotlin.native.binary.gc=pmcs
```

Enable garbage collection manually

To force-start the garbage collector, call `kotlin.native.internal.GC.collect()`. This method triggers a new collection and waits for its completion.

Monitor GC performance

To monitor the GC performance, you can look through its logs and diagnose issues. To enable logging, set the following compiler option in your Gradle build script:

```
-Xruntime-logs=gc=info
```

Currently, the logs are only printed to `stderr`.

On Apple platforms, you can take advantage of the Xcode Instruments toolkit to debug iOS app performance. The garbage collector reports pauses with signposts available in Instruments. Signposts enable custom logging within your app, allowing you to check if a GC pause corresponds to an application freeze.

To track GC-related pauses in your app:

1. To enable the feature, set the following compiler option in your `gradle.properties` file:

   ```
   kotlin.native.binary.enableSafepointSignposts=true
   ```

2. Open Xcode, go to **Product** | **Profile** or press Cmd + I. This action compiles your app and launches Instruments.
3. In the template selection, select **os_signpost**.
4. Configure it by specifying `org.kotlinlang.native.runtime` as **subsystem** and `safepoint` as **category**.
5. Click the red record button to run your app and start recording signpost events:

Tracking GC pauses as signposts

Here, each blue blob on the lowest graph represents a separate signpost event, which is a GC pause.

Disable garbage collection

It's recommended to keep the GC enabled. However, you can disable it in certain cases, such as for testing purposes or if you encounter issues and have a short-lived program. To do so, set the following binary option in your `gradle.properties` file:

```
kotlin.native.binary.gc=noop
```

With this option enabled, the GC doesn't collect Kotlin objects, so memory consumption will keep rising as long as the program runs. Be careful not to exhaust the system memory.

Memory consumption

Kotlin/Native uses its own memory allocator. It divides system memory into pages, allowing independent sweeping in consecutive order. Each allocation becomes a memory block within a page, and the page keeps track

of block sizes. Different page types are optimized for various allocation sizes. The consecutive arrangement of memory blocks ensures efficient iteration through all allocated blocks.

When a thread allocates memory, it searches for a suitable page based on the allocation size. Threads maintain a set of pages for different size categories. Typically, the current page for a given size can accommodate the allocation. If not, the thread requests a different page from the shared allocation space. This page may already be available, require sweeping, or have to be created first.

The Kotlin/Native memory allocator comes with protection against sudden spikes in memory allocations. It prevents situations where the mutator starts to allocate a lot of garbage quickly and the GC thread cannot keep up with it, making the memory usage grow endlessly. In this case, the GC forces a stop-the-world phase until the iteration is completed.

You can monitor memory consumption yourself, check for memory leaks, and adjust memory consumption.

Monitor memory consumption

To debug memory issues, you can check memory manager metrics. In addition, it's possible to track Kotlin's memory consumption on Apple platforms.

Check for memory leaks

To access the memory manager metrics, call `kotlin.native.internal.GC.lastGCInfo()`. This method returns statistics for the last run of the garbage collector. The statistics can be useful for:

- Debugging memory leaks when using global variables
- Checking for leaks when running tests

```
import kotlin.native.internal.*
import kotlin.test.*

class Resource

val global = mutableListOf<Resource>()

@OptIn(ExperimentalStdlibApi::class)
fun getUsage(): Long {
    GC.collect()
    return GC.lastGCInfo!!.memoryUsageAfter["heap"]!!.totalObjectsSizeBytes
}

fun run() {
    global.add(Resource())
    // The test will fail if you remove the next line
    global.clear()
}

@Test
fun test() {
    val before = getUsage()
    // A separate function is used to ensure that all temporary objects are cleared
    run()
    val after = getUsage()
    assertEquals(before, after)
}
```

Track memory consumption on Apple platforms

When debugging memory issues on Apple platforms, you can see how much memory is reserved by Kotlin code. Kotlin's share is tagged with an identifier and can be tracked through tools like VM Tracker in Xcode Instruments.

The feature is available only for the default Kotlin/Native memory allocator when *all* the following conditions are met:

- **Tagging enabled**. The memory should be tagged with a valid identifier. Apple recommends numbers between 240 and 255; the default value is 246.

  If you set up the `kotlin.native.binary.mmapTag=0` Gradle property, tagging is disabled.

- **Allocation with mmap**. The allocator should use the `mmap` system call to map files into memory.

  If you set up the `kotlin.native.binary.disableMmap=true` Gradle property, the default allocator uses `malloc` instead of `mmap`.

- **Paging enabled**. Paging of allocations (buffering) should be enabled.

  If you set up the `kotlin.native.binary.pagedAllocator=false` Gradle property, the memory is reserved on a per-object basis instead.

Adjust memory consumption

If you experience unexpectedly high memory consumption, try the following solutions:

Update Kotlin

Update Kotlin to the latest version. We're constantly improving the memory manager, so even a simple compiler update might improve memory consumption.

Experimental

Disable allocator paging

You can disable paging of allocations (buffering) so that the memory allocator reserves memory on a per-object basis. In some cases, it may help you satisfy strict memory limitations or reduce memory consumption on the application's startup.

To do that, set the following option in your `gradle.properties` file:

```
kotlin.native.binary.pagedAllocator=false
```

With allocator paging disabled, tracking memory consumption on Apple platforms is not possible.

Experimental

Enable support for Latin-1 strings

By default, strings in Kotlin are stored using UTF-16 encoding, where each character is represented by two bytes. In some cases, it leads to strings taking up twice as much space in the binary compared to the source code and reading data taking up twice as much memory.

To reduce the application's binary size and adjust memory consumption, you can enable support for Latin-1-encoded strings. The Latin-1 (ISO 8859-1) encoding represents each of the first 256 Unicode characters by just one byte.

To enable it, set the following option in your `gradle.properties` file:

```
kotlin.native.binary.latin1Strings=true
```

With the Latin-1 support, strings are stored in Latin-1 encoding as long as all the characters fall within its range. Otherwise, the default UTF-16 encoding is used.

> While the feature is Experimental, the cinterop extension functions `String.pin`, `String.usePinned`, and `String.refTo` become less efficient. Each call to them may trigger an automatic string conversion to UTF-16.

If none of these options helped, create an issue in YouTrack.

Unit tests in the background

In unit tests, nothing processes the main thread queue, so don't use `Dispatchers.Main` unless it was mocked. Mocking it can be done by calling `Dispatchers.setMain` from `kotlinx-coroutines-test`.

If you don't rely on `kotlinx.coroutines` or if `Dispatchers.setMain` doesn't work for you for some reason, try the following workaround for implementing the test launcher:

```
package testlauncher

import platform.CoreFoundation.*
import kotlin.native.concurrent.*
import kotlin.native.internal.test.*
import kotlin.system.*

fun mainBackground(args: Array<String>) {
    val worker = Worker.start(name = "main-background")
    worker.execute(TransferMode.SAFE, { args.freeze() }) {
        val result = testLauncherEntryPoint(it)
        exitProcess(result)
    }
    CFRunLoopRun()
    error("CFRunLoopRun should never return")
}
```

Then, compile the test binary with the `-e testlauncher.mainBackground` compiler option.

What's next

- Migrate from the legacy memory manager
- Check the specifics of integration with Swift/Objective-C ARC

Integration with Swift/Objective-C ARC

Kotlin and Objective-C use different memory management strategies. Kotlin has a tracing garbage collector, while Objective-C relies on automatic reference counting (ARC).

The integration between these strategies is usually seamless and generally requires no additional work. However, there are some specifics you should keep in mind:

Threads

Deinitializers

Deinitialization on the Swift/Objective-C objects and the objects they refer to is called on the main thread if these objects are passed to Kotlin on the main thread, for example:

```
// Kotlin
class KotlinExample {
    fun action(arg: Any) {
        println(arg)
    }
}
```

```
// Swift
class SwiftExample {
    init() {
        print("init on \(Thread.current)")
    }

    deinit {
        print("deinit on \(Thread.current)")
    }
}

func test() {
    KotlinExample().action(arg: SwiftExample())
}
```

The resulting output:

```
init on <_NSMainThread: 0x600003bc0000>{number = 1, name = main}
shared.SwiftExample
deinit on <_NSMainThread: 0x600003bc0000>{number = 1, name = main}
```

Deinitialization on the Swift/Objective-C objects is called on a special GC thread instead of the main one if:

- Swift/Objective-C objects are passed to Kotlin on a thread other than main.
- The main dispatch queue isn't processed.

If you want to call deinitialization on a special GC thread explicitly, set `kotlin.native.binary.objcDisposeOnMain=false` in your `gradle.properties`. This option enables deinitialization on a special GC thread, even if Swift/Objective-C objects were passed to Kotlin on the main thread.

A special GC thread complies with the Objective-C runtime, meaning that it has a run loop and drain autorelease pools.

Completion handlers

When calling Kotlin suspending functions from Swift, completion handlers might be called on threads other than the main one, for example:

```kotlin
// Kotlin
// coroutineScope, launch, and delay are from kotlinx.coroutines
suspend fun asyncFunctionExample() = coroutineScope {
    launch {
        delay(1000L)
        println("World!")
    }
    println("Hello")
}
```

```swift
// Swift
func test() {
    print("Running test on \(Thread.current)")
    PlatformKt.asyncFunctionExample(completionHandler: { _ in
        print("Running completion handler on \(Thread.current)")
    })
}
```

The resulting output:

```
Running test on <_NSMainThread: 0x600001b100c0>{number = 1, name = main}
Hello
World!
Running completion handler on <NSThread: 0x600001b45bc0>{number = 7, name = (null)}
```

Garbage collection and lifecycle

Object reclamation

An object is reclaimed only during the garbage collection. This applies to Swift/Objective-C objects that cross interop boundaries into Kotlin/Native, for example:

```kotlin
// Kotlin
class KotlinExample {
    fun action(arg: Any) {
        println(arg)
    }
}
```

```
// Swift
class SwiftExample {
    deinit {
        print("SwiftExample deinit")
    }
}

func test() {
    swiftTest()
    kotlinTest()
}

func swiftTest() {
    print(SwiftExample())
    print("swiftTestFinished")
}

func kotlinTest() {
    KotlinExample().action(arg: SwiftExample())
    print("kotlinTest finished")
}
```

The resulting output:

```
shared.SwiftExample
SwiftExample deinit
swiftTestFinished
shared.SwiftExample
kotlinTest finished
SwiftExample deinit
```

Objective-C objects lifecycle

The Objective-C objects might live longer than they should, which sometimes might cause performance issues. For example, when a long-running loop creates several temporary objects that cross the Swift/Objective-C interop boundary on each iteration.

In the GC logs, there's a number of stable refs in the root set. If this number keeps growing, it may indicate that the Swift/Objective-C objects are not freed up when they should. In this case, try the `autoreleasepool` block around loop bodies that do interop calls:

```
// Kotlin
fun growingMemoryUsage() {
    repeat(Int.MAX_VALUE) {
        NSLog("$it\n")
    }
}

fun steadyMemoryUsage() {
    repeat(Int.MAX_VALUE) {
        autoreleasepool {
            NSLog("$it\n")
        }
    }
}
```

Garbage collection of Swift and Kotlin objects' chains

Consider the following example:

```
// Kotlin
interface Storage {
    fun store(arg: Any)
}

class KotlinStorage(var field: Any? = null) : Storage {
    override fun store(arg: Any) {
        field = arg
    }
}

class KotlinExample {
    fun action(firstSwiftStorage: Storage, secondSwiftStorage: Storage) {
        // Here, we create the following chain:
        // firstKotlinStorage -> firstSwiftStorage -> secondKotlinStorage -> secondSwiftStorage.
        val firstKotlinStorage = KotlinStorage()
        firstKotlinStorage.store(firstSwiftStorage)
        val secondKotlinStorage = KotlinStorage()
        firstSwiftStorage.store(secondKotlinStorage)
        secondKotlinStorage.store(secondSwiftStorage)
    }
}
```

```
// Swift
class SwiftStorage : Storage {

    let name: String

    var field: Any? = nil

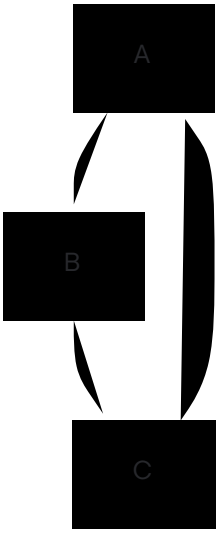
    init(_ name: String) {
        self.name = name
    }

    func store(arg: Any) {
        field = arg
    }

    deinit {
        print("deinit SwiftStorage \(name)")
    }
}

func test() {
    KotlinExample().action(
        firstSwiftStorage: SwiftStorage("first"),
        secondSwiftStorage: SwiftStorage("second")
    )
}
```

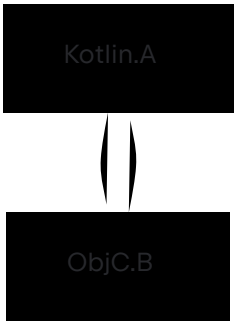
It takes some time between "deinit SwiftStorage first" and "deinit SwiftStorage second" messages to appear in the log. The reason is that `firstKotlinStorage` and `secondKotlinStorage` are collected in different GC cycles. Here's the sequence of events:



1. `KotlinExample.action` finishes. `firstKotlinStorage` is considered "dead" because nothing references it, while `secondKotlinStorage` is not because it is referenced by `firstSwiftStorage`.

2. First GC cycle starts, and `firstKotlinStorage` is collected.
3. There are no references to `firstSwiftStorage`, so it is "dead" as well, and `deinit` is called.
4. Second GC cycle starts. `secondKotlinStorage` is collected because `firstSwiftStorage` is no longer referencing it.
5. `secondSwiftStorage` is finally reclaimed.

It requires two GC cycles to collect these four objects because deinitialization of Swift and Objective-C objects happens after the GC cycle. The limitation stems from `deinit`, which can call arbitrary code, including the Kotlin code that cannot be run during the GC pause.



Retain cycles

In a *retain cycle*, a number of objects refer each other using strong references cyclically:

Kotlin's tracing GC and Objective-C's ARC handle retain cycles differently. When objects become unreachable, Kotlin's GC can properly reclaim such cycles, while Objective-C's ARC cannot. Therefore, retain cycles of Kotlin objects can be reclaimed, while retain cycles of Swift/Objective-C objects cannot.

Consider the case when a retain cycle contains both Objective-C and Kotlin objects:

This involves combining Kotlin's and Objective-C's memory management models that cannot handle (reclaim) retain cycles together. That means if at least one Objective-C object is present, the retain cycle of a whole graph of objects cannot be reclaimed, and it's impossible to break the cycle from the Kotlin side.

Unfortunately, no special instruments are currently available to automatically detect retain cycles in Kotlin/Native code. To avoid retain cycles, use weak or unowned references.

Support for background state and App Extensions

The current memory manager does not track application state by default and does not integrate with App Extensions out of the box.

It means that the memory manager doesn't adjust GC behavior accordingly, which might be harmful in some cases. To change this behavior, add the following Experimental binary option to your `gradle.properties`:

```
kotlin.native.binary.appStateTracking=enabled
```

It turns off a timer-based invocation of the garbage collector when the application is in the background, so GC is called only when memory consumption becomes too high.

What's next

Learn more about Swift/Objective-C interoperability.

Migrate to the new memory manager

> Support for the legacy memory manager has been completely removed in Kotlin 1.9.20. Migrate your projects to the current memory model, enabled by default since Kotlin 1.7.20.

This guide compares the new Kotlin/Native memory manager with the legacy one and describes how to migrate your projects.

The most noticeable change in the new memory manager is lifting restrictions on object sharing. You don't need to freeze objects to share them between threads, specifically:

- Top-level properties can be accessed and modified by any thread without using `@SharedImmutable`.
- Objects passing through interop can be accessed and modified by any thread without freezing them.
- `Worker.executeAfter` no longer requires operations to be frozen.
- `Worker.execute` no longer requires producers to return an isolated object subgraph.
- Reference cycles containing `AtomicReference` and `FreezableAtomicReference` do not cause memory leaks.

Apart from easy object sharing, the new memory manager also brings other major changes:

- Global properties are initialized lazily when the file they are defined in is accessed first. Previously, global properties were initialized at the program startup. As a workaround, you can mark properties that must be initialized at the program start with the `@EagerInitialization` annotation. Before using, check its documentation.
- `by lazy {}` properties support thread-safety modes and do not handle unbounded recursion.
- Exceptions that escape `operation` in `Worker.executeAfter` are processed like in other runtime parts, by trying to execute a user-defined unhandled exception hook or terminating the program if the hook was not found or failed with an exception itself.
- Freezing is deprecated and always disabled.

Follow these guidelines to migrate your projects from the legacy memory manager:

Update Kotlin

The new Kotlin/Native memory manager has been enabled by default since Kotlin 1.7.20. Check the Kotlin version and update to the latest one if necessary.

Update dependencies

kotlinx.coroutines

Update to version 1.6.0 or later. Do not use versions with the `native-mt` suffix.

There are also some specifics with the new memory manager you should keep in mind:

- Every common primitive (channels, flows, coroutines) works through the Worker boundaries, since freezing is not required.
- `Dispatchers.Default` is backed by a pool of Workers on Linux and Windows and by a global queue on Apple targets.
- Use `newSingleThreadContext` to create a coroutine dispatcher that is backed by a Worker.
- Use `newFixedThreadPoolContext` to create a coroutine dispatcher backed by a pool of `N` Workers.
- `Dispatchers.Main` is backed by the main queue on Darwin and by a standalone Worker on other platforms.

Ktor

Update to version 2.0 or later.

Other dependencies

The majority of libraries should work without any changes, however, there might be exceptions.

Make sure that you update dependencies to the latest versions, and there is no difference between library versions for the legacy and the new memory manager.

Update your code

To support the new memory manager, remove usages of the affected API:

Old API	What to do
`@SharedImmutable`	You can remove all usages, though there are no warnings for using this API in the new memory manager.
The `FreezableAtomicReference` class	Use `AtomicReference` instead.
The `FreezingException` class	Remove all usages.
The `InvalidMutabilityException` class	Remove all usages.
The `IncorrectDereferenceException` class	Remove all usages.

Old API	What to do
The `freeze()` function	Remove all usages.
The `isFrozen` property	You can remove all usages. Since freezing is deprecated, the property always returns `false`.
The `ensureNeverFrozen()` function	Remove all usages.
The `atomicLazy()` function	Use `lazy()` instead.
The `MutableData` class	Use any regular collection instead.
The `WorkerBoundReference<out T : Any>` class	Use `T` directly.
The `DetachedObjectGraph<T>` class	Use `T` directly. To pass the value through the C interop, use the StableRef class.

What's next

- Check the specifics of integration with Swift/Objective-C ARC
- Learn how to reference objects safely from different coroutines

Kotlin/Native binary options

This page lists helpful Kotlin/Native binary options that you can use to configure Kotlin/Native final binaries and the ways to set up binary options in your project.

How to enable

You can enable binary options in the `gradle.properties` file, your build file, or pass them as compiler arguments.

In Gradle properties

You can set binary options in your project's `gradle.properties` file using the `kotlin.native.binary` property. For example:

```
kotlin.native.binary.latin1Strings=true
```

In your build file

You can set binary options for your project in your `build.gradle.kts` file:

-

For specific binaries using the `binaryOption` attribute. For example:

```
kotlin {
    iosArm64 {
        binaries {
            framework {
                binaryOption("smallBinary", "true")
            }
        }
    }
}
```

- As `-Xbinary=$option=$value` compiler options in the `freeCompilerArgs` attribute. For example:

```
kotlin {
    iosArm64 {
        compilations.configureEach {
            compilerOptions.configure {
                freeCompilerArgs.add("-Xbinary=smallBinary=true")
            }
        }
    }
}
```

In the command-line compiler

You can pass binary options as `-Xbinary=$option=$value` directly in the command line when executing the Kotlin/Native compiler. For example:

```
kotlinc-native main.kt -Xbinary=enableSafepointSignposts=true
```

Binary options

This table is not an exhaustive list of all the existing options, only the most notable ones.

Option	Values	Description	Status
`enableReleaseBinaryCache`	• `true` • `false` (default)	Enables the compiler to use caches in release mode, making builds faster at the expense of some compiler optimizations.	Experimental since 2.4.20
`objcExportBlockExplicitParameterNames`	• `true` • `false (default)`	Adds explicit parameter names to function types for exported Objective-C headers.	Experimental since 2.2.20

Option	Values	Description	Status
`smallBinary`	• `true` • `false` (default)	Decreases the binary size for release binaries.	Experimental since 2.2.20
`stackProtector`	• `yes` • `strong` • `all` • `no` (default)	Enables stack canaries: use `yes` for vulnerable functions, `all` for all functions, and `strong` to use a stronger heuristic.	Available since 2.2.20
`pagedAllocator`	• `true` (default) • `false`	Controls paging of allocations (buffering). When `false`, the memory allocator reserves memory on a per-object basis.	Experimental since 2.2.0
`latin1Strings`	• `true` • `false` (default)	Controls support for Latin-1-encoded strings to reduce application binary size and adjust memory consumption.	Experimental since 2.2.0
`mmapTag`	`UInt`	Controls memory tagging, necessary for memory consumption tracking on Apple platforms. Values `240` - `255` are available (default is `246`); `0` disables tagging.	Available since 2.2.0
`disableMmap`	• `true` • `false` (default)	Controls the default allocator. When `true`, uses the `malloc` memory allocator instead of `mmap`.	Available since 2.2.0
`gc`	• `cms` (default) • `pmcs` • `stwms`	Controls garbage collection behavior: •	`cms` is default since 2.4.0

Option	Values	Description	Status
	• `noop` • `cms` uses concurrent mark and sweep • `pmcs` uses parallel mark concurrent sweep • `stwms` uses simple stop-the-world mark and sweep • `noop` disables garbage collection		
`gcMarkSingleThreaded`	• `true` • `false` (default)	Disables parallelization of the mark phase in garbage collection. May increase GC pause time on large heaps.	Available since 1.7.20
`enableSafepointSignposts`	• `true` • `false` (default)	Enables tracking GC-related pauses in the project for debugging in Xcode Instruments.	Available since 2.0.20
`preCodegenInlineThreshold`	`UInt`	Configures inlining optimization pass in the Kotlin IR compiler, which comes before the actual code generation phase (disabled by default). The recommended number of tokens (code units parsed by the compiler) is 40.	Experimental since 2.1.20
`objcDisposeOnMain`	• `true` (default) • `false`	Controls deinitialization of Swift/Objective-C objects. When `false`, deinitialization happens on a special GC thread instead of the main one.	Available since 1.9.0
`appStateTracking`	• `enabled` •	Controls timer-based invocation of the garbage collector when	Experimental since 1.7.20

Option	Values	Description	Status
	`disabled` (default)	the application runs in the background. When `enabled`, GC is called only when memory consumption becomes too high.	
`bundleId`	• `String`	Sets bundle ID (`CFBundleIdentifier`) in the `Info.plst` file.	Available since 1.7.20
`bundleShortVersionString`	• `String`	Sets short bundle version (`CFBundleShortVersionString`) in the `Info.plst` file.	Available since 1.7.20
`bundleVersion`	• `String`	Sets bundle version (`CFBundleVersion`) in the `Info.plst` file.	Available since 1.7.20
`sourceInfoType`	• `libbacktrace` • `coresymbolication` (Apple targets) • `noop` (default)	Adds file locations and line numbers to exception stack traces. `coresymbolication` is only available for Apple targets and enabled by default for macOS and Apple simulators in debug mode.	Experimental since 1.6.20

For more information on stability levels, see the documentation.

What's next

Learn how to build final native binaries.

Debugging Kotlin/Native

The Kotlin/Native compiler can generate binaries with debug information, as well as create debug symbol files for symbolicating crash reports.

The debug information is compatible with the DWARF 2 specification, so modern debugger tools, like LLDB and GDB can:

- Set breakpoints
- Use stepping
- Inspect variable and type information

> Supporting the DWARF 2 specification means that the debugger tool recognizes Kotlin as C89, because before the DWARF 5 specification, there is no identifier for the Kotlin language type in the specification.

Generate binaries with debug information

When debugging in IntelliJ IDEA, Android Studio, or Xcode, binaries with debug information are generated automatically (unless the build is configured differently).

You can enable debugging manually and produce binaries that include debug information by:

- **Using Gradle tasks**. To get debug binaries, use `linkDebug*` Gradle tasks, for example:

  ```
  ./gradlew linkDebugFrameworkNative
  ```

  The tasks differ depending on the binary type (for example, `linkDebugSharedNative`) or your target (for example, `linkDebugExecutableMacosArm64`).

- **Using the command-line compiler**. In the command line, compile your Kotlin/Native binary with the `-g` option:

  ```
  kotlinc-native hello.kt -g -o terminator
  ```

Then launch your debugger tool. For example:

```
lldb terminator.kexe
```

The debugger outputs:

```
$ cat - > hello.kt
fun main(args: Array<String>) {
  println("Hello world")
  println("I need your clothes, your boots and your motorcycle")
}
$ dist/bin/konanc -g hello.kt -o terminator
KtFile: hello.kt
$ lldb terminator.kexe
(lldb) target create "terminator.kexe"
Current executable set to 'terminator.kexe' (x86_64).
(lldb) b kfun:main(kotlin.Array<kotlin.String>)
Breakpoint 1: where = terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) + 4 at hello.kt:2,
address = 0x00000001000012e4
(lldb) r
Process 28473 launched: '/Users/minamoto/ws/.git-trees/debugger-fixes/terminator.kexe' (x86_64)
Process 28473 stopped
* thread #1, queue = 'com.apple.main-thread', stop reason = breakpoint 1.1
    frame #0: 0x00000001000012e4 terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) at hello.kt:2
   1    fun main(args: Array<String>) {
-> 2      println("Hello world")
   3      println("I need your clothes, your boots and your motorcycle")
   4    }
(lldb) n
Hello world
Process 28473 stopped
* thread #1, queue = 'com.apple.main-thread', stop reason = step over
    frame #0: 0x00000001000012f0 terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) at hello.kt:3
   1    fun main(args: Array<String>) {
   2      println("Hello world")
-> 3      println("I need your clothes, your boots and your motorcycle")
   4    }
(lldb)
```

Set breakpoints

Modern debuggers provide several ways to set a breakpoint. See below for a tool-by-tool breakdown:

LLDB

- By name:

```
(lldb) b -n kfun:main(kotlin.Array<kotlin.String>)
Breakpoint 4: where = terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) + 4 at hello.kt:2,
address = 0x00000001000012e4
```

  `-n` is optional, it's applied by default.

- By location (filename, line number):

```
(lldb) b -f hello.kt -l 1
Breakpoint 1: where = terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) + 4 at hello.kt:2,
address = 0x00000001000012e4
```

- By address:

```
(lldb) b -a 0x00000001000012e4
Breakpoint 2: address = 0x00000001000012e4
```

- By regex. You might find it useful for debugging generated artifacts, like a lambda (with the `#` symbol in the name):

```
(lldb) b -r main\(
3: regex = 'main\(', locations = 1
  3.1: where = terminator.kexe`kfun:main(kotlin.Array<kotlin.String>) + 4 at hello.kt:2, address =
terminator.kexe[0x00000001000012e4], unresolved, hit count = 0
```

GDB

- By regex:

```
(gdb) rbreak main(
Breakpoint 1 at 0x1000109b4
struct ktype:kotlin.Unit &kfun:main(kotlin.Array<kotlin.String>);
```

- By name is *not* possible because `:` is a separator for the breakpoint by location:

```
(gdb) b kfun:main(kotlin.Array<kotlin.String>)
No source file named kfun.
Make breakpoint pending on future shared library load? (y or [n]) y
Breakpoint 1 (kfun:main(kotlin.Array<kotlin.String>)) pending
```

- By location:

```
(gdb) b hello.kt:1
Breakpoint 2 at 0x100001704: file /Users/minamoto/ws/.git-trees/hello.kt, line 1.
```

- By address:

```
(gdb) b *0x100001704
Note: breakpoint 2 also set at pc 0x100001704.
Breakpoint 3 at 0x100001704: file /Users/minamoto/ws/.git-trees/hello.kt, line 2.
```

Use stepping

Stepping through functions works mostly the same way as for C/C++ programs.

Inspect variables

Variable inspection for `var` variables works out of the box for both primitive and non-primitive types:

```
$ cat -n main.kt
     1  fun main(args: Array<String>) {
     2      var x = 1
     3      var y = 2
     4      var p = Point(x, y)
     5      println("p = $p")
     6  }
     7
     8  data class Point(val x: Int, val y: Int)

$ lldb ./program.kexe -o 'b main.kt:5' -o
(lldb) target create "./program.kexe"
Current executable set to './program.kexe' (x86_64).
(lldb) b main.kt:5
Breakpoint 1: where = program.kexe`kfun:main(kotlin.Array<kotlin.String>) + 289 at main.kt:5
(lldb) r
Process 4985 stopped
* thread #1, name = 'program.kexe', stop reason = breakpoint 1.1
    frame #0: program.kexe`kfun:main(kotlin.Array<kotlin.String>) at main.kt:5
   2        var x = 1
   3        var y = 2
   4        var p = Point(x, y)
-> 5        println("p = $p")
   6    }
   7
   8    data class Point(val x: Int, val y: Int)

Process 4985 launched: './program.kexe' (x86_64)
(lldb) fr var
(int) x = 1
(int) y = 2
(ObjHeader *) p = Point(x=1, y=2)

(lldb) v p->x
(int32_t) p->x = 1
```

Debug iOS applications

Debugging iOS applications sometimes involves analyzing crash reports in detail. Crash reports typically require symbolication, the process of translating memory addresses into readable source code locations.

To symbolicate addresses in Kotlin code (for example, for stack trace elements corresponding to Kotlin code), you need a special debug symbol (`.dSYM`) file. This file maps memory addresses in crash reports with actual locations in the source code, such as functions or line numbers.

The Kotlin/Native compiler generates `.dSYM` files for release (optimized) binaries on Apple platforms by default. When building in Xcode, the IDE looks for `.dSYM` files in standard locations and uses them automatically for symbolication. Xcode automatically detects `.dSYM` files in projects created from IntelliJ IDEA templates.

On other platforms, you can add debug information into the produced binaries (which increases their size) using the `-Xadd-light-debug` compiler option:

Kotlin

```
kotlin {
    targets.withType<org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget> {
        binaries.all {
            freeCompilerArgs += "-Xadd-light-debug=enable"
        }
    }
}
```

Groovy

```
kotlin {
    targets.withType(org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget) {
        binaries.all {
            freeCompilerArgs += "-Xadd-light-debug=enable"
        }
    }
}
```

For more information about crash reports, see the Apple documentation.

Known issues

- Performance of Python bindings.
- Expression evaluation in debugger tools is not supported, and currently there are no plans for implementing it.

What's next?

Learn how to improve crash reports for unhandled Kotlin exceptions in iOS code

Kotlin/Native supported targets and hosts

This document describes which targets and hosts are supported by the Kotlin/Native compiler.

We can adjust the list of supported targets and hosts, the number of tiers, and their features as we go.

Target tiers

The Kotlin/Native compiler supports a number of different targets, though the level of support for them varies. To clarify these levels, we've broken up the targets into several tiers depending on how well the compiler supports them.

Tier tables have the following columns:

- **Gradle target name** is a target name that is used in the Kotlin Multiplatform Gradle plugin to enable the target.
- **Target triple** is a target name according to the `<architecture>-<vendor>-<system>-<abi>` structure that compilers commonly use.

- **Running tests** indicates whether the target allows users to run tests out of the box in Gradle and IDE (not to be confused with CI tests that are run for targets themselves).

  This is only available on a native host for the specific target. For example, you can run `macosArm64` and `iosArm64` tests only on the macOS ARM64 host.

Tier 1

- The target is regularly tested on CI to be able to compile and run.
- We provide a source and binary compatibility between compiler releases.

Gradle target name	Target triple	Running tests	Description
Apple macOS hosts only:			
`macosArm64`	`aarch64-apple-macos`	✅	Apple macOS 12.0 and later on Apple Silicon platforms
`iosSimulatorArm64`	`aarch64-apple-ios-simulator`	✅	Apple iOS simulator 15.0 and later on Apple Silicon platforms
`iosArm64`	`aarch64-apple-ios`		Apple iOS and iPadOS 15.0 and later on ARM64 platforms

Tier 2

- The target is regularly tested on CI to be able to compile but may not be automatically tested to be able to run.
- We're doing our best to provide source and binary compatibility between compiler releases.

Gradle target name	Target triple	Running tests	Description
`linuxX64`	`x86_64-unknown-linux-gnu`	✅	Linux on x86_64 platforms
`linuxArm64`	`aarch64-unknown-linux-gnu`		Linux on ARM64 platforms
Apple macOS hosts only:			
`watchosSimulatorArm64`	`aarch64-apple-watchos-simulator`	✅	Apple watchOS simulator 8.0 and later on Apple Silicon platforms

Gradle target name	Target triple	Running tests	Description
`watchosArm64`	`arm64_32-apple-watchos`		Apple watchOS 8.0 and later on ARM64 platforms with ILP32
`tvosSimulatorArm64`	`aarch64-apple-tvos-simulator`	✅	Apple tvOS simulator 15.0 and later on Apple Silicon platforms
`tvosArm64`	`aarch64-apple-tvos`		Apple tvOS 15.0 and later on ARM64 platforms

Tier 3

- The target is not guaranteed to be tested on CI.
- We can't promise a source and binary compatibility between different compiler releases, though such changes for these targets are quite rare.

> The Tier 3 targets are not in active development and may come with breaking issues. Use them with caution.

Gradle target name	Target triple	Running tests	Description
`androidNativeArm32`	`arm-unknown-linux-androideabi`		Android NDK on ARM32 platforms
`androidNativeArm64`	`aarch64-unknown-linux-android`		Android NDK on ARM64 platforms
`androidNativeX86`	`i686-unknown-linux-android`		Android NDK on x86 platforms
`androidNativeX64`	`x86_64-unknown-linux-android`		Android NDK on x86_64 platforms
`mingwX64`	`x86_64-pc-windows-gnu`	✅	64-bit Windows 10 and later using MinGW compatibility layer
Apple macOS hosts only:			
`watchosDeviceArm64`	`aarch64-apple-watchos`		Apple watchOS 8.0 and later on ARM64 platforms

Gradle target name	Target triple	Running tests	Description
`iosX64`	`x86_64-apple-ios-simulator`		Apple iOS simulator 15.0 and later on x86-64 platforms

Deprecated targets

The following targets are deprecated and scheduled for removal:

Target	Deprecation start	Description
`watchosArm32`	Kotlin 2.4.20	Apple watchOS devices on ARM32 platforms
`macosX64`	Kotlin 2.3.20	Apple macOS on x86_64 platforms
`watchosX64`	Kotlin 2.3.20	Apple watchOS 64-bit simulator on x86_64 platforms
`tvosX64`	Kotlin 2.3.20	Apple tvOS simulator on x86_64 platforms
`linuxArm32Hfp`	Kotlin 1.8.20	Linux on ARM32 platforms

Supporting lower Apple target versions

Currently, the default minimum supported versions of Apple targets are:

- For iOS and tvOS, 15.0.
- For macOS, 12.0.
- For watchOS, 8.0.

If your project needs to support a version lower than the default one, use the `freeCompilerArgs` option in your build file:

```
kotlin {
    targets.withType<org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget>().configureEach {
        binaries.configureEach {
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.ios=14.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.macos=11.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.tvos=14.0"
            freeCompilerArgs += "-Xoverride-konan-properties=minVersion.watchos=7.0"
        }
    }
}
```

For library authors

We don't recommend library authors to test more targets or provide stricter guarantees than the Kotlin/Native compiler does. You can use the following approach when considering support for native targets:

-

Support all the targets from tiers 1, 2, and 3.

- Regularly test targets from tiers 1 and 2 that support running tests out of the box.

The Kotlin team uses this approach in the official Kotlin libraries, for example, kotlinx.coroutines and kotlinx.serialization.

Hosts

The Kotlin/Native compiler supports the following hosts:

Host OS	Building final binaries	Producing `.klib` artifacts
macOS on Apple silicon (ARM64)	Any supported target	Any supported target
macOS on Intel chips (x86_64)	Any supported target	Any supported target
Linux with x86_64 architecture	Any supported target, except for Apple targets	Any supported target, Apple targets only without cinterop dependencies
Windows (MinGW toolchain) with x86_64 architecture	Any supported target, except for Apple targets	Any supported target, Apple targets only without cinterop dependencies

Building final binaries

To produce final binaries, you can compile for supported targets only on *supported hosts*. For example, you cannot do it on FreeBSD or on a Linux machine running on the ARM64 architecture.

Building final binaries for Apple targets on Linux and Windows is also not possible.

Producing `.klib` artifacts

Generally, Kotlin/Native allows any *supported host* to produce `.klib` artifacts for supported targets.

However, artifact production for Apple targets still has some limitations on Linux and Windows. If your project uses cinterop dependencies (including CocoaPods), you must use a macOS host.

For example, you can produce a `.klib` for `macosArm64` target on a Windows machine running on the x86_64 architecture only if there are no cinterop dependencies.

What's next?

- Build final native binaries
- Compilation for Apple targets

Tips for improving compilation time

The Kotlin/Native compiler is constantly receiving updates that improve its performance. With the latest Kotlin/Native compiler and a properly configured build environment, you can significantly improve the compilation times of your projects with Kotlin/Native targets.

Read on for our tips on how to speed up the Kotlin/Native compilation process.

General recommendations

Use the latest version of Kotlin

This way, you always get the latest performance improvements. The most recent Kotlin version is 2.4.20.

Avoid creating huge classes

Try to avoid huge classes that take a long time to compile and load during execution.

Preserve downloaded and cached components between builds

When compiling projects, Kotlin/Native downloads the required components and caches some results of its work to the `$USER_HOME/.konan` directory. The compiler uses this directory for subsequent compilations, making them take less time to complete.

When building in containers (such as Docker) or with continuous integration systems, the compiler may have to create the `~/.konan` directory from scratch for each build. To avoid this step, configure your environment to preserve `~/.konan` between builds. For example, redefine its location using the `konan.data.dir` Gradle property.

Alternatively, you can use the `-Xkonan-data-dir` compiler option to configure your custom path to the directory via the `cinterop` and `konanc` tools.

Gradle configuration

The first compilation with Gradle usually takes more time than subsequent ones due to the need to download the dependencies, build caches, and perform additional steps. You should build your project at least twice to get an accurate reading of the actual compilation times.

Below are some recommendations for configuring Gradle for better compilation performance.

Increase Gradle heap size

To increase the Gradle heap size, add `org.gradle.jvmargs=-Xmx3g` to your `gradle.properties` file.

If you use parallel builds, you might need to choose the right number of workers with the `org.gradle.workers.max` property or the `--max-workers` command-line option. The default value is the number of CPU processors.

Build only necessary binaries

Don't run Gradle tasks that build the whole project, such as `build` or `assemble`, unless you really need to. These tasks build the same code more than once, increasing the compilation times. In typical cases, such as running tests from IntelliJ IDEA or starting the app from Xcode, the Kotlin tooling avoids executing unnecessary tasks.

If you have a non-typical case or build configuration, you might need to choose the task yourself:

- `linkDebug*`. To run your code during development, you usually need only one binary, so running the corresponding `linkDebug*` task should be enough.
- `embedAndSignAppleFrameworkForXcode`. Since iOS simulators and devices have different processor architectures, it's a common approach to distribute a Kotlin/Native binary as a universal (fat) framework.

  However, during local development, it's faster to build the `.framework` file only for the platform you're using. To build a platform-specific framework, use the embedAndSignAppleFrameworkForXcode task.

Build only for necessary targets

Similarly to the recommendation above, don't build a binary for all native platforms at once. For example, compiling an XCFramework (using an `*XCFramework` task) builds the same code for all targets, which takes proportionally more time than building for a single target.

If you do need XCFrameworks for your setup, you can reduce the number of targets. For example, you don't need `iosX64` if you don't run this project on iOS simulators on Intel-based Macs.

> Binaries for different targets are built with `linkDebug*$Target` and `linkRelease*$Target` Gradle tasks. You can look for the executed tasks in the build log or in the Gradle build scan by running a Gradle build with the `--scan` option.

Don't build unnecessary release binaries

Kotlin/Native supports two build modes, debug and release. Release is highly optimized, and this takes a lot of time: compilation of release binaries takes an order of magnitude more time than debug binaries.

Apart from an actual release, all these optimizations might be unnecessary in a typical development cycle. If you use a task with `Release` in its name during the development process, consider replacing it with `Debug`. Similarly, instead of running `assembleXCFramework`, you can run `assembleSharedDebugXCFramework`, for example.

> Release binaries are built with `linkRelease*` Gradle tasks. You can check for them in the build log or in the Gradle build scan by running a Gradle build with the `--scan` option.

Experimental

Enable caches for release binaries

By default, Kotlin/Native compiles release binaries in the link-time optimization (LTO) mode: all modules are compiled and optimized together. This makes release binaries faster at runtime but significantly increases compilation time.

If you prefer to prioritize faster compilation over some compiler optimizations, you can enable caching in release mode. To enable caching, add both following options to your `gradle.properties` file:

```
# Enables the compiler to use caches in release mode
kotlin.native.binary.enableReleaseBinaryCache=true
# Makes the Kotlin Gradle plugin invoke the compiler with `-Xauto-cache-from` and related options
kotlin.internal.native.enableReleaseBinaryCache=true
```

The feature is in active development, so runtime performance still has room for improvement. Performance improvements are planned in upcoming Kotlin releases.

Experimental

Reduce the size of release binaries

To reduce the size of release binaries and improve build time, try enabling the binary option `smallBinary`.

It effectively sets `-Oz` as the default optimization argument for the compiler during the LLVM compilation phase. The option is still Experimental and might affect runtime performance in some cases.

Don't use transitive export

Using `transitiveExport = true` disables dead code elimination in many cases, so the compiler has to process a lot of unused code. It increases the compilation time. Instead, use the `export` method explicitly for exporting the required projects and dependencies.

Don't export modules too much

Try to avoid unnecessary module export. Each exported module negatively affects compilation time and binary size.

Use Gradle build caching

Enable the Gradle build cache feature:

- **Local build cache**. For local caching, add `org.gradle.caching=true` to your `gradle.properties` file or run the build with the `--build-cache` option in the command line.
- **Remote build cache**. Learn how to configure the remote build cache for continuous integration environments.

Use Gradle configuration cache

The Gradle configuration cache improves build performance by caching the results of the configuration phase. It also enables parallel execution of independent tasks within a single project and implicitly enables the `org.gradle.parallel` property, allowing tasks across different projects to execute in parallel.

To use the Gradle configuration cache, add the `org.gradle.configuration-cache=true` property to your `gradle.properties` file.

The configuration cache also enables running `link*` tasks in parallel which could heavily load the machine, specifically with a lot of CPU cores. This issue will be fixed in KT-70915.

Enable previously disabled features

You might have disabled some Kotlin/Native features in the past to work around build issues. For example:

- `kotlin.native.disableCompilerDaemon=true` disables the Gradle daemon.
- `disableNativeCache` disables the compilation cache.

The issues that originally required these workarounds might have already been fixed. If your `gradle.properties` file or Gradle build files contain these lines, remove them and check whether the build completes successfully.

Beta

Try incremental compilation of klib artifacts

With incremental compilation, if only a part of the `klib` artifact produced by the project module changes, just a part of `klib` is further recompiled into a binary.

This feature is in Beta. To enable it, add the following option to your `gradle.properties` file:

```
kotlin.incremental.native=true
```

If you face any problems, create an issue in YouTrack.

Windows configuration

Windows Security may slow down the Kotlin/Native compiler. You can avoid this by adding the `.konan` directory, which is located in `%USERPROFILE%` by default, to Windows Security exclusions. Learn how to add exclusions to Windows Security.

LLVM configuration

If the above tips didn't help with improving compilation time, consider customizing the LLVM backend.

Tips for customizing LLVM backend

The Kotlin/Native compiler uses LLVM to optimize and generate binary executables for different target platforms. A noticeable part of the compilation time is also spent in LLVM, and for large apps, this can end up taking an unacceptably long time.

You can customize how Kotlin/Native uses LLVM and adjust the list of optimization passes.

Examine the build log

Let's take a look at the build log to understand how much compilation time is spent on LLVM optimization passes:

1. Run the `linkRelease*` Gradle task with `-Pkotlin.internal.compiler.arguments.log.level=warning` option to make Gradle output LLVM profiling details, for example:

   ```
   ./gradlew linkReleaseExecutableMacosArm64 -Pkotlin.internal.compiler.arguments.log.level=warning
   ```

   While executing, the task prints the necessary compiler arguments, for example:

```
> Task :linkReleaseExecutableMacosArm64
Run in-process tool "konanc"
Entry point method = org.jetbrains.kotlin.cli.utilities.MainKt.daemonMain
Classpath = [
        /Users/user/.konan/kotlin-native-prebuilt-macos-aarch64-2.2.0/konan/lib/kotlin-native-
compiler-embeddable.jar
        /Users/user/.konan/kotlin-native-prebuilt-macos-aarch64-2.2.0/konan/lib/trove4j.jar
]
Arguments = [
        -Xinclude=...
        -library
        /Users/user/.konan/kotlin-native-prebuilt-macos-aarch64-2.2.0/klib/common/stdlib
        -no-endorsed-libs
        -nostdlib
        ...
]
```

2. Run the command line compiler with the provided arguments plus the `-Xprofile-phases` argument, for example:

```
/Users/user/.konan/kotlin-native-prebuilt-macos-aarch64-2.2.0/bin/kotlinc-native \
-Xinclude=... \
-library /Users/user/.konan/kotlin-native-prebuilt-macos-aarch64-2.2.0/klib/common/stdlib \
... \
-Xprofile-phases
```

3. Examine the generated output in the build log. The log can contain tens of thousands of lines; sections with LLVM profiling are at the end.

Here is an excerpt from such a run of a simple Kotlin/Native program:

```
Frontend: 275 msec
PsiToIr: 1186 msec
...
... 30k lines
...
LinkBitcodeDependencies: 476 msec

ModuleBitcodeOptimization: 8118 msec
...
LTOBitcodeOptimization: 1399 msec
...
```

The Kotlin/Native compiler runs two separate sequences of LLVM optimizations: the module passes and the link-time passes. For a typical compilation, the two pipelines are run back to back, and the only real distinction is in which LLVM optimization passes they run.

In the log above, the two LLVM optimizations are `ModuleBitcodeOptimization` and `LTOBitcodeOptimization`. The formatted tables are the optimizations' output with timing for each pass.

Customize LLVM optimization passes

If one of the passes above seems unreasonably long, you can skip it. However, this might hurt runtime performance, so you should check for changes in the benchmarks' performance afterward.

Currently, there is no direct way to disable a given pass. However, you can provide a new list of passes to run by using the following compiler options:

Option	Default value for release binary
`-Xllvm-module-passes`	`"default<O3>"`
`-Xllvm-lto-passes`	`"internalize,globaldce,lto<O3>"`

The default values are unfolded to a long list of actual passes, from which you need to exclude the undesired ones.

To get the list of actual passes, run the `opt` tool, which is automatically downloaded with the LLVM distribution to the `~/.konan/dependencies/llvm-{VERSION}-{ARCH}-{OS}-dev-{BUILD}/bin` directory.

For example, to get the list of the link-time passes, run:

```
opt -print-pipeline-passes -passes="internalize,globaldce,lto<O3>" < /dev/null
```

This outputs a warning and a long list of passes, which depends on the LLVM version.

There are two differences between the list of passes from the `opt` tool and the passes that Kotlin/Native compiler actually runs:

- Since `opt` is a debug tool, it includes one or more `verify` passes, which are not normally run.
- Kotlin/Native disables the `devirt` passes since the Kotlin compiler already does them itself.

After disabling any passes, always rerun performance tests to check if the runtime performance degradation is acceptable.

License files for the Kotlin/Native binaries

Like many other open-source projects, Kotlin relies on third-party code, meaning that the Kotlin project includes some code not developed by JetBrains or the Kotlin programming language contributors. Sometimes it is derived work, such as code rewritten from C++ to Kotlin.

You can find licenses for the third-party work used in Kotlin in our GitHub repository:

- Kotlin compiler
- Kotlin/Native

In particular, the Kotlin/Native compiler produces binaries that can include third-party code, data, or derived work. This means that the Kotlin/Native-compiled binaries are subject to the terms and conditions of the third-party licenses.

In practice, if you distribute a Kotlin/Native-compiled final binary, you should always include the necessary license files in your binary distribution. The files should be accessible to users of your distribution in a readable form.

Always include the following license files for the corresponding projects:

Project	Files to be included
Kotlin	• Apache License 2.0
Apache Harmony	• Apache Harmony copyright notice
GWT	
Guava	
libbacktrace	3-clause BSD license with copyright notice
mimalloc	MIT license Include in case you use the mimalloc memory allocator instead of the default one (the `-Xallocator=mimalloc` compiler option is set).
Unicode character database	Unicode license
Multi-producer/multi-consumer bounded queue	Copyright notice

The `mingwX64` target requires additional license files:

Project	Files to be included
MinGW-w64 headers and runtime libraries	• MinGW-w64 runtime license • Winpthreads license

None of these libraries require the distributed Kotlin/Native binaries to be open-sourced.

Kotlin/Native FAQ

How do I run my program?

Define a top-level function `fun main(args: Array<String>)` or just `fun main()` if you are not interested in passed arguments, please ensure it's not in a package. Also, compiler switch `-entry` could be used to make any function taking `Array<String>` or no arguments and return `Unit` as an entry point.

What is Kotlin/Native memory management model?

Kotlin/Native uses an automated memory management scheme that is similar to what Java or Swift provide.

Learn about the Kotlin/Native memory manager

How do I create a shared library?

Use the `-produce dynamic` compiler option or `binaries.sharedLib()` in your Gradle build file:

```
kotlin {
    iosArm64("mylib") {
        binaries.sharedLib()
    }
}
```

It produces a platform-specific shared object (`.so` on Linux, `.dylib` on macOS, and `.dll` on Windows targets) and a C language header, allowing the use of all public APIs available in your Kotlin/Native program from C/C++ code.

Complete the Kotlin/Native as a dynamic library tutorial

How do I create a static library or an object file?

Use the `-produce static` compiler option or `binaries.staticLib()` in your Gradle build file:

```
kotlin {
    iosArm64("mylib") {
        binaries.staticLib()
    }
}
```

It produces a platform-specific static object (`.a` library format) and a C language header, allowing you to use all the public APIs available in your Kotlin/Native program from C/C++ code.

How do I run Kotlin/Native behind a corporate proxy?

As Kotlin/Native needs to download a platform-specific toolchain, you need to specify `-Dhttp.proxyHost=xxx -Dhttp.proxyPort=xxx` as the compiler's or `gradlew` arguments, or set it via the `JAVA_OPTS` environment variable.

How do I specify a custom Objective-C prefix/name for my Kotlin framework?

Use the `-module-name` compiler option or matching Gradle DSL statement.

Kotlin

```
kotlin {
    iosArm64("myapp") {
        binaries.framework {
            freeCompilerArgs += listOf("-module-name", "TheName")
        }
    }
}
```

Groovy

```
kotlin {
    iosArm64("myapp") {
        binaries.framework {
            freeCompilerArgs += ["-module-name", "TheName"]
        }
    }
}
```

How do I rename the iOS framework?

The default name for an iOS framework is `<project name>.framework`. To set a custom name, use the `baseName` option. This will also set the module name.

```
kotlin {
    iosArm64("myapp") {
       binaries {
          framework {
              baseName = "TheName"
          }
       }
    }
}
```

How do I enable bitcode for my Kotlin framework?

Bitcode embedding was deprecated in Xcode 14 and removed in Xcode 15 for all Apple targets. The Kotlin/Native compiler does not support bitcode embedding since Kotlin 2.0.20.

If you're using earlier versions of Xcode but want to upgrade to Kotlin 2.0.20 or later versions, disable bitcode embedding in your Xcode projects.

How do I get better crash reports for iOS?

When an unhandled Kotlin exception reaches iOS code, crash reporting tools may show a vague report stating an internal Kotlin/Native issue instead of the actual line of code where the exception was thrown. This happens because the original Kotlin stack trace is lost by the time the crash is recorded.

You can work around this problem with third-party solutions like NSExceptionKt, which converts uncaught Kotlin exceptions into `NSException` instances so that your crash reporting tool captures the correct stack trace. It provides dedicated integrations for popular crash reporting tools:

- Bugsnag
- Firebase Crashlytics

How do I reference objects safely from different coroutines?

To safely access or update an object across multiple coroutines in Kotlin/Native, consider using concurrency-safe constructs, such as `@Volatile` and `AtomicReference`.

Use `@Volatile` to annotate a `var` property. This makes all reads and writes to the property's backing field atomic. In addition, writes become immediately visible to other threads. When another thread accesses this property, it observes not only the updated value but also the changes that happened before the update.

Alternatively, use AtomicReference, which supports atomic reads and updates. On Kotlin/Native, it wraps a volatile variable and performs atomic operations. Kotlin also provides a set of types for atomic operations tailored to specific data types. You can use `AtomicInt`, `AtomicLong`, `AtomicBoolean`, `AtomicArray`, as well as `AtomicIntArray` and `AtomicLongArray`.

For more information about access to shared mutable state, see the Coroutines documentation.

How can I compile my project with unreleased versions of Kotlin/Native?

First, please consider trying preview versions.

In case you need an even more recent development version, you can build Kotlin/Native from source code: clone the Kotlin repository and follow these steps.

Kotlin for Android

Android mobile development has been Kotlin-first since Google I/O in 2019.

Over 50% of professional Android developers use Kotlin as their primary language, while only 30% use Java as their main language. 70% of developers whose primary language is Kotlin say that Kotlin makes them more productive.

Using Kotlin for Android development, you can benefit from:

- **Less code combined with greater readability**. Spend less time writing your code and working to understand the code of others.
- **Fewer common errors**. Apps built with Kotlin are 20% less likely to crash based on Google's internal data.
- **Kotlin support in Jetpack libraries**. Jetpack Compose is Android's recommended modern toolkit for building native UI in Kotlin. KTX extensions add Kotlin language features, like coroutines, extension functions, lambdas, and named parameters to existing Android libraries.

- **Support for multiplatform development**. Kotlin Multiplatform allows development for not only Android but also iOS, backend, and web applications. Some Jetpack libraries are already multiplatform. Compose Multiplatform, JetBrains' declarative UI framework based on Kotlin and Jetpack Compose, makes it possible to share UIs across platforms – iOS, Android, desktop, and web.
- **Mature language and environment**. Since its creation in 2011, Kotlin has developed continuously, not only as a language but as a whole ecosystem with robust tooling. Now it's seamlessly integrated into Android Studio and is actively used by many companies for developing Android applications.
- **Interoperability with Java**. You can use Kotlin along with the Java programming language in your applications without needing to migrate all your code to Kotlin.
- **Easy learning**. Kotlin is very easy to learn, especially for Java developers.
- **Big community**. Kotlin has great support and many contributions from the community, which is growing all over the world. Over 95% of the top thousand Android apps use Kotlin.

Many startups and Fortune 500 companies have already developed Android applications using Kotlin, see the list on the Google website for Android developers.

To start using Kotlin for:

- Android development, read Google's documentation for developing Android apps with Kotlin.
- Developing cross-platform mobile applications, see Create an app with shared logic and native UI.

Introduction to library authors' guidelines

This guide contains a summary of best practices and ideas to consider when designing libraries.

To be effective, a library must achieve certain fundamental objectives. Specifically, it should:

- Define its problem domain and implement a set of related functional requirements that solve the problems it defined. For example, an HTTP client may aim to support all HTTP request types and understand the various headers, content types, and status codes.
- Meet the non-functional criteria appropriate to the problem domain. These typically involve performance, reliability, security, and usability. The relative importance of these criteria varies widely. For example, a library designed for batch processing may not require the same level of performance as one intended for day trading.

> The process of identifying and defining functional and non-functional requirements is a complex topic that has been extensively studied in software engineering. This guide does not cover these topics in depth, as they are beyond its scope.

The main focus of this guide is to explore the characteristics that a library must have to stay relevant and popular with its users. These characteristics include:

- **Minimize mental complexity:** All developers must consider the readability and maintainability of their code. It's crucial to reduce the mental effort required for others to read, understand, and use your APIs. Achieving this involves creating libraries that are clear, consistent, predictable, and easy to debug.
- **Backward compatibility:** When releasing a new version of an API, ensure the existing API remains operational. Clearly communicate and document any breaking changes well in advance. Provide a straightforward, clear, and gradual pathway for users to adopt the new API or design changes.
- **Informative documentation:** The documentation that accompanies the library needs to do more than repeat function and type declarations. It should be comprehensive and specifically tailored to the library's audience. It

should accurately reflect the needs and scenarios of various user roles, ensuring it provides essential information without being overly simplistic or complex. Always include clear examples, balancing explanatory text with practical code samples.

Additionally, **building your Kotlin library with multiplatform support** can broaden its applicability across projects targeting various environments. Designing APIs to work reliably in both shared and platform-specific code can improve the library's versatility and usability across all supported targets.

The following sections dig deeper into these characteristics, with practical advice on how you can provide the best possible experience to users of your libraries.

What's next

- Explore strategies for minimizing mental complexity in Minimizing mental complexity.
- Learn about maintaining backward compatibility in Backward compatibility.
- For an extensive overview on effective documentation practices, see Informative documentation.
- Discover best practices for building multiplatform libraries in Building Kotlin library for multiplatform.

Minimizing mental complexity overview

Users need to quickly and accurately build a mental model of your library's functions and abstractions before using it. The best way to achieve this is by minimizing the amount of complexity they encounter.

Strategies for minimizing mental complexity include:

- **Simplicity:** Strive for an API that provides the most functionality with the fewest components, reusing existing Kotlin types and structures to avoid redundancy. Where possible, create a small set of core abstractions and build additional functionality on top of them.
- **Readability:** Write the API in a declarative style to make the code's intent clear. Choose names for abstractions directly from the problem domain, unless it's absolutely necessary to invent new ones. Use basic data types for their intended purposes. Clearly distinguish between core and optional functionality.
- **Consistency:** Maintain a single, clear approach for every design aspect of your API. Use uniform naming conventions, error handling strategies, and patterns, whether they are object-oriented or functional.
- **Predictability:** Design your library to adhere to the 'principle of least surprise'. Ensure the default settings match the most common use cases, allowing users to accomplish their tasks with the simplest and shortest code. Allow extensions to your library only in clearly specified ways to maintain consistency and predictability.
- **Debuggability:** Ensure your library aids users in troubleshooting by facilitating the extraction of information and navigation through nested function calls. When exceptions are thrown, both the type and content of the exception should match the underlying issue, providing all necessary details to effectively diagnose and resolve problems. It should be possible to capture and output the state of domain objects, and to view any intermediate representations.
- **Testability:** Ensure that your library, as well as the code that uses it, can be easily tested.

The following sections give more detailed information on implementing these strategies in Kotlin.

Next step

To begin exploring these strategies in depth, you can start with learning about simplicity in the next section.

Proceed to the next part

Simplicity

The fewer concepts your users need to understand and the more explicitly these are communicated, the simpler their mental model is likely to be. This can be achieved by limiting the number of operations and abstractions in the API.

Ensure that the visibility of declarations in your library is set appropriately to keep internal implementation details out of the public API. Only APIs that are explicitly designed and documented for public use should be accessible to users.

In the next part of the guide, we'll discuss some guidelines for promoting simplicity.

Use explicit API mode

We recommend using the explicit API mode feature of the Kotlin compiler, which forces you to explicitly state your intentions when you're designing the API for your library.

With explicit API mode, you must:

- Add visibility modifiers to your declarations to make them public, instead of relying on the default public visibility. This ensures that you've considered what you're exposing as part of the public API.
- Define the types for all your public functions and properties to prevent unintended changes to your API from inferred types.

Reuse existing concepts

One way to limit the size of your API is to reuse existing types. For example, instead of creating a new type for durations, you can use `kotlin.time.Duration`. This approach not only streamlines development but also improves interoperability with other libraries.

Be careful when relying on types from third-party libraries or platform-specific types, as they can tie your library to these elements. In such cases, the costs may outweigh the benefits.

Reusing common types such as `String`, `Long`, `Pair`, and `Triple` can be effective, but this should not stop you from developing abstract data types if they better encapsulate domain-specific logic.

Define and build on top of core API

Another route to simplicity is to define a small conceptual model based around a limited set of core operations. Once the behavior of these operations is clearly documented, you can expand the API by developing new operations that build directly on or combine these core functions.

For example:

- In the Kotlin Flows API, common operations like `filter` and `map` are built on top of the `transform` operation.

- In the Kotlin Time API the `measureTime` function utilizes `TimeSource.Monotonic`.

While it's often beneficial to base additional operations on these core components, it's not always necessary. You may find opportunities to introduce optimized or platform-specific variations that expand the functionality or adapt more broadly to different inputs.

As long as users are able to solve non-trivial problems with the core operations and can refactor their solutions with additional operations without altering any behavior, the simplicity of the conceptual model is preserved.

Next step

In the next part of the guide, you'll learn about readability.

Proceed to the next part

Readability

Creating a readable API involves more than just writing clean code. It requires thoughtful design that simplifies integration and usage. This section explores how you can enhance API readability by structuring your library with composability in mind, utilizing domain-specific languages (DSLs) for concise and expressive setup, and using extension functions and properties for clear and maintainable code.

Prefer Explicit Composability

Libraries often provide advanced operators that allow for customization. For example, an operation might permit users to supply their own data structures, networking channels, timers, or lifecycle observers. However, introducing these customization options through additional function parameters can significantly increase the complexity of the API.

Instead of adding more parameters for customization, it's more effective to design an API where different behaviors can be composed together. For example, in the coroutine Flows API both buffering and conflation are implemented as separate functions. These can be chained together with more basic operations like `filter` and `map`, instead of each basic operation accepting parameters to control buffering and conflation.

Another example involves the Modifiers API in Jetpack Compose. This allows Composable components to accept a single `Modifier` parameter that handles common customization options, such as padding, sizing, and background color. This approach avoids the need for each Composable to accept separate parameters for these customizations, streamlining the API and reducing complexity.

```
Box(
    modifier = Modifier
        .padding(10.dp)
        .onClick { println("Box clicked!") }
        .fillMaxWidth()
        .fillMaxHeight()
        .verticalScroll(rememberScrollState())
        .horizontalScroll(rememberScrollState())
) {
    // Box content goes here
}
```

Use DSLs

A Kotlin library can significantly improve readability by providing a builder DSL. Using a DSL allows you to concisely repeat domain-specific data declarations. For example, consider the following sample from a Ktor-based server application:

```
fun Application.module() {
    install(ContentNegotiation) {
        json(Json {
            prettyPrint = true
            isLenient = true
        })
    }
    routing {
        post("/article") {
            call.respond<String>(HttpStatusCode.Created, ...)
        }
        get("/article/list") {
            call.respond<List<CreateArticle>>(...)
        }
        get("/article/{id}") {
            call.respond<Article>(...)
        }
    }
}
```

This sets up an application, installing the `ContentNegotiation` plugin configured to use Json serialization, and sets up routing so that the application responds to requests on various `/article` endpoints.

For a detailed description of creating DSLs, see Type-safe builders. The following points are worth noting in the context of creating libraries:

- The functions used in the DSL are builder functions, which take a lambda with receiver as the final parameter. This design allows these functions to be called without parentheses, making the syntax clearer. The lambda being passed can be used to configure the entity being created. In the example above the lambda passed to the `routing` function is used to configure the details of the routing.
- Factory functions that create instances of classes should have the same name as the return type and start with a capital letter. You can see this in the sample above with the creation of the `Json` instance. These functions may still take lambda parameters for configuration. For more information, see Coding conventions.
- As it's not possible to ensure that required properties have been set within the lambda supplied to a builder function at compile time, we recommend passing required values as function parameters.

Using DSLs to build objects not only improves readability but also improves backward compatibility, and simplifies the documentation process. For example, take the following function:

```
fun Json(prettyPrint: Boolean, isLenient: Boolean): Json
```

This function could replace the `Json{}` DSL builder. However, the DSL approach has noticeable benefits:

- Backward compatibility is easier to maintain with the DSL builder than with this function, as adding new configuration options simply means adding new properties (or in other examples, new functions), which is a backward-compatible change, unlike changing the parameter list of an existing function.
- It also makes creating and maintaining documentation easier. You can document each property separately at its point of declaration, instead of having to document many parameters of a function, all in one place.

Use extension functions and properties

We recommend using extension functions and properties to improve readability.

Classes and interfaces should define the core concept of a type. Additional functionality and information should be written as extension functions and properties. This makes it clear to the reader that the additional functionality can be implemented on top of the core concept, and additional information can be calculated from the data in the type.

For example, the `CharSequence` type (which `String` also implements) only contains the most basic information and operators to access its contents:

```
interface CharSequence {
    val length: Int
    operator fun get(index: Int): Char
    fun subSequence(startIndex: Int, endIndex: Int): CharSequence
}
```

Functionality commonly associated with strings is mostly defined as extension functions, which can all be implemented on top of the core concepts and basic APIs of the type:

```
inline fun CharSequence.isEmpty(): Boolean = length == 0
inline fun CharSequence.isNotEmpty(): Boolean = length > 0

inline fun CharSequence.trimStart(predicate: (Char) -> Boolean): CharSequence {
    for (index in this.indices)
        if (!predicate(this[index]))
            return subSequence(index, length)
    return ""
}
```

Consider declaring computed properties and normal methods as extensions. Only regular properties, overrides, and overloaded operators should be declared as members by default.

Avoid using the boolean type as an argument

Consider the following function:

```
fun doWork(optimizeForSpeed: Boolean) { ... }
```

If you were to provide this function in your API it could be invoked as:

```
doWork(true)
doWork(optimizeForSpeed=true)
```

In the first call it is impossible to infer what the boolean argument is for, unless you are reading the code in an IDE with Parameter Name Hints enabled. Using named arguments does clarify the intention, but there is no way to force your users to adopt this style. Consequently, to improve readability, your code should not use boolean types as arguments.

Alternatively, the API could create a separate function specifically for the task controlled by the boolean argument. This function should have a descriptive name that indicates what it does.

For example, the following extensions are available on the `Iterable` interface:

```
fun <T, R> Iterable<T>.map(transform: (T) -> R): List<R>
fun <T, R : Any> Iterable<T>.mapNotNull(
    transform: (T) -> R?
): List<R>
```

Instead of the single method:

```
fun <T, R> Iterable<T>.map(
    includeNullResults: Boolean = true,
    transform: (T) -> R
): List<R>
```

Another good approach could be to use an `enum` class to define different operation modes. This approach is useful if there are several modes of operation, or if you expect these modes to change over time.

Use numeric types appropriately

Kotlin defines a set of numeric types that you may use as part of your API. Here's how to use them appropriately:

- Use the `Int`, `Long` and `Double` types as arithmetic types. They represent values with which calculations are performed.
- Avoid using arithmetic types for non-arithmetic entities. For example, if you represent an ID as a `Long`, your users might be tempted to compare IDs, on the assumption they are assigned in order. This could lead to unreliable or meaningless results, or create dependencies on implementations that could change without warning. A better strategy is to define a specialized class for the ID abstraction. You could use Inline value classes to build such abstractions without affecting performance. See the `Duration` class for an example.
- The `Byte`, `Float` and `Short` types are memory layout types. They are used to restrict the amount of memory available for storing a value, such as in caches or when transmitting data over a network. These types should only be used when the underlying data reliably fits within that type, and calculations are not required.
- The unsigned integer types `UByte`, `UShort`, `UInt` and `ULong` should be used to utilize the full range of positive values available in a given format. They are suitable for scenarios requiring values beyond the range of signed types or for interoperability with native libraries. However, avoid using them in situations where the domain only requires non-negative integers.

Next step

In the next part of the guide, you'll learn about consistency.

Proceed to the next part

Consistency

Consistency is crucial in API design to ensure ease of use. By maintaining consistent parameter order, naming conventions, and error handling mechanisms, your library will be more intuitive and reliable for users. Following these best practices helps avoid confusion and misuse, leading to a better developer experience and more robust applications.

Preserve parameter order, naming and usage

When designing a library, maintain consistency in the ordering of arguments, the naming scheme, and the use of overloading. For example, if one of your existing methods has `offset` and `length` parameters, you should not switch to alternatives like `startIndex` and `endIndex` for a new method unless there is a compelling reason.

Overloaded functions provided by the library should behave identically. Users expect the behavior to remain consistent when they change the type of a value they pass into your library. For example, these calls all create identical instances, as the input is semantically the same:

```
BigDecimal(200)
BigDecimal(200L)
BigDecimal("200")
```

Avoid mixing parameter names like `startIndex` and `stopIndex` with synonyms like `beginIndex` and `endIndex`. Similarly, choose one term for values in collections, such as `element`, `item`, `entry`, or `entity`, and stick with it.

Name related methods consistently and predictably. As an example, the Kotlin standard library contains pairs like `first` and `firstOrNull`, `single` or `singleOrNull`. These pairs clearly indicate that some might return `null` while others might throw an exception. Parameters should be declared from the general to the specific, so essential inputs appear first and optional inputs last. For example, in `CharSequence.findAnyOf` the `strings` collection goes first, followed by the `startIndex`, and finally the `ignoreCase` flag.

Consider a library managing employee records, and provides the following API to search for employees:

```
fun findStaffBySeniority(
    startIndex: Int,
    minYearsServiceExclusive: Int
): List<Employee>

fun findStaffByAge(
    minAgeInclusive: Int,
    startIndex: Int
): List<Employee>
```

This API would be extremely hard to use correctly. There are multiple parameters of the same type presented in an inconsistent order, and used in an inconsistent way. Users of your library will likely make incorrect assumptions about new functions based on their experience with existing ones.

Use Object-Oriented design for data and state

Kotlin supports both the Object-Oriented and Functional programming styles. Use classes to represent data and state in your API. When the data and state is hierarchical, consider using inheritance.

If all the state required can be passed as parameters, prefer using top-level functions. When calls to these functions will be chained, consider writing them as extension functions to improve readability.

Choose the appropriate error handling mechanism

Kotlin provides several mechanisms for error handling. Your API can throw an exception, return a `null` value, use a custom result type, or use the built-in `Result` type. Ensure that your library uses these options consistently and appropriately.

When data cannot be fetched or calculated, use a nullable return type and return `null` to indicate missing data. In other cases, throw an exception or return a `Result` type.

Consider providing overloads of functions, where one throws an exception, while the other wraps it in a result type instead. In these cases, use the `Catching` suffix to indicate that exceptions are caught in the function. For example, the standard library has the `run` and `runCatching` functions using this convention, and the coroutines library has `receive` and `receiveCatching` methods for channels.

Avoid using exceptions for normal control flow. Design your API to allow for condition checks before attempting operations, thus preventing unnecessary error handling. Command / Query Separation is a useful pattern that can be applied here.

Maintain conventions and quality

The final aspect of consistency relates, not to the design of the library itself, but to maintaining a high level of quality.

You should use automated tools (linters) for static analysis to ensure your code follows both general Kotlin conventions and project-specific conventions.

A Kotlin library should also provide a suite of unit and integration tests covering all documented behaviors of all the API entry points. Tests should include a wide range of inputs, especially known boundary and edge cases. Any untested behavior should be assumed to be (at best) unreliable.

Use this suite of tests during development to verify that changes do not break existing behavior. Run these tests on every release as part of a standardized build and release pipeline. Tools like Kover can be integrated into your build process to measure coverage and generate reports.

Next step

In the next part of the guide, you'll learn about predictability.

Proceed to the next part

Predictability

To design a robust and user-friendly Kotlin library, it's essential to anticipate common use cases, allow for extensibility, and enforce proper usage. Following best practices for default settings, error handling, and state management ensures a seamless experience for users while maintaining the integrity and quality of the library.

Do the right thing by default

Your library should anticipate the "happy path" for each use case, and provide default settings accordingly. Users should not need to supply default values for the library to function correctly.

For example, when using the Ktor `HttpClient` the most common use case is sending a GET request to the server. This can be accomplished using the code below, where only essential information needs to be specified:

```
val client = HttpClient(CIO)
val response: HttpResponse = client.get("https://ktor.io/")
```

It's not necessary to provide values for mandatory HTTP headers or custom event handlers for possible status codes in the response.

If there is no obvious "happy path" for a use case or if a parameter should have a default value but there is no non-contentious option, it likely indicates a flaw in the requirement analysis.

Allow opportunities for extension

When the correct choice cannot be anticipated, allow users to specify their preferred approach. Your library should also let the user supply their own approach or use a third-party extension.

For example, with the Ktor `HttpClient`, users are encouraged to install support for content negotiation when configuring the client, and to specify their preferred serialization formats:

```
val client = HttpClient(CIO) {
    install(ContentNegotiation) {
        json(Json {
            prettyPrint = true
            isLenient = true
        })
    }
}
```

Users can choose which plugins to install or create their own using the separate API for defining client plugins.

Additionally, users can define extension functions and properties for types in the library. As a library author, you can make this easier by designing with extensions in mind, and ensuring your library's types have clear core concepts.

Prevent unwanted and invalid extensions

Users should not be able to extend your library in ways that violate its original design or are impossible within the rules of the problem domain.

For example, when marshaling data to and from JSON, only six types are supported in the output format: `object`, `array`, `number`, `string`, `boolean`, and `null`.

If you create an open class or interface called `JsonElement`, users could create invalid derived types, like `JsonDate`. Instead, you can make the `JsonElement` interface sealed and provide an implementation for each type:

```
sealed interface JsonElement

class JsonNumber(val value: Number) : JsonElement
class JsonObject(val values: Map<String, JsonElement>) : JsonElement
class JsonArray(val values: List<JsonElement>) : JsonElement
class JsonBoolean(val value: Boolean) : JsonElement
class JsonString(val value: String) : JsonElement
object JsonNull : JsonElement
```

Sealed types also enable the compiler to ensure your `when` expressions are exhaustive, without requiring an `else` statement, improving readability and consistency.

Avoid exposing mutable state

When managing multiple values, your API should, whenever possible, accept and/or return read-only collections. Mutable collections are not thread-safe and introduce complexity and unpredictability into your library.

For example, if a user modifies a mutable collection returned from an API entry point, it will be unclear whether they are modifying the implementation's structure or a copy. Similarly, if users can modify the values within a collection after passing it to a library, it will be unclear whether this affects the implementation.

Since arrays are mutable collections, avoid using them in your API. If arrays must be used, make defensive copies before sharing data with users. This ensures your data structures remain unmodified.

This policy of making defensive copies is automatically performed by the compiler for `vararg` arguments. When using the spread operator to pass an existing array where a `vararg` argument is expected, a copy of your array is automatically created.

This behavior is demonstrated in the following example:

```
fun main() {
    fun demo(vararg input: String): Array<out String> = input

    val originalArray = arrayOf("one", "two", "three", "four")
    val newArray = demo(*originalArray)

    originalArray[1] = "ten"

    //prints "one, ten, three, four"
    println(originalArray.joinToString())

    //prints "one, two, three, four"
    println(newArray.joinToString())
}
```

Validate inputs and state

Ensure that your library is used correctly by validating inputs and existing state before implementation proceeds. Use the `require` function to verify inputs and the `check` function to validate existing state.

The `require` function throws an `IllegalArgumentException` if its condition is `false`, causing the function to fail immediately with an appropriate error message:

```
fun saveUser(username: String, password: String) {
    require(username.isNotBlank()) { "Username should not be blank" }
    require(username.all { it.isLetterOrDigit() }) {
        "Username can only contain letters and digits, was: $username"
    }
    require(password.isNotBlank()) { "Password should not be blank" }
    require(password.length >= 7) {
        "Password must contain at least 7 characters"
    }

    /* Implementation can proceed */
}
```

Error messages should include relevant inputs to help users determine the cause of the failure, as shown above by the error message for usernames that contain invalid characters, which includes the incorrect username. An exception to this practice is when including a value in the error message could reveal information that might be

used maliciously as part of a security exploit, which is why the error message for the password's length does not include the password input.

Similarly, the `check` function throws an `IllegalStateException` if its condition is `false`. Use this function to verify the state of an instance, as shown in the example below:

```
class ShoppingCart {
    private val contents = mutableListOf<Item>()

    fun addItem(item: Item) {
        contents.add(item)
    }

    fun purchase(): Amount {
        check(contents.isNotEmpty()) {
            "Cannot purchase an empty cart"
        }
        // Calculate and return amount
    }
}
```

Next step

In the next part of the guide, you'll learn about debuggability.

Proceed to the next part

Debuggability

Users of your library will build on its functionality, and the features they build will contain errors that need to be identified and resolved. This error resolution process might be conducted within a debugger during development or using logging and observability tools in production. Your library can follow these best practices to make debugging it easier.

Provide a toString method for stateful types

For every type that contains state, provide a meaningful `toString` implementation. This implementation should return an intelligible representation of the instance's current content, even for internal types.

Since `toString` representations of types are often written to logs, consider security when implementing this method and avoid returning sensitive user data.

Ensure the format used to describe the state is as consistent as possible across the different types in your library. This format should be explicitly described and thoroughly documented when it is part of a contract implemented by your API. The output from your `toString` methods may support parsing, for example in automated test suites.

For example, consider the following types from a library supporting service subscriptions:

```
enum class SubscriptionResultReason {
    Success, InsufficientFunds, IncompatibleAccount
}

class SubscriptionResult(
    val result: Boolean,
    val reason: SubscriptionResultReason,
    val description: String
)
```

Without a `toString` method, printing a `SubscriptionResult` instance is not very useful:

```
fun main() {
    val result = SubscriptionResult(
       false,
       IncompatibleAccount,
       "Users account does not support this type of subscription"
    )

    //prints 'org.example.SubscriptionResult@13221655'
    println(result)
}
```

Nor is the information readily displayed in the debugger:

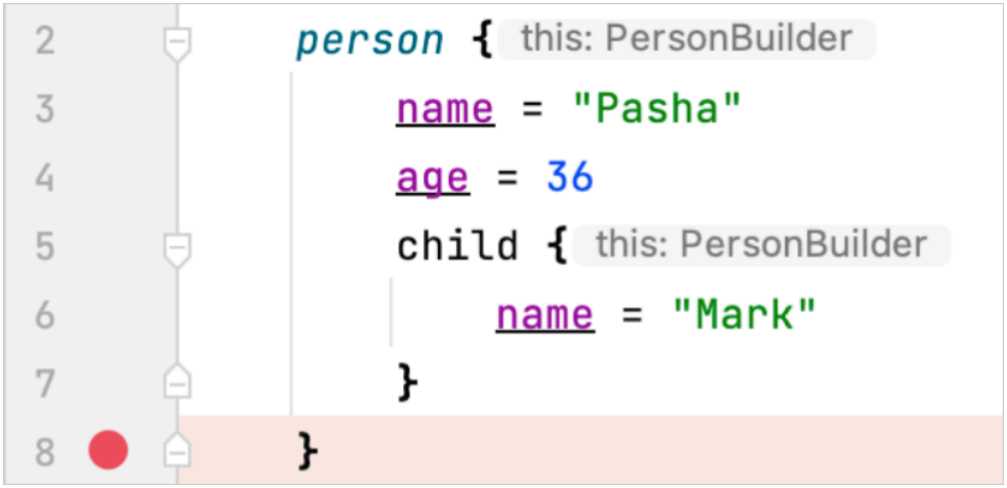
Adding a simple `toString` implementation improves the output significantly in both cases:

```
//prints 'Subscription failed (reason=IncompatibleAccount, description="Users
// account does not support this type of subscription")'
override fun toString(): String {
    val resultText = if(result) "succeeded" else "failed"
    return "Subscription $resultText (reason=$reason, description=\"$description\")"
}
```

While it might be tempting to use data classes to gain a `toString` method automatically, it's not recommended for backward compatibility reasons. Data classes are discussed in more detail in the Avoid using data classes in your API section.

Note that the state described in the `toString` method does not need to be information from the problem domain. It can relate to the status of ongoing requests (as in the example above), the health of connections to external services, or intermediate state within an ongoing operation.

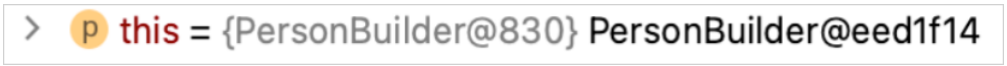
For example, consider the following builder type:



```
class Person(
    val name: String?,
    val age: Int?,
    val children: List<Person>
) {
    override fun toString(): String =
        "Person(name=$name, age=$age, children=$children)"
}

class PersonBuilder {
    var name: String? = null
    var age: Int? = null
    val children = arrayListOf<Person>()

    fun child(personBuilder: PersonBuilder.() -> Unit = {}) {
       children.add(person(personBuilder))
    }
    fun build(): Person = Person(name, age, children)
}



fun person(personBuilder: PersonBuilder.() -> Unit = {}): Person =
    PersonBuilder().apply(personBuilder).build()
```

This is how you would use this type:

Using the builder type example

If you halt the code at the breakpoint displayed on the image above, the information displayed will not be helpful:

Adding a simple `toString` implementation results in a much more helpful output:

```
override fun toString(): String =
    "PersonBuilder(name=$name, age=$age, children=$children)"
```

With this addition, the debugger shows:

This way, you can immediately see which fields are set and which are not.

Adopt and document a policy for handling exceptions

As discussed in the Choose appropriate error handling mechanism section, there are occasions when it's appropriate for your library to throw an exception to signal an error. You may create your own exception types for this purpose.

Libraries that abstract and simplify low-level APIs will also need to handle exceptions thrown by their dependencies. A library might choose to suppress the exception, pass it on as it is, convert it to a different type of an exception, or signal the error to users in a different way.

Any of these options could be valid, depending on the context. For example:

- If a user adopts library A purely for the convenience of simplifying library B, it may be appropriate for library A to rethrow any exceptions generated by library B without modification.
- If library A adopts library B purely as an internal implementation detail, then library-specific exceptions thrown by library B should never be exposed to users of library A.

You must adopt and document a consistent approach to exception handling so users can make productive use of your library. This is especially important for debugging. Users of your library should be able to recognise, in the debugger and in logs, when an exception has originated from your library.

The type of the exception should indicate the type of the error, and the data in the exception should help the user locate the root cause of the issue. A common pattern is to wrap a low-level exception in a library-specific one, with the original exception accessible as the `cause`.

Experimental

Support coroutine stack trace recovery for custom exceptions

You can add support for coroutine stack trace recovery to custom exception types in your library to make them easier to debug. This improves your library's support for the `kotlinx.coroutines` library and other asynchronous runtimes in Kotlin.

When a coroutine receives an exception from another coroutine through a suspending function, stack trace recovery creates a copy of the exception with the stack frames that lead to that function call.

The `kotlinx.coroutines` library performs stack trace recovery automatically for exceptions with constructors that take only an exception message, a cause, both, or no arguments. If an exception type in your library requires additional constructor arguments, such as a line number or an error code, implement the `StackTraceRecoverable` interface.

To implement the interface, override the `copyForStackTraceRecovery()` function. In the override, return a new exception instance for stack trace recovery, or `null` if you don't want the `kotlinx.coroutines` library to copy the exception.

The `StackTraceRecoverable` interface is part of the Kotlin standard library, so implementing it doesn't add a dependency on the `kotlinx.coroutines` library.

Here's an example of a custom exception that preserves a `line` property when it creates a new instance for stack trace recovery:

```
import kotlin.coroutines.ExperimentalStdlibCoroutineSupportApi
import kotlin.coroutines.debug.StackTraceRecoverable

@OptIn(ExperimentalStdlibCoroutineSupportApi::class)
class FileEditException
// The implementation requires a private constructor
// to pass the cause to the IllegalStateException constructor
private constructor(
    val line: Int,
    private val detail: String,
    cause: Throwable?,
) : IllegalStateException("When editing line $line: $detail", cause),
    // Implements StackTraceRecoverable for stack trace recovery
    StackTraceRecoverable<FileEditException> {

    constructor(line: Int, detail: String) : this(line, detail, null)

    // Copies the line number and message details
    override fun copyForStackTraceRecovery(): FileEditException =
        FileEditException(line, detail, this)
    }

fun main() {
    val original = FileEditException(15, "Unexpected token")

    // Normally, you don't need to call this function directly unless you're testing its behavior
    // The kotlinx.coroutines library invokes it automatically during stack trace recovery
    val copy = original.copyForStackTraceRecovery()

    println(copy.message)
    // When editing line 15: Unexpected token

    println(copy.cause == original)
    // true
}
```

Next step

In the next part of the guide, you'll learn about testability.

Proceed to the next part

Testability

In addition to testing your library, ensure that code using your library is also testable.

Avoid global state and stateful top-level functions

Your library should not rely on state in global variables or provide stateful top-level functions as part of its public API. Such variables and functions make testing code that uses the library difficult, as tests need to find ways to control these global values.

For example, a library might define a globally accessible function that provides access to the current time:

```
val instant: Instant = Clock.now()
println(instant)
```

Any code using this API will be difficult to test, as the call to the `now()` function will always return the real current time, while in tests it's often desirable to return fake values instead.

To enable testability, the `kotlinx-datetime` library has an API that lets users get a `Clock` instance, and then use that to get the current time:

```
val clock: Clock = Clock.System
val instant: Instant = clock.now()
println(instant)
```

This allows users of a library to inject a `Clock` instance into their own classes, and replace the real implementation with a fake one during tests.

What's next

If you haven't already, consider checking out these pages:

- Learn about maintaining backward compatibility in the Backward compatibility page.
- For an extensive overview on effective documentation practices, see Informative Documentation.

Backward compatibility guidelines for library authors

The most common motivation for creating a library is to expose functionality to a wider community. This community might be a single team, a company, a particular industry, or a technology platform. In every case backward compatibility will be an important consideration. The wider the community the more important backward compatibility becomes, since you will be less aware of who your users are and what constraints they work within.

Backward compatibility is not a single term, but can be defined at the binary, source and behavioral levels. More information about these types is provided in this section.

Note that:

- It is possible to break binary compatibility without breaking source compatibility, as well as the other way around.
- It is desirable but very difficult to guarantee source compatibility. As a library author, you must consider every possible way a function or type could be invoked or instantiated by a user of the library. Source compatibility is typically an aspiration, not a promise.

The rest of this section describes actions you can take, and tools you can use to help ensure the different kinds of compatibility.

Compatibility types

Binary compatibility means that a new version of a library can replace a previously compiled version of the library. Any software that was compiled against the previous version of the library should continue to work correctly.

> Learn more about binary compatibility in the Binary compatibility validator's README or from the Evolving Java-based APIs document.

Source compatibility means that a new version of a library can replace a previous one without modifying any of the source code that uses the library. However, the outputs from compiling this client code may no longer be compatible with the outputs from compiling the library, so the client code must be rebuilt against the new version of the library to guarantee compatibility.

Behavioral compatibility means that a new version of the library does not modify the existing functionality, except to fix bugs. The same features are involved and they have the same semantics.

Choose compatible language and API versions

When publishing a library, consider both its compile-time and runtime compatibility:

- The language version determines which Kotlin compiler versions can compile code that directly uses your library.
- The API version determines the minimum Kotlin standard library version required at runtime.

In most cases, use the same language and API version.

Setting a newer language version for your library requires your consumers to use a newer Kotlin compiler version:

- On the JVM, consumers can use any compiler version from the previous language version onwards. For example, if your library uses language version 2.2, consumers can use compiler version 2.1.x, 2.2.x or later.
- On other platforms, consumers can use a compiler version the same as the library's configured language version or any later version. This requirement can delay consumers from upgrading to newer versions of your library if they can't upgrade their compiler immediately.

Your consumers also need to provide a Kotlin standard library version that is at least as new as your library's configured API version. This can make upgrades more difficult when the runtime environment is outside their control and it's hard to provide a newer standard library version, such as in Gradle or IDE plugins.

Choose the language and API versions that best fit your library. Newer versions let you adopt the latest Kotlin features, while older versions help more consumers use your library. The best choice depends on your library's use case and the number of consumers who rely on it.

Use the Binary compatibility validator

JetBrains provides a Binary compatibility validator tool, which can be used to ensure binary compatibility across different versions of your API.

This tool is implemented as a Gradle plugin, and it adds two tasks to your build:

- The `apiDump` task creates a human-readable `.api` file that describes your API.
- The `apiCheck` task compares the saved description of the API to classes compiled in the current build.

The `apiCheck` task is invoked at build time by the standard Gradle `check` task. When compatibility is broken, the build fails. At that point, you should run the `apiDump` task manually and compare the differences between the old and new versions. If you are satisfied with the changes, you can update the existing `.api` file, which resides within your VCS.

The validator has experimental support for validating KLibs produced by multiplatform libraries.

Experimental

Binary compatibility validation in the Kotlin Gradle plugin

Starting with version 2.2.0, the Kotlin Gradle plugin supports binary compatibility validation. For more information, see Binary compatibility validation in the Kotlin Gradle plugin.

Specify return types explicitly

As discussed in the Kotlin coding guidelines, you should always explicitly specify function return types and property types within the API. See also the section about Explicit API mode.

Consider the following example, where the library author creates a `JsonDeserializer` and, for convenience, uses an extension function to associate it with the `Int` type:

```
class JsonDeserializer<T>(private val fromJson: (String) -> T) {
    fun deserialize(input: String): T {
        ...
    }
}

fun Int.defaultDeserializer() = JsonDeserializer { ... }
```

Let's say the author replaces this implementation with a `JsonOrXmlDeserializer`:

```
class JsonOrXmlDeserializer<T>(
    private val fromJson: (String) -> T,
    private val fromXML: (String) -> T
) {
    fun deserialize(input: String): T {
        ...
    }
}

fun Int.defaultDeserializer() = JsonOrXmlDeserializer({ ... }, { ... })
```

Existing functionality will continue to work, with the added ability to deserialize XML. However, this breaks binary compatibility.

Avoid adding arguments to existing API functions

Adding non-default arguments to a public API breaks both binary and source compatibility, as users are required to provide more information on an invocation than before. However, even adding default arguments can break compatibility.

For example, imagine you have the following function in `lib.kt`:

```
fun fib() = … // Returns zero
```

And the following function in `client.kt`:

```
fun main() {
    println(fib()) // Prints zero
}
```

Compiling these two files on the JVM would produce the outputs `LibKt.class` and `ClientKt.class`.

Let's say you reimplement and compile the `fib` function to represent the Fibonacci sequence, such that `fib(3)` returns 2, `fib(4)` returns 3, and so on. You add a parameter but give it a default value of zero to preserve the existing behavior:

```
fun fib(input: Int = 0) = … // Returns Fibonacci member
```

You now need to recompile the file `lib.kt`. You might expect that the `client.kt` file does not need to be recompiled, and the associated class file can be invoked as follows:

```
$ kotlin ClientKt.class
```

But if you try this, a `NoSuchMethodError` occurs:

```
Exception in thread "main" java.lang.NoSuchMethodError: 'int LibKt.fib()'
       at LibKt.main(fib.kt:2)
       at LibKt.main(fib.kt)
       …
```

This is because the signature of the method changed in the bytecode generated by the Kotlin/JVM compiler, breaking binary compatibility.

Source compatibility, however, is preserved. If you recompile both files, the program will run as before.

Use overloads to preserve binary compatibility

When adding optional parameters to published APIs, you can use the Experimental `@IntroducedAt` annotation to preserve binary compatibility.

Add the annotation to each new optional parameter with the version in which it was introduced. For example:

```
@OptIn(ExperimentalVersionOverloading::class)
fun fib(@IntroducedAt("1.1") input: Int = 0) = …
```

The compiler uses this information to generate the corresponding hidden overloads.

When writing Kotlin code for the JVM, you can also use the `@JvmOverloads` annotation on functions with default arguments to generate overloads.

> The `@JvmOverloads` annotation doesn't preserve binary compatibility for Kotlin callers. Instead, use the `@IntroducedAt` annotation or add manual overloads when changing published APIs.

You can also create overloads manually instead of using a single function with default arguments. For example, if you want the `fib()` function to accept an `Int` parameter, create a separate overload:

```
fun fib() = …
fun fib(input: Int) = …
```

Avoid widening or narrowing return types

When evolving an API, it is common to want to widen or narrow the return type of a function. For example, in an upcoming version of your API, you might want to switch a return type from `List` to `Collection` or from `Collection` to `List`.

You might want to narrow the type to `List` to meet user requests for indexing support. Conversely, you might want to widen the type to `Collection` because you realize the data you are working with has no natural order.

It is easy to see why widening a return type breaks compatibility. For example, converting from `List` to `Collection` breaks all the code that uses indexing.

You might think that narrowing a return type, for example from `Collection` to `List` would preserve compatibility. Unfortunately, while source compatibility is preserved, binary compatibility is broken.

Let's say you have a demo function in the file `Library.kt`:

```
public fun demo(): Number = 3
```

And a client for the function in `Client.kt`:

```
fun main() {
    println(demo()) // Prints 3
}
```

Let's imagine a scenario where you change the return type of demo and only recompile `Library.kt`:

```
fun demo(): Int = 3
```

When you rerun the client, the following error will occur (on the JVM):

```
Exception in thread "main" java.lang.NoSuchMethodError: 'java.lang.Number Library.demo()'
        at ClientKt.main(call.kt:2)
        at ClientKt.main(call.kt)
        …
```

This happens because of the following instruction in the bytecode generated from the `main` method:

```
0: invokestatic  #12 // Method Library.demo:()Ljava/lang/Number;
```

The JVM is trying to invoke a static method called demo which returns a `Number`. However, as this method no longer exists, you have broken binary compatibility.

Avoid using data classes in your API

In regular development, the strength of data classes is the extra functions that are generated for you. In API design, this strength becomes a weakness.

For example, let's say you use the following data class in your API:

```
data class User(
    val name: String,
    val email: String
)
```

Later, you might want to add a property called `active`:

```
data class User(
    val name: String,
    val email: String,
    val active: Boolean = true
)
```

This would break binary compatibility in two ways. Firstly, the generated constructor will have a different signature. Additionally, the signature of the generated `copy` method changes.

The original signature (on Kotlin/JVM) would be:

```
public final User copy(java.lang.String, java.lang.String)
```

After adding the `active` property, the signature becomes:

```
public final User copy(java.lang.String, java.lang.String, boolean)
```

As with the constructor, this breaks binary compatibility.

It's possible to work around these issues by manually writing a secondary constructor and overriding the `copy` method. However, the effort involved negates the convenience of using a data class.

Another issue with data classes is that changing the order of constructor arguments affects the generated `componentX` methods, which are used for destructuring. Even if it does not break binary compatibility, changing the order will definitely break behavioral compatibility.

Avoid changing annotation targets

When you expose an annotation, avoid changing its allowed targets after publishing your library. Changing them can affect how the same annotation is applied when users recompile existing code.

For example, if an annotation declares only `AnnotationTarget.FIELD`, an unqualified annotation on a property applies to its backing field:

```
@Target(AnnotationTarget.FIELD)
annotation class Example

class User {
    @Example
    val name: String = ""
}
```

If you later add `AnnotationTarget.PROPERTY`, the same unqualified annotation is applied to the property instead:

```
@Target(AnnotationTarget.PROPERTY, AnnotationTarget.FIELD)
annotation class Example

class User {
    @Example
    val name: String = ""
}
```

This happens because the Kotlin compiler chooses the `property` target before the `field` target. The `field` target is used only when `property` isn't applicable.

This can break compatibility for tools and frameworks that expect the annotation on a specific generated element. In particular, the `property` target isn't visible to Java. If Java reflection or Java annotation processors need to find the annotation on the backing field, users must specify the `field` use-site target explicitly:

```
class User {
    @field:Example
    val name: String = ""
}
```

Considerations for using the PublishedApi annotation

Kotlin allows inline functions to be a part of your library's API. Calls to these functions will be inlined into the client code written by your users. This can introduce compatibility issues, so these functions are not allowed to call non-public-API declarations.

If you need to call an internal API of your library from an inlined public function, you can do so by annotating it with `@PublishedApi`. This makes the internal declaration effectively public, as references to it will end up in compiled client code. Therefore, it must be treated the same as public declarations when making changes to it, as these changes might affect binary compatibility.

Evolve APIs pragmatically

There are cases where you need to make breaking changes to your library's API over time by removing or changing an existing declaration. In this section, we'll discuss how to handle such cases pragmatically.

When users upgrade to a newer version of your library, they should not end up with unresolved references to your library's APIs in their project's source code. Instead of immediately removing something from your library's public API, you should follow a deprecation cycle. This way, you give your users time to migrate to an alternative.

Use the `@Deprecated` annotation on the old declaration to indicate that it's being replaced. The parameters of this annotation provide important details about the deprecation:

- The `message` should explain what's being changed and why.
- The `replaceWith` parameter should be used where possible to provide automatic migration to a new API.
- The deprecation's level should be used to deprecate the API gradually. For more information, see the Deprecated page of the Kotlin documentation.

Generally, a deprecation should first produce a warning, then an error, and then hide the declaration. This process should occur across several minor releases, giving users time to make any required changes in their projects. Breaking changes, such as removing an API, should happen only in major releases. A library may adopt different versioning and deprecation strategies, but this must be communicated to its users to set the correct expectations.

You can learn more in the Kotlin Evolution principles document or in the Evolving your Kotlin API painlessly for clients talk by Leonid Startsev from KotlinConf 2023.

Use the RequiresOptIn mechanism

The Kotlin standard library provides the opt-in mechanism to require explicit consent from users before they use a part of your API. This is based on creating marker annotations, which are themselves annotated with

`@RequiresOptIn`. You should use this mechanism to manage expectations concerning source and behavioral compatibility, especially when introducing new APIs to your library.

If you choose to use this mechanism, we recommend following these best practices:

- Use the opt-in mechanism to provide different guarantees to different parts of the API. For example, you could mark features as *Preview*, *Experimental*, and *Delicate*. Each category should be clearly explained in your documentation and in KDoc comments, with appropriate warning messages.
- If your library uses an experimental API, propagate the annotation to your own users. This ensures your users are aware that you have dependencies which are still evolving.
- Avoid using the opt-in mechanism to deprecate already existing declarations in your library. Use `@Deprecated` instead, as described in the Evolve APIs pragmatically section.

- Explore strategies for minimizing mental complexity in the Minimizing mental complexity page.
- For an extensive overview on effective documentation practices, see Informative documentation.

Best practices for library authors to create informative documentation

The documentation you provide for your library is crucial. It can determine whether users investigate your library, adopt it within their projects, and persevere when they encounter difficulties. Developers today have unprecedented choice between languages, libraries, frameworks and platforms. Therefore, it is essential to engage and inform your users; otherwise they may pursue other options.

In the earliest versions of your library, feedback from users will be scarce. Fortunately, creating and refining documentation can serve as a feedback loop to greatly increase the quality of your project. As such, creating documentation should never be seen as a burden, and should not be pushed down the list of priorities when creating a library.

Effective documentation not only informs users but also drives the development and refinement of your library. Here are several key ways documentation can guide your development process:

- You should be able to explain, in a couple of paragraphs, what your library does, who will benefit from using it, and what the advantages are over alternative approaches. If you cannot do this, reconsider the scope and objectives of your project.
- You should be able to create a "Getting Started" guide that can get a potential user up and running as quickly as possible. What counts as *quickly* will depend on the problem domain, but you can compare against similar libraries on other platforms. The guide should hook the user into a feedback loop that keeps getting easier and faster while always producing reliable results. Creating this guide will help you identify sudden increases in complexity (cliff edges) that could hinder the user's progress.
- The act of documenting a function forces you to consider all the edge cases, such as valid ranges of inputs, exceptions that might be thrown, and how performance degrades as the work increases. This can often lead to improvements in the function signatures and the underlying implementation.
- If the code required to initialize your library always eclipses the code required to accomplish a task, rethink your configuration options.

- If you cannot create clear examples of performing basic tasks with standard options, consider optimizing your API for day-to-day use.
- If you cannot demonstrate how to test your library without using real data sources and online services, consider providing test doubles for components that access the network (and the outside world in general).

The sooner you provide documentation for your library, the sooner it can be tested by real-world users. Feedback from these tests can then be used to improve the design.

Provide comprehensive documentation

Your library must provide sufficient documentation to let users adopt it with minimum effort. This documentation should include:

- A Getting Started guide
- An in-depth description of the API
- Longer examples for common use cases (also known as recipes)
- Links to resources such as blogs, articles, webinars, and conference talks

The Getting Started guide should cover how your library integrates with the supported build systems. It should include a brief description of the most commonly used entities, with small examples of how they are used. At each point where the library interacts with the outside world, specify the necessary steps to configure the environment and how to verify that these steps have been completed successfully. State explicitly if no steps are necessary.

If possible, provide separate versions of the documentation for each version of the library you support. This prevents users from viewing information that is either outdated or too recent. When this is not possible, clearly mark sections of the documentation that relate to parts of the API that have been redesigned.

Create personas for your users

Creating and evaluating documentation without a clear understanding of the intended audience is challenging. Defining multiple personas for the types of users who will read your documentation can be helpful.

Consider the user's constraints, such as the pre-existing software stack within which they need to operate. Reviewers of the documentation can adopt these personas to make their conclusions more meaningful.

When you lack specific information about your users, it's best to be pessimistic. For example, do not assume expertise in the latest or most advanced features of Kotlin. Keep your code examples as simple as possible.

Personas are especially useful when real-world users cannot be consulted due to time, budgetary constraints, or confidentiality agreements. Over time, as you gain a better understanding of your users, refine the personas to match their needs more accurately.

Document by example whenever possible

Documentation by example is one of the most cost-effective ways to explain basic concepts to users. Whenever possible, provide simple and clear code examples that help to explain or demonstrate the current topic or concept being discussed.

The KDoc documentation format lets you use inline markup using Markdown in your documentation comments. Use inline code snippets in comments to showcase the usage of an API. For an example, see the source code and rendered documentation of the test dispatchers of the coroutines library.

Providing examples like this can avoid the need to write lengthy descriptions of expected inputs, possible outputs, and failure modes. However, the context for each example needs to be clear, as do the circumstances in which it is relevant. Simply providing a folder of uncommented sample programs does not qualify as documentation.

Thoroughly document your API

Every supported API entry point should be documented using KDoc.

Kotlin's documentation engine, Dokka, includes only public declarations in its outputs by default. As discussed in the Simplicity section, you should minimize your public API and remove public entry points that you don't want users to access. If there are APIs you cannot hide from users by controlling their visibility, omit them from the documentation using the suppress directive.

Begin the description of entry points with a clear, high-level description of what the function does. Avoid simply restating the signature in natural language.

For example, don't say “takes a `String` and returns a `Connection` ” but instead perhaps “Attempts to connect to the database specified by the input string, returning a `Connection` if successful, and throwing a `ConnectionTimeoutException` otherwise”.

Specify each input's expected values and behavior with different inputs. Explain the range of valid values and what happens when invalid values are provided. For example, if a string input is supposed to be a URL, describe what happens when the string is empty, invalid, uses an unsupported protocol, or refers to a location that does not exist.

Document every exception an API entry point may throw. Discuss failure conditions in the general description and reserve the exception section for detailed information. This enhances readability and helps the reader focus. Instead, include this information organically into the general description. Providing usage examples whenever possible also helps users understand how to use the API correctly.

> We recommend learning about technical writing to improve the clarity and effectiveness of your documentation. Consider exploring resources, such as this course from Google (part one and part two).

Document lambda parameters

When an API entry point takes a lambda, the user is providing some functionality that your library will execute on their behalf. This requires extra documentation in at least two areas.

First, document what happens if the lambda throws an exception. Consider addressing the following questions:

- Will this cause an immediate failure, will the lambda be invoked repeatedly, or is there a fallback behavior?
- If the calling function needs to exit, will it rethrow the exception thrown from the lambda or a different one?
- If the exception is different, will it include the original?

Additionally, unless the function is declared as inline,document any special behavior relating to concurrency. Ensure the following are covered:

- Will the lambda be invoked in the same thread as the caller?
- If the lambda is not invoked in the same thread as the caller, which thread (or thread pool) will it be invoked in?
- Could multiple copies of the lambda be run in parallel?
- Which other jobs of work may be using that thread?

- Can the user specify a thread for the library to use?
- Where multiple lambdas are being invoked, what guarantees are provided regarding sequencing?

Use explicit links in documentation

It is very rare for an API entry point to be completely independent of other functionality in your library. Typically, calls must be made in a specific sequence, there are multiple options for performing a particular task, and entry points that perform related tasks are used in similar ways. For example, functions like `format` and `parse` mirror each other.

Use the `@see` tag or internal links to make these relationships explicit in your documentation. This helps the reader by enabling them to chunk the information together, building a better-integrated mental map of the library.

Be self-contained where possible

When describing what makes an input valid, it is tempting to simply refer to the relevant standard, such as those produced by the W3C, IEEE, or Unicode Consortium. While providing these links can be helpful, the reader should not be forced to refer to an external specification to discover basic information, like the set of whitespace characters.

Wherever possible, the documentation should be self-contained. It should provide enough information for the user to understand the typical use of each API entry point. You can refer the user to external documents for edge cases that will not happen in common use.

Use simple English

It's important to use simple and clear English when creating documentation. This ensures that your content is accessible to a global audience, including those whose first language is not English. Avoid using complex words, jargon, Latin phrases, or idiomatic expressions that might confuse readers. Instead, use straightforward language and concise sentences.

Simple English also makes the documentation easier to translate if needed. Clear, unambiguous text reduces the risk of misinterpretation and improves the overall readability.

What's next

If you haven't already, consider checking out these pages:

- Explore strategies for minimizing mental complexity in the Minimizing mental complexity page.
- Learn about maintaining backward compatibility in the Backward compatibility page.

Building a Kotlin library for multiplatform

When creating a Kotlin library, consider building and publishing it with support for Kotlin Multiplatform. This broadens the target audience of your library, making it compatible with projects targeting multiple platforms.

> You can find already available Kotlin Multiplatform libraries for different use cases and target platforms on klibs.io.

The following sections provide guidelines to help you build a Kotlin Multiplatform library effectively.

Maximize your reach

To make your library available to the largest number of projects as a dependency, aim to support as many target platforms of Kotlin Multiplatform as possible.

If your library doesn't support the platforms used by a multiplatform project, whether it's a library or an application, it becomes difficult for that project to depend on your library. In that case, projects can use your library for some platforms and need to implement separate solutions for others, or they will choose an alternative library altogether that supports all their platforms.

To streamline artifact production, use cross-compilation to publish Kotlin Multiplatform libraries from any host. This allows you to generate `.klib` artifacts for Apple targets without an Apple machine.

For Kotlin/Native targets, consider using a tiered approach to support all possible targets.

Design APIs for use from common code

When creating a library, design the APIs to be usable from common Kotlin code, instead of writing platform-specific implementations.

Provide reasonable default configurations when possible and include platform-specific configuration options. Good defaults allow users to use the library's APIs from common Kotlin code, without the need to write platform-specific implementations to configure the library.

Place APIs in the broadest relevant source set using the following priority:

- **The `commonMain` source set:** APIs in the `commonMain` source set are available to all platforms the library supports. Aim to place most of your library's API here.
- **Intermediate source sets:** If some platforms don't support certain APIs, use intermediate source sets to target specific platforms. For example, you can create a `concurrent` source set for targets that support multi-threading or a `nonJvm` source set for all non-JVM targets.
- **Platform-specific source sets:** For platform-specific APIs, use source sets like `androidMain`.

To learn more about the source sets of Kotlin Multiplatform projects, see Hierarchical project structure.

Ensure consistent behavior across platforms

To ensure your library behaves consistently on all supported platforms, APIs in a multiplatform library should accept the same range of valid inputs, perform the same actions, and return the same results across all platforms. Similarly, the library should treat invalid inputs uniformly and report errors or throw exceptions consistently on all platforms.

Inconsistent behavior makes the library difficult to use and forces users to add conditional logic in common code to manage platform-specific differences.

You can use `expect` and `actual` declarations to declare functions in common code with platform-specific implementations that have full access to the native APIs of each platform. These implementations must also have the same behavior to ensure that they can be used reliably from common code.

When APIs behave consistently across platforms, they only need to be documented once in the `commonMain` source set.

> If platform differences are unavoidable, such as when one platform supports a broader set of inputs, minimize them where possible. For example, you might not want to limit one platform's functionality to match the others. In such cases, clearly document the specific differences.

Test on all platforms

Multiplatform libraries can have multiplatform tests written in common code that runs on all platforms. Executing this common test suite regularly on your supported platforms can ensure that the library behaves correctly and consistently.

Regularly testing Kotlin/Native targets across all published platforms can be challenging. However, to ensure broader compatibility, consider publishing the library for all the targets it can support, using a tiered method when testing compatibility.

Use the `kotlin-test` library to write tests in common code and execute them with platform-specific test runners.

Consider non-Kotlin users

Kotlin Multiplatform offers interoperability with native APIs and languages across its supported target platforms. When creating a Kotlin Multiplatform library, consider whether users might need to use your library's types and declarations from languages other than Kotlin.

For example, if some types from your library will be exposed to Swift code through interoperability, design those types to be easily accessible from Swift. The Kotlin-Swift interopedia provides useful insights into how Kotlin APIs appear when called from Swift.

Promote your library

You can feature your library on klibs.io, the search platform where developers discover and evaluate Kotlin Multiplatform libraries.

klibs.io automatically lists libraries that meet its listing criteria. To check whether your library qualifies, see the FAQ.

Get started with Kotlin custom scripting – tutorial

> Kotlin custom scripting is Experimental. It may be dropped or changed at any time. Use it only for evaluation purposes. We appreciate your feedback on it in YouTrack.

Kotlin scripting is the technology that enables executing Kotlin code as scripts without prior compilation or packaging into executables.

For an overview of Kotlin scripting with examples, check out the talk Implementing the Gradle Kotlin DSL by Rodrigo Oliveira from KotlinConf'19.

In this tutorial, you'll create a Kotlin scripting project that executes arbitrary Kotlin code with Maven dependencies. You'll be able to execute scripts like this:

```
@file:Repository("https://maven.pkg.jetbrains.space/public/p/kotlinx-html/maven")
@file:DependsOn("org.jetbrains.kotlinx:kotlinx-html-jvm:0.7.3")

import kotlinx.html.*
import kotlinx.html.stream.*
import kotlinx.html.attributes.*

val addressee = "World"

print(
    createHTML().html {
        body {
            h1 { +"Hello, $addressee!" }
        }
    }
)
```

The specified Maven dependency (`kotlinx-html-jvm` for this example) will be resolved from the specified Maven repository or local cache during execution and used for the rest of the script.

Project structure

A minimal Kotlin custom scripting project contains two parts:

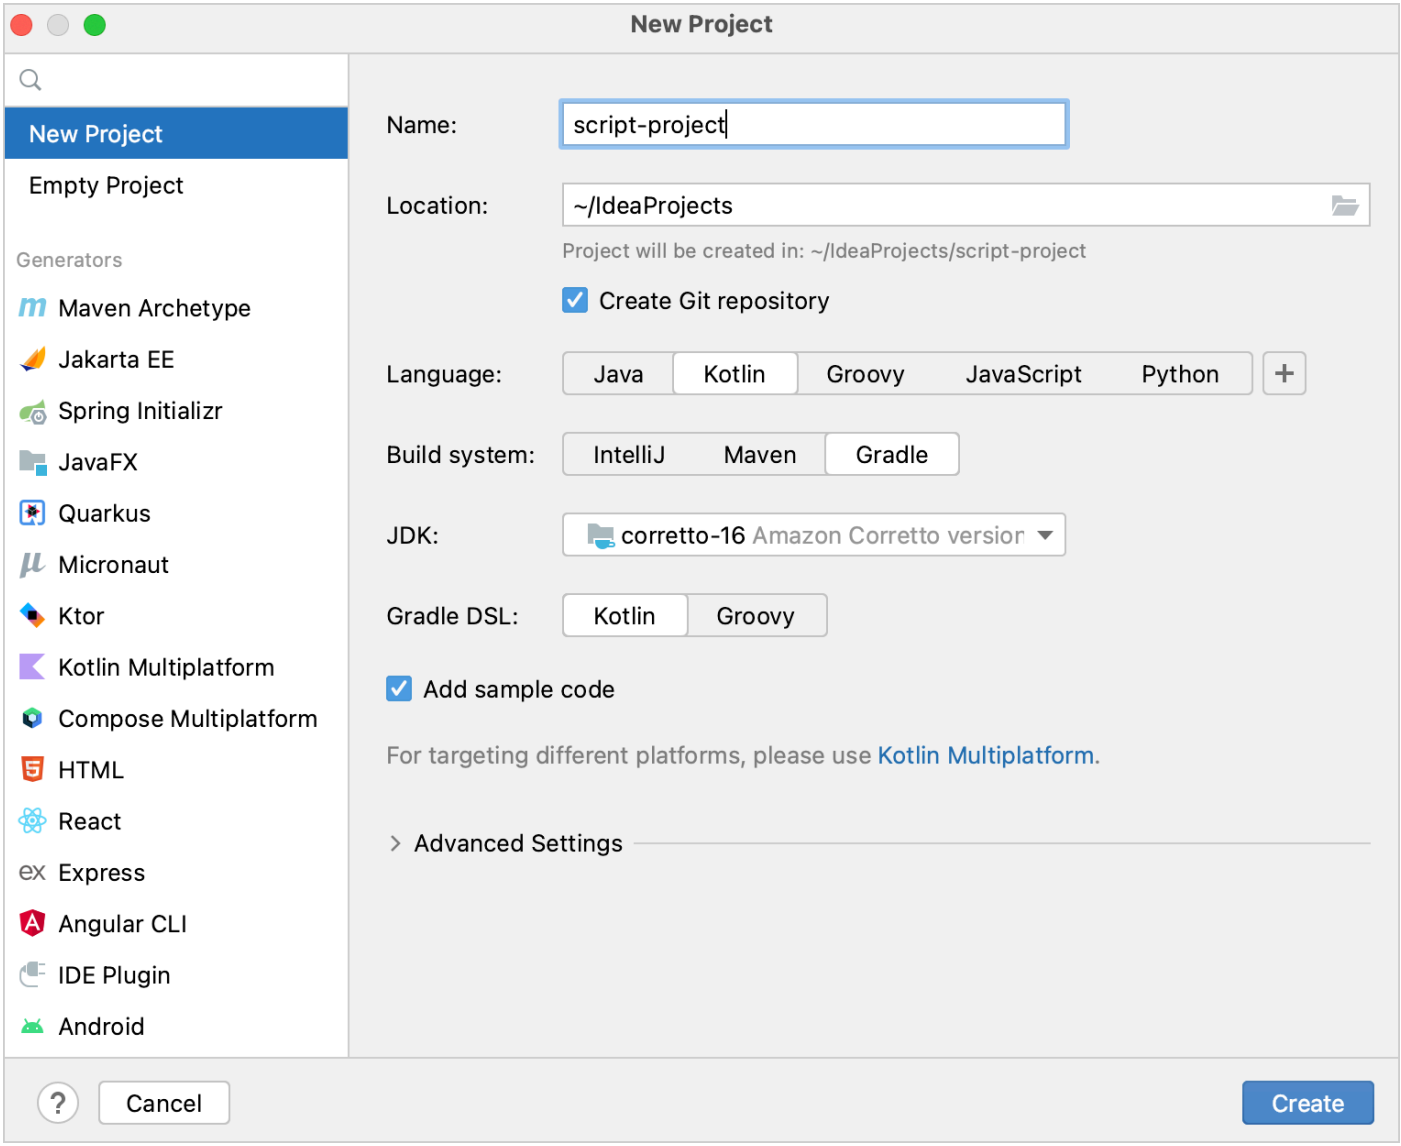
- *Script definition* – a set of parameters and configurations that define how this script type should be recognized, handled, compiled, and executed.
- *Scripting host* – an application or component that handles script compilation and execution – actually running scripts of this type.

With all of this in mind, it's best to split the project into two modules.

Before you start

Download and install the latest version of IntelliJ IDEA.

Create a project



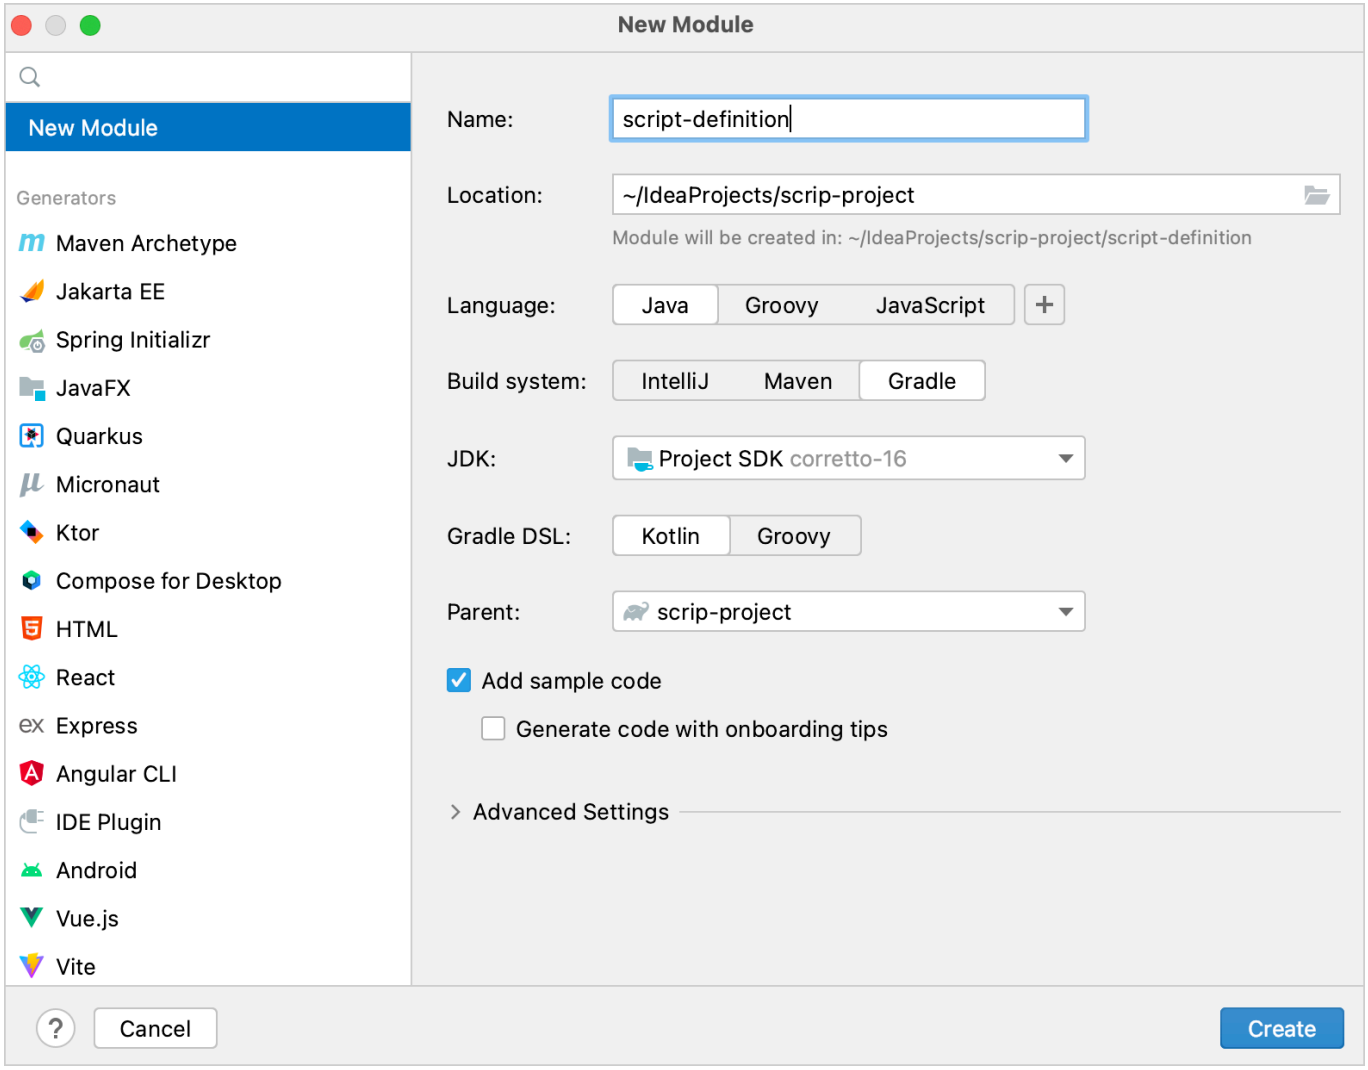
1. In IntelliJ IDEA, select **File** | **New** | **Project**.
2. In the panel on the left, select **New Project**.
3. Name the new project and change its location if necessary.

   > Select the **Create Git repository** checkbox to place the new project under version control. You will be able to do it later at any time.

4. From the **Language** list, select **Kotlin**.
5. Select the **Gradle** build system.
6. From the **JDK** list, select the JDK that you want to use in your project.
   - If the JDK is installed on your computer, but not defined in the IDE, select **Add JDK** and specify the path to the JDK home directory.

- If you don't have the necessary JDK on your computer, select **Download JDK**.

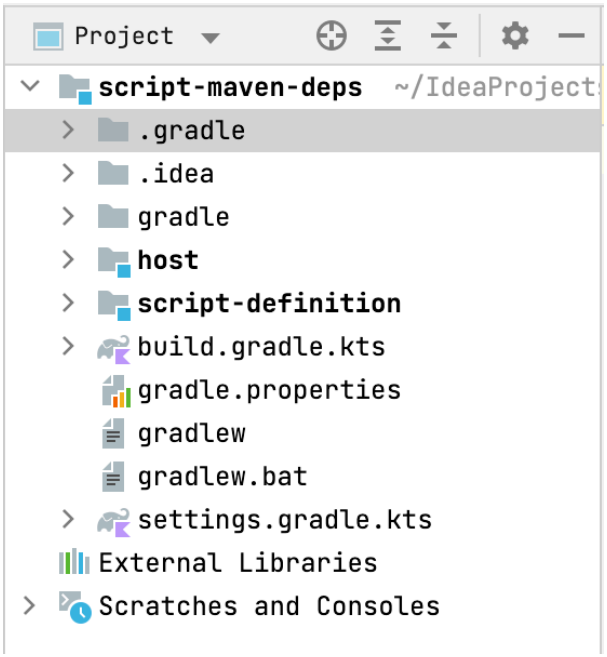
7. Select the Kotlin or Gradle language for the **Gradle DSL**.
8. Click **Create**.



Create a root project for custom Kotlin scripting

Add scripting modules

Now you have an empty Kotlin/JVM Gradle project. Add the required modules, script definition and scripting host:



1. In IntelliJ IDEA, select **File | New | Module**.
2. In the panel on the left, select **New Module**. This module will be the script definition.
3. Name the new module and change its location if necessary.
4. From the **Language** list, select **Java**.
5. Select the **Gradle** build system and Kotlin for the **Gradle DSL** if you want to write the build script in Kotlin.
6. As a module's parent, select the root module.
7. Click **Create**.

Create script definition module

8. In the module's `build.gradle(.kts)` file, remove the `version` of the Kotlin Gradle plugin. It is already in the root project's build script.
9. Repeat previous steps one more time to create a module for the scripting host.

The project should have the following structure:

Custom scripting project structure

You can find an example of such a project and more Kotlin scripting examples in the kotlin-script-examples GitHub repository.

Create a script definition

First, define the script type: what developers can write in scripts of this type and how it will be handled. In this tutorial, this includes support for the `@Repository` and `@DependsOn` annotations in the scripts.

1. In the script definition module, add the dependencies on the Kotlin scripting components in the `dependencies` block of `build.gradle(.kts)`. These dependencies provide the APIs you will need for the script definition:

Kotlin

```
dependencies {
    implementation("org.jetbrains.kotlin:kotlin-scripting-common")
    implementation("org.jetbrains.kotlin:kotlin-scripting-jvm")
    implementation("org.jetbrains.kotlin:kotlin-scripting-dependencies")
    implementation("org.jetbrains.kotlin:kotlin-scripting-dependencies-maven")
    // coroutines dependency is required for this particular definition
    implementation("org.jetbrains.kotlinx:kotlinx-coroutines-core:1.11.0")
}
```

Groovy

```
dependencies {
    implementation 'org.jetbrains.kotlin:kotlin-scripting-common'
    implementation 'org.jetbrains.kotlin:kotlin-scripting-jvm'
    implementation 'org.jetbrains.kotlin:kotlin-scripting-dependencies'
    implementation 'org.jetbrains.kotlin:kotlin-scripting-dependencies-maven'
    // coroutines dependency is required for this particular definition
    implementation 'org.jetbrains.kotlinx:kotlinx-coroutines-core:1.11.0'
}
```

2. Create the `src/main/kotlin/` directory in the module and add a Kotlin source file, for example, `scriptDef.kt`.
3. In `scriptDef.kt`, create a class. It will be a superclass for scripts of this type, so declare it `abstract` or `open`.

```
// abstract (or open) superclass for scripts of this type
abstract class ScriptWithMavenDeps
```

   This class will also serve as a reference to the script definition later.

4. To make the class a script definition, mark it with the `@KotlinScript` annotation. Pass two parameters to the annotation:
   - `fileExtension` – a string ending with `.kts` that defines a file extension for scripts of this type.
   - `compilationConfiguration` – a Kotlin class that extends `ScriptCompilationConfiguration` and defines the compilation specifics for this script definition. You'll create it in the next step.

```
// @KotlinScript annotation marks a script definition class
@KotlinScript(
    // File extension for the script type
    fileExtension = "scriptwithdeps.kts",
    // Compilation configuration for the script type
    compilationConfiguration = ScriptWithMavenDepsConfiguration::class
)
abstract class ScriptWithMavenDeps

object ScriptWithMavenDepsConfiguration: ScriptCompilationConfiguration()
```

> In this tutorial, we provide only the working code without explaining Kotlin scripting API. You can find the same code with a detailed explanation on GitHub.

5. Define the script compilation configuration as shown below.

```
object ScriptWithMavenDepsConfiguration : ScriptCompilationConfiguration(
    {
        // Implicit imports for all scripts of this type
        defaultImports(DependsOn::class, Repository::class)
        jvm {
            // Extract the whole classpath from context classloader and use it as dependencies
            dependenciesFromCurrentContext(wholeClasspath = true)
        }
        // Callbacks
        refineConfiguration {
            // Process specified annotations with the provided handler
            onAnnotations(DependsOn::class, Repository::class, handler =
::configureMavenDepsOnAnnotations)
        }
    }
)
```

The `configureMavenDepsOnAnnotations` function is as follows:

```
// Handler that reconfigures the compilation on the fly
fun configureMavenDepsOnAnnotations(context: ScriptConfigurationRefinementContext):
ResultWithDiagnostics<ScriptCompilationConfiguration> {
    val annotations = context.collectedData?.get(ScriptCollectedData.collectedAnnotations)?.takeIf
{ it.isNotEmpty() }
        ?: return context.compilationConfiguration.asSuccess()
    return runBlocking {
        resolver.resolveFromScriptSourceAnnotations(annotations)
    }.onSuccess {
        context.compilationConfiguration.with {
            dependencies.append(JvmDependency(it))
        }.asSuccess()
    }
}

private val resolver = CompoundDependenciesResolver(FileSystemDependenciesResolver(),
MavenDependenciesResolver())
```

You can find the full code here.

Create a scripting host

The next step is creating the scripting host – the component that handles the script execution.

1. In the scripting host module, add the dependencies in the `dependencies` block of `build.gradle(.kts)`:
   - Kotlin scripting components that provide the APIs you need for the scripting host
   - The script definition module you created previously

Kotlin

```
dependencies {
    implementation("org.jetbrains.kotlin:kotlin-scripting-common")
    implementation("org.jetbrains.kotlin:kotlin-scripting-jvm")
    implementation("org.jetbrains.kotlin:kotlin-scripting-jvm-host")
    implementation(project(":script-definition")) // the script definition module
}
```

Groovy

```
dependencies {
    implementation 'org.jetbrains.kotlin:kotlin-scripting-common'
    implementation 'org.jetbrains.kotlin:kotlin-scripting-jvm'
    implementation 'org.jetbrains.kotlin:kotlin-scripting-jvm-host'
    implementation project(':script-definition') // the script definition module
}
```

2. Create the `src/main/kotlin/` directory in the module and add a Kotlin source file, for example, `host.kt`.

3. Define the `main` function for the application. In its body, check that it has one argument – the path to the script file – and execute the script. You'll define the script execution in a separate function `evalFile` in the next step. Declare it empty for now.

   `main` can look like this:

```
fun main(vararg args: String) {
     if (args.size != 1) {
         println("usage: <app> <script file>")
     } else {
         val scriptFile = File(args[0])
         println("Executing script $scriptFile")
         evalFile(scriptFile)
     }
 }
```

4. Define the script evaluation function. This is where you'll use the script definition. Obtain it by calling `createJvmCompilationConfigurationFromTemplate` with the script definition class as a type parameter. Then call `BasicJvmScriptingHost().eval`, passing it the script code and its compilation configuration. `eval` returns an instance of `ResultWithDiagnostics`, so set it as your function's return type.

```
fun evalFile(scriptFile: File): ResultWithDiagnostics<EvaluationResult> {
     val compilationConfiguration =
createJvmCompilationConfigurationFromTemplate<ScriptWithMavenDeps>()
     return BasicJvmScriptingHost().eval(scriptFile.toScriptSource(), compilationConfiguration,
null)
 }
```

5. Adjust the `main` function to print information about the script execution:

```
fun main(vararg args: String) {
     if (args.size != 1) {
         println("usage: <app> <script file>")
     } else {
         val scriptFile = File(args[0])
         println("Executing script $scriptFile")
         val res = evalFile(scriptFile)
         res.reports.forEach {
             if (it.severity > ScriptDiagnostic.Severity.DEBUG) {
                 println(" : ${it.message}" + if (it.exception == null) "" else ":
${it.exception}")
             }
         }
     }
 }
```

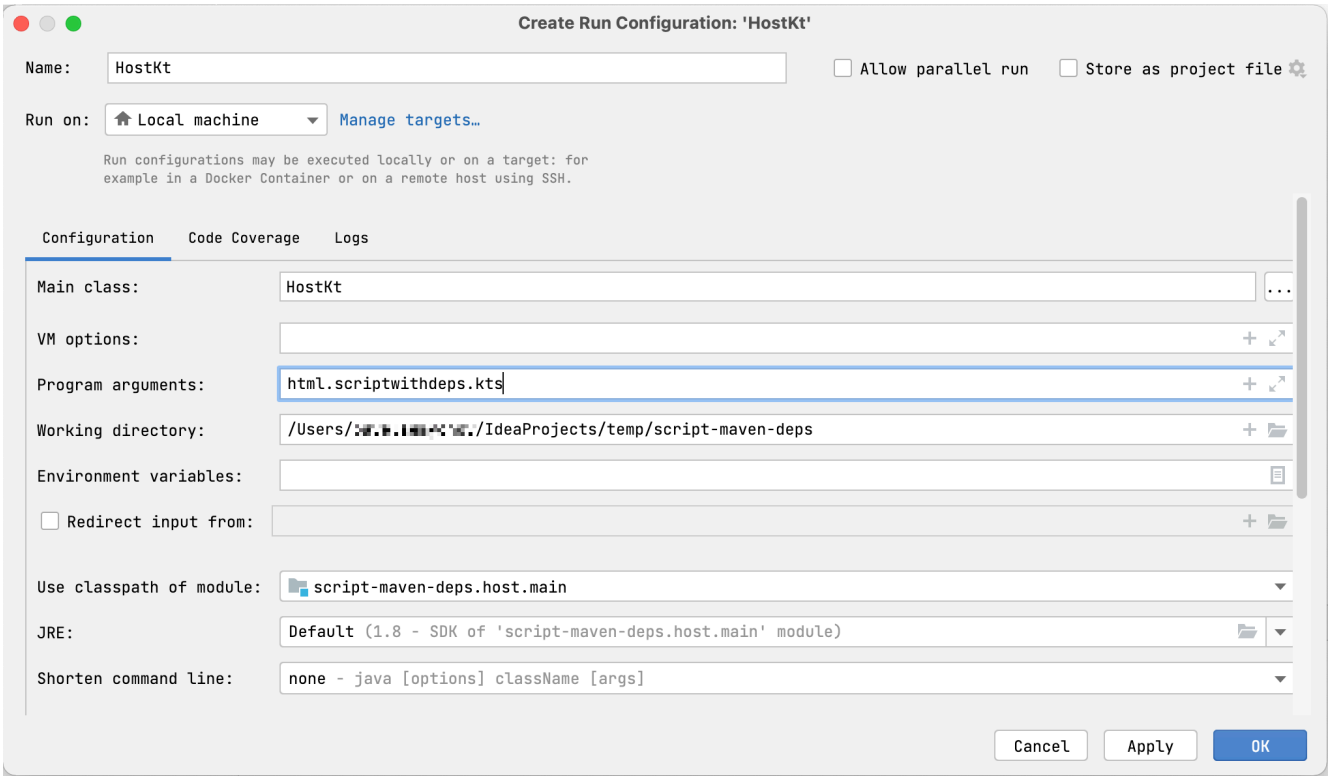
You can find the full code here

Run scripts

To check how your scripting host works, prepare a script to execute and a run configuration.

1. Create the file `html.scriptwithdeps.kts` with the following content in the project root directory:

```
@file:Repository("https://maven.pkg.jetbrains.space/public/p/kotlinx-html/maven")
@file:DependsOn("org.jetbrains.kotlinx:kotlinx-html-jvm:0.7.3")



import kotlinx.html.*; import kotlinx.html.stream.*; import kotlinx.html.attributes.*

val addressee = "World"

print(
    createHTML().html {
        body {
            h1 { +"Hello, $addressee!" }
        }
    }
)
```

   It uses functions from the `kotlinx-html-jvm` library which is referenced in the `@DependsOn` annotation argument.

2. Create a run configuration that starts the scripting host and executes this file:
   1. Open `host.kt` and navigate to the `main` function. It has a **Run** gutter icon on the left.
   2. Right-click the gutter icon and select **Modify Run Configuration**.
   3. In the **Create Run Configuration** dialog, add the script file name to **Program arguments** and click **OK**.

Scripting host run configuration

3. Run the created configuration.

You'll see how the script is executed, resolving the dependency on `kotlinx-html-jvm` in the specified repository and printing the results of calling its functions:

```
<html>
  <body>
    <h1>Hello, World!</h1>
  </body>
</html>
```

Resolving dependencies may take some time on the first run. Subsequent runs will complete much faster because they use downloaded dependencies from the local Maven repository.

What's next?

Once you've created a simple Kotlin scripting project, find more information on this topic:

- Read the Kotlin scripting KEEP
- Browse more Kotlin scripting examples
- Watch the talk Implementing the Gradle Kotlin DSL by Rodrigo Oliveira

IDEs for Kotlin development

JetBrains provides official Kotlin support for the following IDEs and code editors: IntelliJ IDEA and Android Studio. You can also install the official Kotlin by JetBrains extension for Visual Studio Code, which is currently in Alpha.

Other IDEs and code editors only have Kotlin community-supported plugins.

IntelliJ IDEA

IntelliJ IDEA is an IDE designed for JVM languages, such as Kotlin and Java, to maximize developer productivity. It does the routine and repetitive tasks for you by providing clever code completion, static code analysis, and refactorings. It lets you focus on the bright side of software development, making it not only productive but also an enjoyable experience.

The Kotlin plugin is bundled with each IntelliJ IDEA release. Each IDEA release introduces new features and upgrades that improve the experience for Kotlin developers in the IDE. See What's new in IntelliJ IDEA for the latest updates and improvements for Kotlin.

Read more about IntelliJ IDEA in the official documentation.

Android Studio

Android Studio is the official IDE for Android app development, based on IntelliJ IDEA. On top of IntelliJ's powerful code editor and developer tools, Android Studio offers even more features that enhance your productivity when building Android apps.

Kotlin plugin is bundled with each Android Studio release.

Read more about Android Studio in the official documentation.

Visual Studio Code

Visual Studio Code is a code editor with a wide range of extensions, including the official Kotlin by JetBrains extension.

The Kotlin extension provides code completion, navigation, debugging, and other Kotlin development features through the Kotlin Language Server.

For more information, see Kotlin Language Server and Visual Studio Code.

Other IDEs support

JetBrains doesn't provide official Kotlin plugins for other IDEs. You can use the Kotlin Language Server with other code editors.

To use Kotlin in text editors without IDE-related features (such as code formatting, debugging tools, refactoring), you can download the latest Kotlin command-line compiler (`kotlin-compiler-2.4.20.zip`) from Kotlin GitHub Releases and install it manually. Also, you could use package managers, such as Homebrew, SDKMAN!, and Snap package.

Compatibility with the Kotlin language versions

For IntelliJ IDEA and Android Studio, the Kotlin plugin is bundled with each release. When the new Kotlin version is released, these tools will suggest updating Kotlin to the latest version automatically. See the latest supported language version in Kotlin releases.

What's next?

- Create a console application in IntelliJ IDEA
- Create your first cross-platform mobile app using IntelliJ IDEA or Android Studio

Kotlin Language Server

The Kotlin Language Server is JetBrains' official implementation of the Language Server Protocol (LSP) for Kotlin.

The server is based on IntelliJ IDEA, the IntelliJ IDEA Kotlin plugin, JetBrains AIR, and Fleet. It is designed to work with any code editor that supports LSP.

IntelliJ IDEA and Android Studio provide the best Kotlin development experience.

Kotlin in Visual Studio Code

Kotlin Language Server provides official Kotlin language support for Visual Studio Code.

If you use Visual Studio Code for Kotlin development, install the official Kotlin by JetBrains extension from the Visual Studio Marketplace.

For VS Code-compatible editors, such as Cursor or VSCodium, install the extension from the Open VSX Registry.

To activate the **Kotlin by JetBrains** extension, open a Kotlin project in Visual Studio Code, and then open any Kotlin file.

Supported features

The Kotlin Language Server includes core language features such as:

- Support for up-to-date Kotlin language versions
- IntelliJ-powered code completion
- IntelliJ-powered diagnostics and quick fixes for Kotlin and `kotlinx.*` libraries
- Build system support for JVM projects: Gradle, Maven, and experimental Android Gradle Plugin support

  > Support for Kotlin Multiplatform projects is under development.

- Semantic highlighting
- Organize imports
- Rename refactoring
- Code formatting
- Documentation navigation and hover support
- Call hierarchy
- Code folding

Feedback

The Kotlin Language Server is under active development, and feedback is especially valuable during the Alpha stage.

If you run into problems or want to suggest improvements, report them in the Kotlin LSP repository.

What's next?

- Explore the Kotlin Language Server repository on GitHub

Introduction

Dokka is an API documentation engine for Kotlin.

Just like Kotlin itself, Dokka supports mixed-language projects. It understands Kotlin's KDoc comments and Java's Javadoc comments.

Dokka can generate documentation in multiple formats, including its own modern HTML format, Java's Javadoc HTML, as well as the GFM and Jekyll flavors of Markdown.

Here are some libraries that use Dokka for their API reference documentation:

- kotlinx.coroutines

- Bitmovin
- Hexagon
- Ktor
- OkHttp

You can run Dokka using Gradle, Maven or from the command line. It is also highly pluggable.

See Get started with Dokka to take your first steps in using Dokka.

Community

Dokka has a dedicated `#dokka` channel in Kotlin Community Slack where you can chat about Dokka, its plugins and how to develop them, as well as get in touch with maintainers.

Get started with Dokka

Below you can find simple instructions to help you get started with Dokka.

> This guide applies to Dokka Gradle plugin (DGP) v2 mode. The DGP v1 mode is no longer supported. To upgrade from v1 to v2 mode, follow the Migration guide.

Apply the Gradle Dokka plugin

Apply the Dokka Gradle plugin (DGP) in the root build script of your project:

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}
```

Document multi-project builds

When documenting multi-project builds, apply the plugin to every subproject you want to document. Share Dokka configuration across subprojects by using one of the following approaches:

- Convention plugin
- Direct configuration in each subproject if you're not using convention plugins

For more information about sharing Dokka configuration in multi-project builds, see Multi-project configuration.

Generate documentation

To generate documentation, run the following Gradle task:

```
./gradlew :dokkaGenerate
```

This task works for both single and multi-project builds.

Run the `dokkaGenerate` task from the aggregating project by prefixing the task with its project path (`:`). For example:

```
./gradlew :dokkaGenerate

// OR

./gradlew :aggregatingProject:dokkaGenerate
```

Avoid running `./gradlew dokkaGenerate` instead of `./gradlew :dokkaGenerate` or `./gradlew :aggregatingProject:dokkaGenerate`. Without a project path (`:`) prefixing the task, Gradle tries to run all `dokkaGenerate` tasks across the entire build, which may trigger unnecessary work.

You can use different tasks to generate output in HTML, Javadoc or both HTML and Javadoc.

To learn more about using Dokka with Gradle, see Gradle.

This guide applies to Dokka Gradle plugin (DGP) v2 mode. The DGP v1 mode is no longer supported. To upgrade from v1 to v2 mode, follow the Migration guide.

Apply the Gradle Dokka plugin

Apply the Gradle plugin for Dokka in the root build script of your project:

Gradle Groovy DSL

```
plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}
```

Document multi-project builds

When documenting multi-project builds, you need to apply the plugin to every subproject you want to document. Share Dokka configuration across subprojects by using one of the following approaches:

- Convention plugin
- Direct configuration in each subproject if you're not using convention plugins

For more information about sharing Dokka configuration in multi-project builds, see Multi-project configuration.

Generate documentation

To generate documentation, run the following Gradle task:

```
./gradlew :dokkaGenerate
```

This task works for both single and multi-project builds.

Run the `dokkaGenerate` task from the aggregating project by prefixing the task with its project path. For example:

```
./gradlew :dokkaGenerate

// OR

./gradlew :aggregatingProject:dokkaGenerate
```

Avoid running `./gradlew dokkaGenerate` instead of `./gradlew :dokkaGenerate` or `./gradlew :aggregatingProject:dokkaGenerate`. Without a project path (`:`) prefixing the task, Gradle tries to run all `dokkaGenerate` tasks across the entire build, which may trigger unnecessary work.

You can use different tasks to generate output in HTML, Javadoc or both HTML and Javadoc.

To learn more about using Dokka with Gradle, see Gradle.

Add the Maven plugin for Dokka to the `plugins` section of your POM file:

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.dokka</groupId>
            <artifactId>dokka-maven-plugin</artifactId>
            <version>2.2.0</version>
            <executions>
                <execution>
                    <phase>pre-site</phase>
                    <goals>
                        <goal>dokka</goal>
                    </goals>
                </execution>
            </executions>
        </plugin>
    </plugins>
</build>
```

To generate documentation, run the `dokka:dokka` goal.

By default, the output directory is set to `target/dokka`.

To learn more about using Dokka with Maven, see Maven.

Gradle

This guide applies to Dokka Gradle plugin (DGP) v2 mode. The previous DGP v1 mode is no longer supported. If you're upgrading from v1 to v2 mode, see the Migration guide.

To generate documentation for a Gradle-based project, you can use the Gradle plugin for Dokka.

The Dokka Gradle plugin (DGP) comes with basic autoconfiguration for your project, includes Gradle tasks for generating documentation, and provides configuration options to customize the output.

You can play around with Dokka and explore how to configure it for various projects in our Gradle example projects.

Supported versions

Ensure that your project meets the minimum version requirements:

Tool	Version
Gradle	7.6 or higher
Android Gradle plugin	7.0 or higher

Tool	Version
Kotlin Gradle plugin	1.9 or higher

Apply Dokka

The recommended way of applying the Gradle plugin for Dokka is with the plugins block. Add it in the `plugins {}` block of your project's `build.gradle.kts` file:

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}
```

Gradle Groovy DSL

```
plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}
```

When documenting multi-project builds, you need to apply the plugin explicitly to every subproject you want to document. You can configure Dokka directly in each subproject or share Dokka configuration across subprojects using a convention plugin. For more information, see how to configure single-project and multi-project builds.

- Under the hood, Dokka uses the Kotlin Gradle plugin to automatically configure source sets for which documentation is generated. Make sure to apply the Kotlin Gradle Plugin or configure source sets manually.
- If you are using Dokka in a precompiled script plugin, add the Kotlin Gradle plugin as a dependency to ensure it works properly.

Enable build cache and configuration cache

DGP supports Gradle build cache and configuration cache, improving build performance.

- To enable build cache, follow instructions in the Gradle build cache documentation.
- To enable configuration cache, follow instructions in the Gradle configuration cache documentation.

Generate documentation

The Dokka Gradle plugin comes with HTML and Javadoc output formats built in.

Use the following Gradle task to generate documentation:

```
./gradlew :dokkaGenerate
```

The key behavior of the `dokkaGenerate` Gradle task is:

- This task generates documentation for both single and multi-project builds.
- By default, the documentation output format is HTML. You can also generate Javadoc or both HTML and Javadoc formats by adding the appropriate plugins.
- The generated documentation is automatically placed in the `build/dokka/html` directory for both single and multi-project builds. You can change the location (`outputDirectory`).

Configure documentation output format

> The Javadoc output format is in Alpha. You may find bugs and experience migration issues when using it. Successful integration with tools that accept Javadoc as input is not guaranteed. Use it at your own risk.

You can choose to generate the API documentation in HTML, Javadoc, or both formats at the same time:

1. Place the corresponding plugin `id` in the `plugins {}` block of your project's `build.gradle.kts` file:

```
plugins {
    // Generates HTML documentation
    id("org.jetbrains.dokka") version "2.2.0"

    // Generates Javadoc documentation
    id("org.jetbrains.dokka-javadoc") version "2.2.0"

    // Keeping both plugin IDs generates both formats
}
```

2. Run the corresponding Gradle task.

   Here is a list of the plugin `id` and Gradle task that correspond to each format:

	HTML	Javadoc	Both
Plugin `id`	`id("org.jetbrains.dokka")`	`id("org.jetbrains.dokka-javadoc")`	Use both HTML and Javadoc plugins
Gradle task	`./gradlew :dokkaGeneratePublicationHtml`	`./gradlew :dokkaGeneratePublicationJavadoc`	`./gradlew :dokkaGenerate`

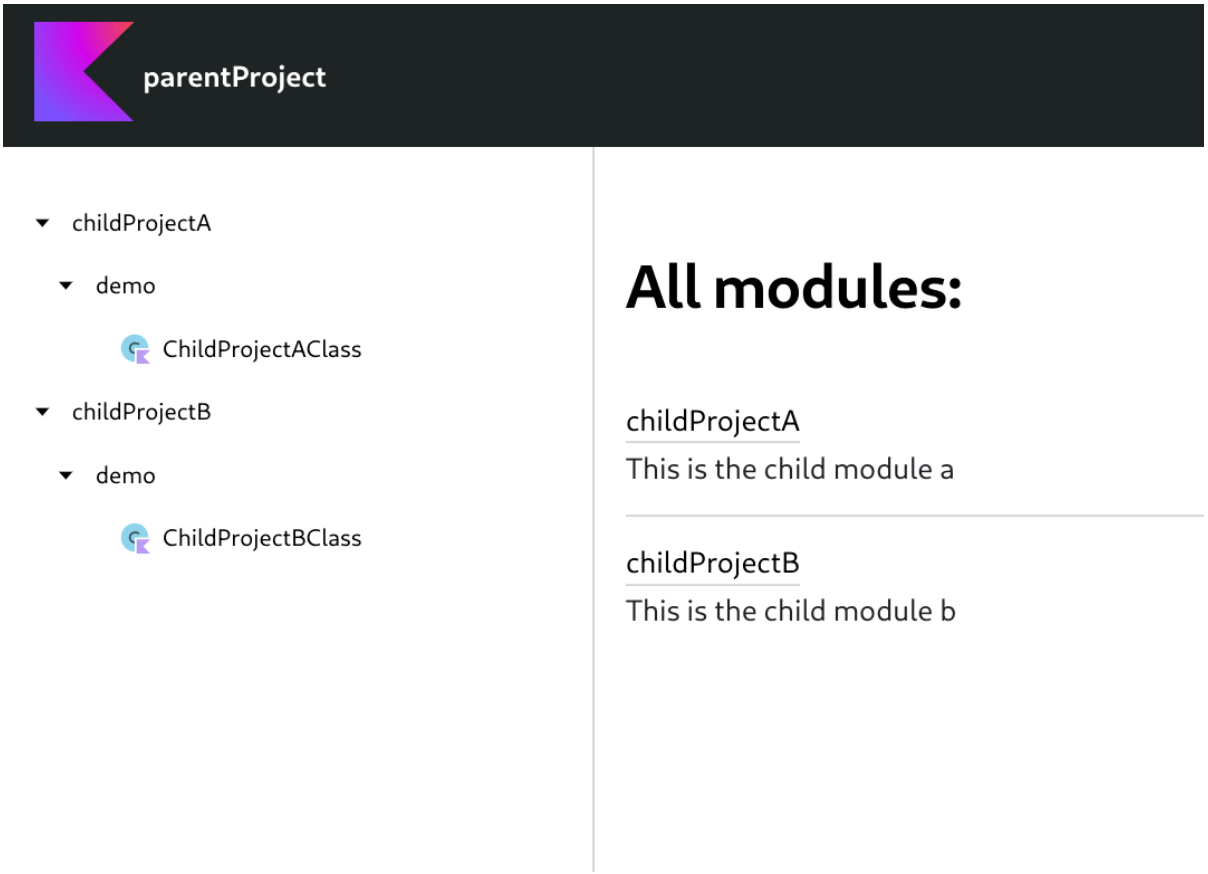
> - The `dokkaGenerate` task generates documentation in all available formats based on the applied plugins. If both the HTML and Javadoc plugins are applied, you can choose to generate only HTML by running the `dokkaGeneratePublicationHtml` task, or only Javadoc by running the `dokkaGeneratePublicationJavadoc` task.

If you're using IntelliJ IDEA, you may see the `dokkaGenerateHtml` Gradle task. This task is simply an alias of `dokkaGeneratePublicationHtml` . Both tasks perform exactly the same operation.

Aggregate documentation output in multi-project builds

Dokka can aggregate documentation from multiple subprojects into a single output or publication.

You have to apply the Dokka plugin to all documentable subprojects before aggregating the documentation.



To aggregate documentation from multiple subprojects, add the `dependencies {}` block in the `build.gradle.kts` file of the root project:

```
dependencies {
    dokka(project(":childProjectA:"))
    dokka(project(":childProjectB:"))
}
```

Given a project with the following structure:

```
.
└── parentProject/
    ├── childProjectA/
    │   └── demo/
    │       └── ChildProjectAClass.kt
    └── childProjectB/
        └── demo/
            └── ChildProjectBClass.kt
```

The generated documentation is aggregated as follows:

Screenshot for output of dokkaHtmlMultiModule task

See our multi-project example for more details.

Directory of aggregated documentation

When DGP aggregates subprojects, each subproject has its own subdirectory within the aggregated documentation. DGP ensures each subproject has a unique directory by retaining the full project structure.

For example, given a project with an aggregation in `:turbo-lib` and a nested subproject `:turbo-lib:maths`, the generated documentation is placed under:

```
turbo-lib/build/dokka/html/turbo-lib/maths/
```

You can revert this behavior by manually specifying the subproject directory. Add the following configuration to the `build.gradle.kts` file of each subproject:

```
// /turbo-lib/maths/build.gradle.kts

plugins {
    id("org.jetbrains.dokka")
}

dokka {
    // Overrides the subproject directory
    modulePath.set("maths")
}
```

This configuration changes the generated documentation for the `:turbo-lib:maths` module to be generated into `turbo-lib/build/dokka/html/maths/`.

Build javadoc.jar

If you want to publish your library to a repository, you may need to provide a `javadoc.jar` file that contains API reference documentation of your library.

For example, if you want to publish to Maven Central, you must supply a `javadoc.jar` alongside your project. However, not all repositories have that rule.

The Gradle plugin for Dokka does not provide any way to do this out of the box, but it can be achieved with custom Gradle tasks. One for generating documentation in HTML format and another one for Javadoc format:

Gradle Kotlin DSL

```
// To generate documentation in HTML
val dokkaHtmlJar by tasks.registering(Jar::class) {
    description = "A HTML Documentation JAR containing Dokka HTML"
    from(tasks.dokkaGeneratePublicationHtml.flatMap { it.outputDirectory })
    archiveClassifier.set("html-doc")
}

// To generate documentation in Javadoc
val dokkaJavadocJar by tasks.registering(Jar::class) {
    description = "A Javadoc JAR containing Dokka Javadoc"
    from(tasks.dokkaGeneratePublicationJavadoc.flatMap { it.outputDirectory })
    archiveClassifier.set("javadoc")
}
```

Gradle Groovy DSL

```
// To generate documentation in HTML
tasks.register('dokkaHtmlJar', Jar) {
    description = 'A HTML Documentation JAR containing Dokka HTML'
    from(tasks.named('dokkaGeneratePublicationHtml').flatMap { it.outputDirectory })
    archiveClassifier.set('html-doc')
}

// To generate documentation in Javadoc
tasks.register('dokkaJavadocJar', Jar) {
    description = 'A Javadoc JAR containing Dokka Javadoc'
    from(tasks.named('dokkaGeneratePublicationJavadoc').flatMap { it.outputDirectory })
    archiveClassifier.set('javadoc')
}
```

If you publish your library to Maven Central, you can use services like javadoc.io to host your library's API documentation for free and without any setup. It takes documentation pages straight from the `javadoc.jar`. It works well with the HTML format as demonstrated in this example.

Configuration examples

Depending on the type of project that you have, the way you apply and configure Dokka differs slightly. However, configuration options themselves are the same, regardless of the type of your project.

For simple and flat projects with a single `build.gradle.kts` or `build.gradle` file found in the root of your project, see Single-project configuration.

For a more complex build with subprojects and multiple nested `build.gradle.kts` or `build.gradle` files, see Multi-project configuration.

Single-project configuration

Single-project builds usually have only one `build.gradle.kts` or `build.gradle` file in the root of the project. They can be either single-platform or multiplatform and typically have the following structure:

Single platform:

Kotlin

```
.
├── build.gradle.kts
└── src/
    └── main/
        └── kotlin/
            └── HelloWorld.kt
```

Multiplatform:

```
.
├── build.gradle.kts
└── src/
    ├── commonMain/
    │   └── kotlin/
    │       └── Common.kt
    ├── jvmMain/
    │   └── kotlin/
    │       └── JvmUtils.kt
    └── nativeMain/
        └── kotlin/
            └── NativeUtils.kt
```

Single platform:

Groovy

```
.
├── build.gradle
└── src/
    └── main/
        └── kotlin/
            └── HelloWorld.kt
```

Multiplatform:

```
.
├── build.gradle
└── src/
    ├── commonMain/
    │   └── kotlin/
    │       └── Common.kt
    ├── jvmMain/
    │   └── kotlin/
    │       └── JvmUtils.kt
    └── nativeMain/
        └── kotlin/
            └── NativeUtils.kt
```

Apply the Dokka Gradle plugin in your root `build.gradle.kts` file and configure it using the top-level `dokka {}` DSL:

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}

dokka {
    dokkaPublications.html {
        moduleName.set("MyProject")
        outputDirectory.set(layout.buildDirectory.dir("documentation/html"))
        includes.from("README.md")
    }

    dokkaSourceSets.main {
        sourceLink {
            localDirectory.set(file("src/main/kotlin"))
            remoteUrl.set(URI("https://github.com/your-repo"))
            remoteLineSuffix.set("#L")
        }
    }
}
```

Inside `./build.gradle`:

Gradle Groovy DSL

```
plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}

dokka {
    dokkaPublications {
        html {
            moduleName.set("MyProject")
            outputDirectory.set(layout.buildDirectory.dir("documentation/html"))
            includes.from("README.md")
        }
    }

    dokkaSourceSets {
        named("main") {
            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl.set(new URI("https://github.com/your-repo"))
                remoteLineSuffix.set("#L")
            }
        }
    }
}
```

This configuration applies Dokka to your project, sets up the documentation output directory, and defines the main source set. You can extend it further by adding custom assets, visibility filters, or plugin configurations within the same `dokka {}` block. For more information, see Configuration options.

Multi-project configuration

Multi-project builds usually contain several nested `build.gradle.kts` files and have a structure similar to the following:

Kotlin

```
.
├── build.gradle.kts
├── settings.gradle.kts
├── subproject-A/
│   ├── build.gradle.kts
│   └── src/
│       └── main/
│           └── kotlin/
│               └── HelloFromA.kt
└── subproject-B/
    ├── build.gradle.kts
    └── src/
        └── main/
            └── kotlin/
                └── HelloFromB.kt
```

Groovy

```
.
├── build.gradle
├── settings.gradle
├── subproject-A/
│   ├── build.gradle
│   └── src/
│       └── main/
│           └── kotlin/
│               └── HelloFromA.kt
└── subproject-B/
    ├── build.gradle
    └── src/
        └── main/
            └── kotlin/
                └── HelloFromB.kt
```

Single and multi-project documentation share the same configuration model using the top-level `dokka {}` DSL.

There are two ways of configuring Dokka in multi-project builds:

- Shared configuration via a convention plugin **(preferred)**: defining a convention plugin and applying it to all subprojects. This centralizes your Dokka settings.
- Manual configuration: applying the Dokka plugin and repeating the same `dokka {}` block in each subproject. You don't need convention plugins.

After configuring your subprojects, you can aggregate the documentation from multiple subprojects into a single output. For more information, see Aggregate documentation output in multi-project-builds.

For a multi-project example, see the Dokka GitHub repository.

Shared configuration via a convention plugin

Follow the next steps to set up a convention plugin and apply it to your subprojects.

Set up the buildSrc directory

1. In your project root, create a `buildSrc` directory containing two files:
   - `settings.gradle.kts`
   - `build.gradle.kts`
2. In the `buildSrc/settings.gradle.kts` file, add the following snippet:

```
rootProject.name = "buildSrc"
```

3. In the `buildSrc/build.gradle.kts` file, add the following snippet:

```
plugins {
    `kotlin-dsl`
}

repositories {
    mavenCentral()
    gradlePluginPortal()
}

dependencies {
    implementation("org.jetbrains.dokka:dokka-gradle-plugin:2.2.0")
}
```

Set up the Dokka convention plugin

After setting up the `buildSrc` directory, set up the Dokka convention plugin:

1. Create a `buildSrc/src/main/kotlin/dokka-convention.gradle.kts` file to host the convention plugin.
2. In the `dokka-convention.gradle.kts` file, add the following snippet:

```
plugins {
    id("org.jetbrains.dokka")
}

dokka {
    // The shared configuration goes here
}
```

You need to add the shared Dokka configuration common to all subprojects within the `dokka {}` block. Also, you don't need to specify a Dokka version. The version is already set in the `buildSrc/build.gradle.kts` file.

Apply the convention plugin to your subprojects

Apply the Dokka convention plugin across your subprojects by adding it to each subproject's `build.gradle.kts` file:

```
plugins {
    id("dokka-convention")
}
```

Manual configuration

If your project doesn't use convention plugins, you can reuse the same Dokka configuration pattern by manually copying the same `dokka {} block` into each subproject:

1. Apply the Dokka plugin in every subproject's `build.gradle.kts` file:

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}
```

2. Declare the shared configuration in each subproject's `dokka {}` block. Because there's no convention plugin centralizing the configuration, you duplicate any configuration you want across subprojects. For more information, see configuration options.

Parent project configuration

In multi-project builds, you can configure settings that apply to the entire documentation in the root project. This can include defining the output format, output directory, documentation subproject name, aggregating documentation from all subprojects, and other configuration options:

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}

dokka {
    // Sets properties for the whole project
    dokkaPublications.html {
        moduleName.set("My Project")
        outputDirectory.set(layout.buildDirectory.dir("docs/html"))
        includes.from("README.md")
    }

    dokkaSourceSets.configureEach {
        documentedVisibilities.set(setOf(VisibilityModifier.Public)) // OR
documentedVisibilities(VisibilityModifier.Public)
    }
}

// Aggregates subproject documentation
dependencies {
    dokka(project(":childProjectA"))
    dokka(project(":childProjectB"))
}
```

Additionally, each subproject can have its own `dokka {}` block if it needs custom configuration. In the following example, the subproject applies the Dokka plugin, sets a custom subproject name, and includes additional documentation from its `README.md` file:

```
// subproject/build.gradle.kts
plugins {
    id("org.jetbrains.dokka")
}

dokka {
    dokkaPublications.html {
        moduleName.set("Child Project A")
        includes.from("README.md")
    }
}
```

Dokka Gradle configuration options

Dokka has many configuration options to customize your and your reader's experience.

Below are detailed descriptions for each configuration section and some examples. You can also find an example with all configuration options applied.

For more details on applying configuration blocks for single-project and multi-project builds, see Configuration examples.

General configuration

Here is an example of the general Dokka Gradle plugin configuration:

- Use the top-level `dokka {}` DSL configuration.
- In DGP, you declare Dokka publication configurations in the `dokkaPublications{}` block.
- The default publications are `html` and `javadoc`.
- The syntax of `build.gradle.kts` files differs from regular `.kt` files (such as those used for Kotlin custom plugins) because Gradle's Kotlin DSL uses type-safe accessors.

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}

dokka {
    dokkaPublications.html {
        moduleName.set(project.name)
        moduleVersion.set(project.version.toString())
        // Standard output directory for HTML documentation
        outputDirectory.set(layout.buildDirectory.dir("dokka/html"))
        failOnWarning.set(false)
        suppressInheritedMembers.set(false)
        suppressObviousFunctions.set(true)
        offlineMode.set(false)
        includes.from("packages.md", "extra.md")

        // Output directory for additional files
        // Use this block instead of the standard when you
        // want to change the output directory and include extra files
        outputDirectory.set(rootDir.resolve("docs/api/0.x"))

        // Use fileTree to add multiple files
        includes.from(
            fileTree("docs") {
                include("**/*.md")
            }
        )
    }
}
```

For more information about working with files, see the Gradle docs.

Kotlin custom plugin

```kotlin
// CustomPlugin.kt

import org.gradle.api.Plugin
import org.gradle.api.Project
import org.jetbrains.dokka.gradle.DokkaExtension

abstract class CustomPlugin : Plugin<Project> {
    override fun apply(project: Project) {
        project.plugins.apply("org.jetbrains.dokka")

        project.extensions.configure(DokkaExtension::class.java) { dokka ->

            dokka.moduleName.set(project.name)
            dokka.moduleVersion.set(project.version.toString())

            dokka.dokkaPublications.named("html") { publication ->
                // Standard output directory for HTML documentation
                publication.outputDirectory.set(project.layout.buildDirectory.dir("dokka/html"))
                publication.failOnWarning.set(true)
                publication.suppressInheritedMembers.set(true)
                publication.offlineMode.set(false)
                publication.suppressObviousFunctions.set(true)
                publication.includes.from("packages.md", "extra.md")

                // Output directory for additional files
                // Use this instead of the standard block when you
                // want to change the output directory and include extra files
                html.outputDirectory.set(project.rootDir.resolve("docs/api/0.x"))
            }
        }
    }
}
```

Gradle Groovy DSL

```
plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}

dokka {
    dokkaPublications {
        html {
            // Sets general module information
            moduleName.set(project.name)
            moduleVersion.set(project.version.toString())

            // Standard output directory for HTML documentation
            outputDirectory.set(layout.buildDirectory.dir("dokka/html"))

            // Core Dokka options
            failOnWarning.set(false)
            suppressInheritedMembers.set(false)
            suppressObviousFunctions.set(true)
            offlineMode.set(false)
            includes.from(files("packages.md", "extra.md"))

            // Output directory for additional files
            // Use this block instead of the standard when you want to
            // change the output directory and include extra files
            outputDirectory.set(file("$rootDir/docs/api/0.x"))
        }
    }
}
```

moduleName

The display name for the project's documentation. It appears in the table of contents, navigation, headers, and log messages. In multi-project builds, each subproject's `moduleName` is used as its section title in aggregated documentation.

Default: Gradle project name

moduleVersion

The subproject version displayed in the generated documentation. In single-project builds, it is used as the project version. In multi-project builds, each subproject's `moduleVersion` is used when aggregating documentation.

Default: Gradle project version

outputDirectory

The directory where the generated documentation is stored.

This setting applies to all documentation formats (HTML, Javadoc, etc.) generated by the `dokkaGenerate` task.

Default: `build/dokka/html`

Output directory for additional files

You can specify the output directory and include additional files for both single and multi-project builds. For multi-project builds, set the output directory and include additional files in the configuration of the root project.

failOnWarning

Determines whether Dokka should fail the build when a warning occurs during documentation generation. The process waits until all errors and warnings have been emitted first.

This setting works well with `reportUndocumented`.

Default: `false`

suppressInheritedMembers
Whether to suppress inherited members that aren't explicitly overridden in a given class.

Note: This suppresses functions such as `equals`, `hashCode`, and `toString`, but does not suppress synthetic functions such as `dataClass.componentN` and `dataClass.copy`. Use `suppressObviousFunctions` for that.

Default: `false`

suppressObviousFunctions
Whether to suppress obvious functions.

A function is considered to be obvious if it is:

- Inherited from `kotlin.Any`, `Kotlin.Enum`, `java.lang.Object` or `java.lang.Enum`, such as `equals`, `hashCode`, `toString`.
- Synthetic (generated by the compiler) and does not have any documentation, such as `dataClass.componentN` or `dataClass.copy`.

Default: `true`

offlineMode
Whether to resolve remote files and links over your network.

This includes package-lists used for generating links to external documentation.. For example, this allows to make classes from the standard library clickable in your documentation.

Setting this to `true` can significantly speed up build times in certain cases, but can also worsen user experience. For example, by not resolving class and member links from your dependencies, including the standard library.

Note: You can cache fetched files locally and provide them to Dokka as local paths. See the externalDocumentationLinks section.

Default: `false`

includes
A list of Markdown files that contain subproject and package documentation. The Markdown files must match the required format.

The contents of the specified files are parsed and embedded into documentation as subproject and package descriptions.

See Dokka Gradle example for an example of what it looks like and how to use it.

Source set configuration

Dokka allows configuring some options for Kotlin source sets:

Gradle Kotlin DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

dokka {
    // ..
    // General configuration section
    // ..

    // Source sets configuration
    dokkaSourceSets {
        // Example: Configuration exclusive to the 'linux' source set
        named("linux") {
            dependentSourceSets{named("native")}
            sourceRoots.from(file("linux/src"))
        }

        configureEach {
            suppress.set(false)
            displayName.set(name)
            documentedVisibilities.set(setOf(VisibilityModifier.Public)) // OR
documentedVisibilities(VisibilityModifier.Public)
            reportUndocumented.set(false)
            skipEmptyPackages.set(true)
            skipDeprecated.set(false)
            suppressGeneratedFiles.set(true)
            jdkVersion.set(8)
            languageVersion.set("1.7")
            apiVersion.set("1.7")
            sourceRoots.from(file("src"))
            classpath.from(file("libs/dependency.jar"))
            samples.from("samples/Basic.kt", "samples/Advanced.kt")

            sourceLink {
                // Source link section
            }
            perPackageOption {
                // Package options section
            }
            externalDocumentationLinks {
                // External documentation links section
            }
        }
    }
}
```

Gradle Groovy DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

dokka {
    // ..
    // General configuration section
    // ..

    dokkaSourceSets {
        // Example: Configuration exclusive to the 'linux' source set
        named("linux") {
            dependentSourceSets { named("native") }
            sourceRoots.from(file("linux/src"))
        }

        configureEach {
            suppress.set(false)
            displayName.set(name)
            documentedVisibilities.set([VisibilityModifier.Public] as Set) // OR
documentedVisibilities(VisibilityModifier.Public)
            reportUndocumented.set(false)
            skipEmptyPackages.set(true)
            skipDeprecated.set(false)
            suppressGeneratedFiles.set(true)
            jdkVersion.set(8)
            languageVersion.set("1.7")
            apiVersion.set("1.7")
            sourceRoots.from(file("src"))
            classpath.from(file("libs/dependency.jar"))
            samples.from("samples/Basic.kt", "samples/Advanced.kt")

            sourceLink {
                // Source link section
            }
            perPackageOption {
                // Package options section
            }
            externalDocumentationLinks {
                // External documentation links section
            }
        }
    }
}
```

suppress
Whether this source set should be skipped when generating documentation.

Default: `false`

displayName
The display name used to refer to this source set.

The name is used both externally (for example, as the source set name visible to documentation readers) and internally (for example, for logging messages of `reportUndocumented`).

By default, the value is deduced from information provided by the Kotlin Gradle plugin.

documentedVisibilities
Defines which visibility modifiers Dokka should include in the generated documentation.

Use them if you want to document `protected`, `internal`, and `private` declarations, as well as if you want to exclude `public` declarations and only document internal API.

Additionally, you can use Dokka's `documentedVisibilities()` function to add documented visibilities.

This can be configured for each individual package.

Default: `VisibilityModifier.Public`

reportUndocumented

Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

This can be configured for each individual package.

Default: `false`

skipEmptyPackages

Whether to skip packages that contain no visible declarations after various filters have been applied.

For example, if `skipDeprecated` is set to `true` and your package contains only deprecated declarations, it is considered to be empty.

Default: `true`

skipDeprecated

Whether to document declarations annotated with `@Deprecated`.

This can be configured for each individual package.

Default: `false`

suppressGeneratedFiles

Whether to document generated files.

Generated files are expected to be present under the `{project}/{buildDir}/generated` directory.

If set to `true`, it effectively adds all files from that directory to the `suppressedFiles` option, so you can configure it manually.

Default: `true`

suppressAnnotatedWith

A set of annotation fully qualified names (FQNs) to suppress declarations annotated with.

Any declaration annotated with one of these annotations is excluded from the generated documentation.

jdkVersion

The JDK version to use when generating external documentation links for Java types.

For example, if you use `java.util.UUID` in some public declaration signature, and this option is set to `8`, Dokka generates an external documentation link to JDK 8 Javadocs for it.

Default: `8`

languageVersion

The Kotlin language version used for setting up analysis and @sample environment.

By default, the latest language version available to Dokka's embedded compiler is used.

apiVersion

The Kotlin API version used for setting up analysis and @sample environment.

By default, it is deduced from `languageVersion`.

sourceRoots

The source code roots to be analyzed and documented. Acceptable inputs are directories and individual `.kt` and `.java` files.

By default, source roots are deduced from information provided by the Kotlin Gradle plugin.

classpath

The classpath for analysis and interactive samples.

This is useful if some types that come from dependencies are not resolved or picked up automatically.

This option accepts both `.jar` and `.klib` files.

By default, the classpath is deduced from information provided by the Kotlin Gradle plugin.

samples

A list of directories or files that contain sample functions which are referenced via the @sample KDoc tag.

Source link configuration

Configure source links to help readers find the source for each declaration in a remote repository. Use the `dokkaSourceSets.main {}` block for this configuration.

The `sourceLinks {}` configuration block allows you to add a `source` link to each signature that leads to the `remoteUrl` with a specific line number. The line number is configurable by setting `remoteLineSuffix`.

For an example, see the documentation for the `count()` function in `kotlinx.coroutines`.

The syntax of `build.gradle.kts` files differs from regular `.kt` files (such as those used for custom Gradle plugins) because Gradle's Kotlin DSL uses type-safe accessors:

Gradle Kotlin DSL

```
// build.gradle.kts

dokka {
    dokkaSourceSets.main {
        sourceLink {
            localDirectory.set(file("src/main/kotlin"))
            remoteUrl("https://github.com/your-repo")
            remoteLineSuffix.set("#L")
        }
    }
}
```

Kotlin custom plugin

```kotlin
// CustomPlugin.kt

import org.gradle.api.Plugin
import org.gradle.api.Project
import org.jetbrains.dokka.gradle.DokkaExtension

abstract class CustomPlugin : Plugin<Project> {
    override fun apply(project: Project) {
        project.plugins.apply("org.jetbrains.dokka")
        project.extensions.configure(DokkaExtension::class.java) { dokka ->
            dokka.dokkaSourceSets.named("main") { dss ->
                dss.includes.from("README.md")
                dss.sourceLink {
                    it.localDirectory.set(project.file("src/main/kotlin"))
                    it.remoteUrl("https://example.com/src")
                    it.remoteLineSuffix.set("#L")
                }
            }
        }
    }
}
```

Gradle Groovy DSL

```groovy
dokka {
    dokkaSourceSets {
        main {
            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl.set(new URI("https://github.com/your-repo"))
                remoteLineSuffix.set("#L")
            }
        }
    }
}
```

localDirectory

The path to the local source directory. The path must be relative to the root of the current project.

remoteUrl

The URL of the source code hosting service that can be accessed by documentation readers, like GitHub, GitLab, Bitbucket, or any hosting service that provides stable URLs for source files. This URL is used to generate source code links of declarations.

remoteLineSuffix

The suffix used to append the source code line number to the URL. This helps readers navigate not only to the file, but to the specific line number of the declaration.

The number itself is appended to the specified suffix. For example, if this option is set to `#L` and the line number is 10, the resulting URL suffix is `#L10`.

Suffixes used by popular services:

- GitHub: `#L`
- GitLab: `#L`

- Bitbucket: `#lines-`

Default: `#L`

Package options

The `perPackageOption` configuration block allows setting some options for specific packages matched by `matchingRegex`:

Gradle Kotlin DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

dokka {
    dokkaPublications.html {
        dokkaSourceSets.configureEach {
            perPackageOption {
                matchingRegex.set(".*api.*")
                suppress.set(false)
                skipDeprecated.set(false)
                reportUndocumented.set(false)
                documentedVisibilities.set(setOf(VisibilityModifier.Public)) // OR
documentedVisibilities(VisibilityModifier.Public)
            }
        }
    }
}
```

Gradle Groovy DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

dokka {
    dokkaPublications {
        html {
            dokkaSourceSets.configureEach {
                perPackageOption {
                    matchingRegex.set(".*api.*")
                    suppress.set(false)
                    skipDeprecated.set(false)
                    reportUndocumented.set(false)
                    documentedVisibilities.set([VisibilityModifier.Public] as Set)
                }
            }
        }
    }
}
```

matchingRegex

The regular expression that is used to match the package.

Default: `.*`

suppress

Whether the package should be skipped when generating documentation.

Default: `false`

skipDeprecated
Whether to document declarations annotated with `@Deprecated`.

This can be configured on the source set level.

Default: `false`

reportUndocumented
Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

This can be configured on the source set level.

Default: `false`

documentedVisibilities
Defines which visibility modifiers Dokka should include in the generated documentation.

Use them if you want to document `protected`, `internal`, and `private` declarations within this package, as well as if you want to exclude `public` declarations and only document internal API.

Additionally, you can use Dokka's `documentedVisibilities()` function to add documented visibilities.

This can be configured on the source set level.

Default: `VisibilityModifier.Public`

External documentation links configuration

The `externalDocumentationLinks {}` block allows the creation of links that lead to the externally hosted documentation of your dependencies.

For example, if you are using types from `kotlinx.serialization`, by default they are not clickable in your documentation, as if they are unresolved. However, since the API reference documentation for `kotlinx.serialization` is built by Dokka and is published on kotlinlang.org, you can configure external documentation links for it. This allows Dokka to generate links for types from the library, making them resolve successfully and clickable.

By default, external documentation links for Kotlin standard library, JDK, Android SDK, and AndroidX are configured.

Register external documentation links using the `register()` method to define each link. The `externalDocumentationLinks` API uses this method aligning with Gradle DSL conventions:

Gradle Kotlin DSL

```
dokka {
    dokkaSourceSets.configureEach {
        externalDocumentationLinks.register("example-docs") {
            url("https://example.com/docs/")
            packageListUrl("https://example.com/docs/package-list")
        }
    }
}
```

Gradle Groovy DSL

```
dokka {
    dokkaSourceSets.configureEach {
        externalDocumentationLinks.register("example-docs") {
            url.set(new URI("https://example.com/docs/"))
            packageListUrl.set(new URI("https://example.com/docs/package-list"))
        }
    }
}
```

url

The root URL of documentation to link to. It must contain a trailing slash.

Dokka does its best to automatically find `package-list` for the given URL, and link declarations together.

If the automatic resolution fails or if you want to use locally cached files instead, consider setting the `packageListUrl` option.

packageListUrl

The exact location of a `package-list`. This is an alternative to relying on Dokka automatically resolving it.

Package lists contain information about the documentation and the project itself, such as subproject and package names.

This can also be a locally cached file to avoid network calls.

Complete configuration

Below you can see all possible configuration options applied at the same time:

Gradle Kotlin DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}

dokka {
    dokkaPublications.html {
        moduleName.set(project.name)
        moduleVersion.set(project.version.toString())
        outputDirectory.set(layout.buildDirectory.dir("dokka/html"))
        failOnWarning.set(false)
        suppressInheritedMembers.set(false)
        suppressObviousFunctions.set(true)
        offlineMode.set(false)
        includes.from("packages.md", "extra.md")
   }

    dokkaSourceSets {
        // Example: Configuration exclusive to the 'linux' source set
        named("linux") {
            dependentSourceSets{named("native")}
            sourceRoots.from(file("linux/src"))
        }

        configureEach {
            suppress.set(false)
            displayName.set(name)
            documentedVisibilities.set(setOf(VisibilityModifier.Public)) // OR
documentedVisibilities(VisibilityModifier.Public)
            reportUndocumented.set(false)
            skipEmptyPackages.set(true)
            skipDeprecated.set(false)
            suppressGeneratedFiles.set(true)
            jdkVersion.set(8)
            languageVersion.set("1.7")
            apiVersion.set("1.7")
            sourceRoots.from(file("src"))
            classpath.from(file("libs/dependency.jar"))
            samples.from("samples/Basic.kt", "samples/Advanced.kt")

            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl("https://example.com/src")
                remoteLineSuffix.set("#L")
            }

            externalDocumentationLinks {
                url = URL("https://example.com/docs/")
                packageListUrl = File("/path/to/package-list").toURI().toURL()
            }

            perPackageOption {
                matchingRegex.set(".*api.*")
                suppress.set(false)
                skipDeprecated.set(false)
                reportUndocumented.set(false)
                documentedVisibilities.set(
                    setOf(
                        VisibilityModifier.Public,
```

```
                        VisibilityModifier.Private,
                        VisibilityModifier.Protected,
                        VisibilityModifier.Internal,
                        VisibilityModifier.Package
                    )
                )
            }
        }
    }
}
```

Gradle Groovy DSL

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}

dokka {
    dokkaPublications {
        html {
            moduleName.set(project.name)
            moduleVersion.set(project.version.toString())
            outputDirectory.set(layout.buildDirectory.dir("dokka/html"))
            failOnWarning.set(false)
            suppressInheritedMembers.set(false)
            suppressObviousFunctions.set(true)
            offlineMode.set(false)
            includes.from("packages.md", "extra.md")
        }
    }

    dokkaSourceSets {
        // Example: Configuration exclusive to the 'linux' source set
        named("linux") {
            dependentSourceSets { named("native") }
            sourceRoots.from(file("linux/src"))
        }

        configureEach {
            suppress.set(false)
            displayName.set(name)
            documentedVisibilities.set([VisibilityModifier.Public] as Set)
            reportUndocumented.set(false)
            skipEmptyPackages.set(true)
            skipDeprecated.set(false)
            suppressGeneratedFiles.set(true)
            jdkVersion.set(8)
            languageVersion.set("1.7")
            apiVersion.set("1.7")
            sourceRoots.from(file("src"))
            classpath.from(file("libs/dependency.jar"))
            samples.from("samples/Basic.kt", "samples/Advanced.kt")

            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl.set(new URI("https://example.com/src"))
                remoteLineSuffix.set("#L")
            }

            externalDocumentationLinks {
                url.set(new URI("https://example.com/docs/"))
                packageListUrl.set(new File("/path/to/package-list").toURI().toURL())
            }

            perPackageOption {
                matchingRegex.set(".*api.*")
                suppress.set(false)
                skipDeprecated.set(false)
                reportUndocumented.set(false)
                documentedVisibilities.set([
                        VisibilityModifier.Public,
```

```
                        VisibilityModifier.Private,
                        VisibilityModifier.Protected,
                        VisibilityModifier.Internal,
                        VisibilityModifier.Package
                ] as Set)
            }
        }
    }
}
```

Dokka Gradle troubleshooting

This page describes common issues you may encounter when generating documentation with Dokka in a Gradle build.

If your issue is not listed here, report any feedback or problems in our issue tracker or chat with the Dokka community in the official Kotlin Slack. Get a Slack invite here.

Memory issues

In large projects, Dokka can consume a significant amount of memory to generate documentation. This can exceed Gradle's memory limits, especially when processing large volumes of data.

When Dokka generation runs out of memory, the build fails, and Gradle can throw exceptions like `java.lang.OutOfMemoryError: Metaspace`.

Active efforts are underway to improve Dokka's performance, although some limitations stem from Gradle.

If you encounter memory issues, try these workarounds:

- Increasing heap space
- Running Dokka within the Gradle process

Increase heap space

One way to resolve memory issues is to increase the amount of Java heap memory for the Dokka generator process. In the `build.gradle.kts` file, adjust the following configuration option:

```
dokka {
        // Dokka generates a new process managed by Gradle
        dokkaGeneratorIsolation = ProcessIsolation {
            // Configures heap size
            maxHeapSize = "4g"
        }
    }
```

In this example, the maximum heap size is set to 4 GB (`"4g"`). Adjust and test the value to find the optimal setting for your build.

If you find that Dokka requires a considerably expanded heap size, for example, significantly higher than Gradle's own memory usage, create an issue on Dokka's GitHub repository.

> You have to apply this configuration to each subproject. It is recommended that you configure Dokka in a convention plugin applied to all subprojects.

Run Dokka within the Gradle process

When both the Gradle build and Dokka generation require a lot of memory, they may run as separate processes, consuming significant memory on a single machine.

To optimize memory usage, you can run Dokka within the same Gradle process instead of as a separate process. This allows you to configure the memory for Gradle once instead of allocating it separately for each process.

To run Dokka within the same Gradle process, adjust the following configuration option in the `build.gradle.kts` file:

```
dokka {
        // Runs Dokka in the current Gradle process
        dokkaGeneratorIsolation = ClassLoaderIsolation()
    }
```

As with increasing heap space, test this configuration to confirm it works well for your project.

For more details on configuring Gradle's JVM memory, see the Gradle documentation.

> Changing the Java options for Gradle launches a new Gradle daemon, which may stay alive for a long time. You can manually stop any other Gradle processes.
>
> Additionally, Gradle issues with the `ClassLoaderIsolation()` configuration may cause memory leaks.

Migrate to Dokka Gradle plugin v2

> This page is only relevant if you are using DGPv1 and want to migrate to DGPv2. Starting from Dokka 2.1.0, DGP v2 is enabled by default. If you are using Dokka 2.1.0 or later, you can skip this page and go directly to the Dokka Gradle docs.

The Dokka Gradle plugin (DGP) is a tool for generating comprehensive API documentation for Kotlin projects built with Gradle.

DGP seamlessly processes both Kotlin's KDoc comments and Java's Javadoc comments to extract information and create structured documentation in HTML or Javadoc format.

The Dokka Gradle plugin v2 mode is enabled by default and aligns with Gradle best practices:

- Adopts Gradle types, which leads to better performance.
- Uses an intuitive top-level DSL configuration instead of a low-level task-based setup, which simplifies the build scripts and their readability.
- Takes a more declarative approach to documentation aggregation, which makes multi-project documentation easier to manage.
- Uses a type-safe plugin configuration, which improves the reliability and maintainability of your build scripts.
- Fully supports Gradle configuration cache and build cache, which improves performance and simplifies build work.

Read this guide for further information on changes and migration from DGP v1 to v2 modes.

Before you start

Before starting the migration, complete the following steps.

Verify supported versions

Ensure that your project meets the minimum version requirements:

Tool	Version
Gradle	7.6 or higher
Android Gradle plugin	7.0 or higher
Kotlin Gradle plugin	1.9 or higher

Enable DGP v2

Update the Dokka version to 2.2.0 in the `plugins {}` block of your project's `build.gradle.kts` file:

```
plugins {
    kotlin("jvm") version "2.1.10"
    id("org.jetbrains.dokka") version "2.2.0"
}
```

Alternatively, you can use version catalog to enable the Dokka Gradle plugin v2.

By default, DGP v2 generates documentation in HTML format. To generate Javadoc or both HTML and Javadoc formats, add the appropriate plugins. For more information about the plugins, see Select documentation output format.

Enable migration helpers

In the project's `gradle.properties` file, set the following Gradle property to activate DGP v2 with helpers:

```
org.jetbrains.dokka.experimental.gradle.pluginMode=V2EnabledWithHelpers
```

If your project doesn't have a `gradle.properties` file, create one in the root directory of your project.

This property activates the DGP v2 plugin with migration helpers. These helpers prevent compilation errors when build scripts reference tasks from DGP v1 that are no longer available in DGP v2.

Migration helpers do not actively assist with the migration. They only keep your build script from breaking while you transition to the new API.

After completing the migration, disable the migration helpers.

Sync your project with Gradle

After enabling DGP v2 and migration helpers, sync your project with Gradle to ensure DGP v2 is properly applied:

- If you use IntelliJ IDEA, click the **Reload All Gradle Projects** button in the Gradle tool window.
- If you use Android Studio, select **File** | **Sync Project with Gradle Files**.

Migrate your project

After updating the Dokka Gradle plugin to v2, follow the migration steps applicable to your project.

Adjust configuration options

DGP v2 introduces some changes in the Gradle configuration options. In the `build.gradle.kts` file, adjust the configuration options according to your project setup.

Top-level DSL configuration in DGP v2

Replace the configuration syntax of DGP v1 with the top-level `dokka {}` DSL configuration of DGP v2:

Configuration in DGP v1:

```
tasks.withType<DokkaTask>().configureEach {
    suppressInheritedMembers.set(true)
    failOnWarning.set(true)
    dokkaSourceSets {
        named("main") {
            moduleName.set("Project Name")
            includes.from("README.md")
            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl.set(URL("https://example.com/src"))
                remoteLineSuffix.set("#L")
            }
        }
    }
}

tasks.dokkaHtml {
    pluginConfiguration<DokkaBase, DokkaBaseConfiguration> {
        customStyleSheets.set(listOf("styles.css"))
        customAssets.set(listOf("logo.png"))
        footerMessage.set("(c) Your Company")
    }
}
```

Configuration in DGP v2:

The syntax of `build.gradle.kts` files differs from regular `.kt` files (such as those used for custom Gradle plugins) because Gradle's Kotlin DSL uses type-safe accessors.

Gradle Kotlin DSL

```
// build.gradle.kts

dokka {
    moduleName.set("Project Name")
    dokkaPublications.html {
        suppressInheritedMembers.set(true)
        failOnWarning.set(true)
    }
    dokkaSourceSets.main {
        includes.from("README.md")
        sourceLink {
            localDirectory.set(file("src/main/kotlin"))
            remoteUrl("https://example.com/src")
            remoteLineSuffix.set("#L")
        }
    }
    pluginsConfiguration.html {
        customStyleSheets.from("styles.css")
        customAssets.from("logo.png")
        footerMessage.set("(c) Your Company")
    }
}
```

Kotlin custom plugin

```
// CustomPlugin.kt

import org.gradle.api.Plugin
import org.gradle.api.Project
import org.jetbrains.dokka.gradle.DokkaExtension
import org.jetbrains.dokka.gradle.engine.plugins.DokkaHtmlPluginParameters

abstract class CustomPlugin : Plugin<Project> {
    override fun apply(project: Project) {
        project.plugins.apply("org.jetbrains.dokka")

        project.extensions.configure(DokkaExtension::class.java) { dokka ->

            dokka.dokkaPublications.named("html") { publication ->
                publication.suppressInheritedMembers.set(true)
                publication.failOnWarning.set(true)
            }

            dokka.dokkaSourceSets.named("main") { dss ->
                dss.includes.from("README.md")
                dss.sourceLink {
                    it.localDirectory.set(project.file("src/main/kotlin"))
                    it.remoteUrl("https://example.com/src")
                    it.remoteLineSuffix.set("#L")
                }
            }

            dokka.pluginsConfiguration.named("html", DokkaHtmlPluginParameters::class.java) { html ->
                html.customStyleSheets.from("styles.css")
                html.customAssets.from("logo.png")
                html.footerMessage.set("(c) Your Company")
            }
        }
    }
}
```

Visibility settings

Set the `documentedVisibilities` property from `Visibility.PUBLIC` to `VisibilityModifier.Public`.

Configuration in DGP v1:

```
import org.jetbrains.dokka.DokkaConfiguration.Visibility

// ...
documentedVisibilities.set(
    setOf(Visibility.PUBLIC)
)
```

Configuration in DGP v2:

```
import org.jetbrains.dokka.gradle.engine.parameters.VisibilityModifier

// ...
documentedVisibilities.set(
    setOf(VisibilityModifier.Public)
)

// OR

documentedVisibilities(VisibilityModifier.Public)
```

Additionally, use DGP v2's utility function to add documented visibilities:

```
fun documentedVisibilities(vararg visibilities: VisibilityModifier): Unit =
    documentedVisibilities.set(visibilities.asList())
```

Source links

Configure source links to allow navigation from the generated documentation to the corresponding source code in a remote repository. Use the `dokkaSourceSets.main{}` block for this configuration.

Configuration in DGP v1:

```
tasks.withType<DokkaTask>().configureEach {
    dokkaSourceSets {
        named("main") {
            sourceLink {
                localDirectory.set(file("src/main/kotlin"))
                remoteUrl.set(URL("https://github.com/your-repo"))
                remoteLineSuffix.set("#L")
            }
        }
    }
}
```

Configuration in DGP v2:

The syntax of `build.gradle.kts` files differs from regular `.kt` files (such as those used for custom Gradle plugins) because Gradle's Kotlin DSL uses type-safe accessors.

Gradle Kotlin DSL

```
// build.gradle.kts

dokka {
    dokkaSourceSets.main {
        sourceLink {
            localDirectory.set(file("src/main/kotlin"))
            remoteUrl("https://github.com/your-repo")
            remoteLineSuffix.set("#L")
        }
    }
}
```

Kotlin custom plugin

```kotlin
// CustomPlugin.kt

import org.gradle.api.Plugin
import org.gradle.api.Project
import org.jetbrains.dokka.gradle.DokkaExtension

abstract class CustomPlugin : Plugin<Project> {
    override fun apply(project: Project) {
        project.plugins.apply("org.jetbrains.dokka")
        project.extensions.configure(DokkaExtension::class.java) { dokka ->
            dokka.dokkaSourceSets.named("main") { dss ->
                dss.includes.from("README.md")
                dss.sourceLink {
                    it.localDirectory.set(project.file("src/main/kotlin"))
                    it.remoteUrl("https://example.com/src")
                    it.remoteLineSuffix.set("#L")
                }
            }
        }
    }
}
```

Since the source link configuration has changed, use the `URI` class instead of `URL` to specify the remote URL.

Configuration in DGP v1:

```kotlin
remoteUrl.set(URL("https://github.com/your-repo"))
```

Configuration in DGP v2:

```kotlin
remoteUrl.set(URI("https://github.com/your-repo"))

// or

remoteUrl("https://github.com/your-repo")
```

Additionally, DGP v2 has two utility functions for setting the URL:

```kotlin
fun remoteUrl(@Language("http-url-reference") value: String): Unit =
    remoteUrl.set(URI(value))

// and

fun remoteUrl(value: Provider<String>): Unit =
    remoteUrl.set(value.map(::URI))
```

External documentation links

Register external documentation links using the `register()` method to define each link. The `externalDocumentationLinks` API uses this method aligning with Gradle DSL conventions.

Configuration in DGP v1:

```
tasks.dokkaHtml {
    dokkaSourceSets {
        configureEach {
            externalDocumentationLink {
                url = URL("https://example.com/docs/")
                packageListUrl = File("/path/to/package-list").toURI().toURL()
            }
        }
    }
}
```

Configuration in DGP v2:

```
dokka {
    dokkaSourceSets.configureEach {
        externalDocumentationLinks.register("example-docs") {
            url("https://example.com/docs/")
            packageListUrl("https://example.com/docs/package-list")
        }
    }
}
```

Custom assets

Use the `customAssets` property with collections of files (`FileCollection`) instead of lists (`var List<File>`).

Configuration in DGP v1:

```
customAssets = listOf(file("example.png"), file("example2.png"))
```

Configuration in DGP v2:

```
customAssets.from("example.png", "example2.png")
```

Output directory

Use the `dokka {}` block to specify the output directory for the generated Dokka documentation.

Configuration in DGP v1:

```
tasks.dokkaHtml {
    outputDirectory.set(layout.buildDirectory.dir("dokkaDir"))
}
```

Configuration in DGP v2:

```
dokka {
    dokkaPublications.html {
        outputDirectory.set(layout.buildDirectory.dir("dokkaDir"))
    }
}
```

Output directory for additional files

Specify the output directory and include additional files for both single-module and multi-module projects inside the `dokka {}` block.

In DGP v2, the configuration for single-module and multi-module projects is unified. Instead of configuring `dokkaHtml` and `dokkaHtmlMultiModule` tasks separately, specify the settings in `dokkaPublications.html {}` within the `dokka {}` block.

For multi-module projects, set the output directory and include additional files (such as `README.md`) in the configuration of the root project.

Configuration in DGP v1:

```
tasks.dokkaHtmlMultiModule {
    outputDirectory.set(rootDir.resolve("docs/api/0.x"))
    includes.from(project.layout.projectDirectory.file("README.md"))
}
```

Configuration in DGP v2:

The syntax of `build.gradle.kts` files differs from regular `.kt` files (such as those used for custom Gradle plugins) because Gradle's Kotlin DSL uses type-safe accessors.

Gradle Kotlin DSL

```
// build.gradle.kts

dokka {
    dokkaPublications.html {
        outputDirectory.set(rootDir.resolve("docs/api/0.x"))
        includes.from(project.layout.projectDirectory.file("README.md"))
    }
}
```

Kotlin custom plugin

```
// CustomPlugin.kt

import org.gradle.api.Plugin
import org.gradle.api.Project
import org.jetbrains.dokka.gradle.DokkaExtension

abstract class CustomPlugin : Plugin<Project> {
    override fun apply(project: Project) {
        project.plugins.apply("org.jetbrains.dokka")
        project.extensions.configure(DokkaExtension::class.java) { dokka ->
            dokka.dokkaPublications.named("html") { html ->
                html.outputDirectory.set(project.rootDir.resolve("docs/api/0.x"))
                html.includes.from(project.layout.projectDirectory.file("README.md"))
            }
        }
    }
}
```

Configure Dokka plugins

Configuring built-in Dokka plugins with JSON is deprecated in favor of a type-safe DSL. This change improves compatibility with Gradle's incremental build system and improves task input tracking.

Configuration in DGP v1:

In DGP v1, Dokka plugins were configured manually using JSON. This approach caused issues with registering task inputs for Gradle up-to-date checks.

Here is an example of the deprecated JSON-based configuration for the Dokka Versioning plugin:

```
tasks.dokkaHtmlMultiModule {
    pluginsMapConfiguration.set(
        mapOf(
            "org.jetbrains.dokka.versioning.VersioningPlugin" to """
                { "version": "1.2", "olderVersionsDir": "$projectDir/dokka-docs" }
                """.trimIndent()
        )
    )
}
```

Configuration in DGP v2:

In DGP v2, Dokka plugins are configured using type-safe DSL. To configure Dokka plugins in a type-safe way, use the `pluginsConfiguration{}` block:

```
dokka {
    pluginsConfiguration {
        versioning {
            version.set("1.2")
            olderVersionsDir.set(projectDir.resolve("dokka-docs"))
        }
    }
}
```

For an example of the DGP v2 configuration, see the Dokka's versioning plugin.

DGP v2 allows you to extend its functionality by configuring custom plugins. Custom plugins enable additional processing or modifications to the documentation generation process.

Share Dokka configuration across subprojects

DPG v2 moves away from using `subprojects {}` or `allprojects {}` to share configuration across subprojects. In future Gradle versions, using these approaches will lead to errors.

Follow the steps below to properly share Dokka configuration in multi-module projects with existing convention plugins or without convention plugins.

After sharing the Dokka configuration, you can aggregate the documentation from multiple subprojects into a single output. For more information, see Update documentation aggregation in multi-module projects.

For a multi-module project example, see the Dokka GitHub repository.

Multi-module projects without convention plugins

If your project doesn't use convention plugins, you can still share Dokka configurations by directly configuring each subproject. This involves manually setting up the shared configuration in each subproject's `build.gradle.kts` file. While this approach is less centralized, it avoids the need for additional setups like convention plugins.

Otherwise, if your project uses convention plugins, you can also share the Dokka configuration in multi-module projects by creating a convention plugin in the `buildSrc` directory, and then applying the plugin to your subprojects.

Set up the buildSrc directory

1. In your project root, create a `buildSrc` directory containing two files:
   - `settings.gradle.kts`
   - `build.gradle.kts`
2. In the `buildSrc/settings.gradle.kts` file, add the following snippet:

```
rootProject.name = "buildSrc"
```

3. In the `buildSrc/build.gradle.kts` file, add the following snippet:

```
plugins {
    `kotlin-dsl`
}

repositories {
    mavenCentral()
    gradlePluginPortal()
}

dependencies {
    implementation("org.jetbrains.dokka:dokka-gradle-plugin:2.2.0")
}
```

Set up the Dokka convention plugin

After setting up the `buildSrc` directory:

1. Create a `buildSrc/src/main/kotlin/dokka-convention.gradle.kts` file to host the convention plugin.
2. In the `dokka-convention.gradle.kts` file, add the following snippet:

```
plugins {
    id("org.jetbrains.dokka")
}

dokka {
    // The shared configuration goes here
}
```

You need to add the shared Dokka configuration common to all subprojects within the `dokka {}` block. Also, you don't need to specify a Dokka version. The version is already set in the `buildSrc/build.gradle.kts` file.

Apply the convention plugin to your subprojects

Apply the Dokka convention plugin across your subprojects by adding it to each subproject's `build.gradle.kts` file:

```
plugins {
    id("dokka-convention")
}
```

Multi-module projects with convention plugins

If you already have convention plugins, create a dedicated Dokka convention plugin following Gradle's documentation.

Then, follow the steps to set up the Dokka convention plugin and apply it across your subprojects.

Update documentation aggregation in multi-module projects

Dokka can aggregate the documentation from multiple subprojects into a single output or publication.

As explained, apply the Dokka plugin to all documentable subprojects before aggregating the documentation.

Aggregation in DGP v2 uses the `dependencies {}` block instead of tasks and can be added in any `build.gradle.kts` file.

In DGP v1, aggregation was implicitly created in the root project. To replicate this behavior in DGP v2, add the `dependencies {}` block in the `build.gradle.kts` file of the root project.

Aggregation in DGP v1:

```
tasks.dokkaHtmlMultiModule {
        // ...
    }
```

Aggregation in DGP v2:

```
dependencies {
    dokka(project(":some-subproject:"))
    dokka(project(":another-subproject:"))
}
```

Change directory of aggregated documentation

When DGP aggregates subprojects, each subproject has its own subdirectory within the aggregated documentation.

In DGP v2, the aggregation mechanism has been updated to better align with Gradle conventions. DGP v2 now preserves the full subproject directory to prevent conflicts when aggregating documentation in any location.

Aggregation directory in DGP v1:

In DGP v1, aggregated documentation was placed in a collapsed directory structure. For example, given a project with an aggregation in `:turbo-lib` and a nested subproject `:turbo-lib:maths`, the generated documentation was placed under:

```
turbo-lib/build/dokka/html/maths/
```

Aggregation directory in DGP v2:

DGP v2 ensures each subproject has a unique directory by retaining the full project structure. The same aggregated documentation now follows this structure:

```
turbo-lib/build/dokka/html/turbo-lib/maths/
```

This change prevents subprojects with the same name from clashing. However, since the directory structure has changed, external links may become outdated, potentially causing `404` errors.

Revert to the DGP v1 directory behavior

If your project depends on the directory structure used in DGP v1, you can revert this behavior by manually specifying the subproject directory. Add the following configuration to the `build.gradle.kts` file of each subproject:

```
// /turbo-lib/maths/build.gradle.kts

plugins {
    id("org.jetbrains.dokka")
}

dokka {
    // Overrides the subproject directory to match the V1 structure
    modulePath.set("maths")
}
```

Generate documentation with the updated task

DGP v2 has renamed the Gradle tasks that generate the API documentation.

Task in DGP v1:

```
./gradlew dokkaHtml

// or

./gradlew dokkaHtmlMultiModule
```

Task in DGP v2:

```
./gradlew :dokkaGenerate
```

The `dokkaGenerate` task generates the API documentation in the `build/dokka/` directory.

In the DGP v2 version, the `dokkaGenerate` task name works for both single and multi-module projects. You can use different tasks to generate output in HTML, Javadoc or both HTML and Javadoc. For more information, see Select documentation output format.

Select documentation output format

> The Javadoc output format is in Alpha. You may find bugs and experience migration issues when using it. Successful integration with tools that accept Javadoc as input is not guaranteed. Use it at your own risk.

The default output format for DGP v2 is HTML. However, you can choose to generate the API documentation in HTML, Javadoc, or both formats at the same time:

1. Place the corresponding plugin `id` in the `plugins {}` block of your project's `build.gradle.kts` file:

```
plugins {
    // Generates HTML documentation
    id("org.jetbrains.dokka") version "2.2.0"

    // Generates Javadoc documentation
    id("org.jetbrains.dokka-javadoc") version "2.2.0"

    // Keeping both plugin IDs generates both formats
}
```

2. Run the corresponding Gradle task.

Here is a list of the plugin `id` and Gradle task that correspond to each format:

	HTML	Javadoc	Both
Plugin `id`	`id("org.jetbrains.dokka")`	`id("org.jetbrains.dokka-javadoc")`	Use both HTML and Javadoc plugins
Gradle task	`./gradlew :dokkaGeneratePublicationHtml`	`./gradlew :dokkaGeneratePublicationJavadoc`	`./gradlew :dokkaGenerate`

> The `dokkaGenerate` task generates documentation in all available formats based on the applied plugins. If both the HTML and Javadoc plugins are applied, you can choose to generate only HTML by running the `dokkaGeneratePublicationHtml` task, or only Javadoc by running the `dokkaGeneratePublicationJavadoc` task.

If you're using IntelliJ IDEA, you may see the `dokkaGenerateHtml` Gradle task. This task is simply an alias of `dokkaGeneratePublicationHtml`. Both tasks perform exactly the same operation.

Address deprecations and removals

- **Output format support:** DGP v2 only supports HTML and Javadoc output. Experimental formats like Markdown and Jekyll are no longer supported.
- **Collector task:** `DokkaCollectorTask` has been removed. Now, you need to generate the documentation separately for each subproject and then aggregate the documentation if necessary.

Finalize your migration

After you've migrated your project, perform these steps to wrap up and improve performance.

Set the opt-in flag

After successful migration, set the following opt-in flag without helpers in the project's `gradle.properties` file:

```
org.jetbrains.dokka.experimental.gradle.pluginMode=V2Enabled
```

If you removed references to Gradle tasks from DGP v1 that are no longer available in DGP v2, you shouldn't see compilation errors related to it.

Enable build cache and configuration cache

DGP v2 now supports Gradle build cache and configuration cache, improving build performance.

- To enable build cache, follow instructions in the Gradle build cache documentation.
- To enable configuration cache, follow instructions in the Gradle configuration cache documentation.

What's next

- Explore more DGP v2 project examples.
- Get started with Dokka.
- Learn more about Dokka plugins.

Maven

To generate documentation for a Maven-based project, you can use the Maven plugin for Dokka.

> Compared to the Gradle plugin for Dokka, the Maven plugin has only basic features and does not provide support for multi-module builds.

You can play around with Dokka and see how it can be configured for a Maven project by visiting our Maven example project.

Apply Dokka

To apply Dokka, you need to add `dokka-maven-plugin` to the `plugins` section of your POM file:

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.dokka</groupId>
            <artifactId>dokka-maven-plugin</artifactId>
            <version>2.2.0</version>
            <executions>
                <execution>
                    <phase>pre-site</phase>
                    <goals>
                        <goal>dokka</goal>
                    </goals>
                </execution>
            </executions>
        </plugin>
    </plugins>
</build>
```

Generate documentation

The following goals are provided by the Maven plugin:

Goal	Description
`dokka:dokka`	Generates documentation with Dokka plugins applied. HTML format by default.

Experimental

Goal	Description
`dokka:javadoc`	Generates documentation in Javadoc format.
`dokka:javadocJar`	Generates a `javadoc.jar` file that contains documentation in Javadoc format.

Other output formats

By default, the Maven plugin for Dokka builds documentation in HTML output format.

All other output formats are implemented as Dokka plugins. In order to generate documentation in the desired format, you have to add it as a Dokka plugin to the configuration.

For example, to use the experimental GFM format, you have to add `gfm-plugin` artifact:

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    ...
    <configuration>
        <dokkaPlugins>
            <plugin>
                <groupId>org.jetbrains.dokka</groupId>
                <artifactId>gfm-plugin</artifactId>
                <version>2.2.0</version>
            </plugin>
        </dokkaPlugins>
    </configuration>
</plugin>
```

With this configuration, running the `dokka:dokka` goal produces documentation in GFM format.

To learn more about Dokka plugins, see Dokka plugins.

Build javadoc.jar

If you want to publish your library to a repository, you may need to provide a `javadoc.jar` file that contains API reference documentation of your library.

For example, if you want to publish to Maven Central, you must supply a `javadoc.jar` alongside your project. However, not all repositories have that rule.

Unlike the Gradle plugin for Dokka, the Maven plugin comes with a ready-to-use `dokka:javadocJar` goal. By default, it generates documentation in Javadoc output format in the `target` folder.

If you are not satisfied with the built-in goal or want to customize the output (for example, you want to generate documentation in HTML format instead of Javadoc), similar behavior can be achieved by adding the Maven JAR plugin with the following configuration:

```
<plugin>
    <groupId>org.apache.maven.plugins</groupId>
    <artifactId>maven-jar-plugin</artifactId>
    <version>3.3.0</version>
    <executions>
        <execution>
            <goals>
                <goal>test-jar</goal>
            </goals>
        </execution>
        <execution>
            <id>dokka-jar</id>
            <phase>package</phase>
            <goals>
                <goal>jar</goal>
            </goals>
            <configuration>
                <classifier>dokka</classifier>
                <classesDirectory>${project.build.directory}/dokka</classesDirectory>
                <skipIfEmpty>true</skipIfEmpty>
            </configuration>
        </execution>
    </executions>
</plugin>
```

The documentation and the `.jar` archive for it are then generated by running `dokka:dokka` and `jar:jar@dokka-jar` goals:

```
mvn dokka:dokka jar:jar@dokka-jar
```

If you publish your library to Maven Central, you can use services like javadoc.io to host your library's API documentation for free and without any setup. It takes documentation pages straight from the `javadoc.jar`. It works well with the HTML format as demonstrated in this example.

Configuration example

Maven's plugin configuration block can be used to configure Dokka.

Here is an example of a basic configuration that only changes the output location of your documentation:

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    ...
    <configuration>
        <outputDir>${project.basedir}/target/documentation/dokka</outputDir>
    </configuration>
</plugin>
```

Configuration options

Dokka has many configuration options to tailor your and your reader's experience.

Below are some examples and detailed descriptions for each configuration section. You can also find an example with all configuration options applied at the bottom of the page.

General configuration

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>

        <samples>
            <dir>${project.basedir}/samples</dir>
        </samples>
        <sourceLinks>
            <!-- Separate section -->
        </sourceLinks>
        <externalDocumentationLinks>
            <!-- Separate section -->
        </externalDocumentationLinks>
        <perPackageOptions>
            <!-- Separate section -->
        </perPackageOptions>
    </configuration>
</plugin>
```

skip
Whether to skip documentation generation.

Default: `false`

moduleName
The display name used to refer to the project/module. It's used for the table of contents, navigation, logging, etc.

Default: `{project.artifactId}`

outputDir
The directory to where documentation is generated, regardless of format.

Default: `{project.basedir}/target/dokka`

failOnWarning
Whether to fail documentation generation if Dokka has emitted a warning or an error. The process waits until all errors and warnings have been emitted first.

This setting works well with `reportUndocumented`.

Default: `false`

suppressObviousFunctions
Whether to suppress obvious functions.

A function is considered to be obvious if it is:

- Inherited from `kotlin.Any`, `Kotlin.Enum`, `java.lang.Object` or `java.lang.Enum`, such as `equals`, `hashCode`, `toString`.
- Synthetic (generated by the compiler) and does not have any documentation, such as `dataClass.componentN` or `dataClass.copy`.

Default: `true`

suppressInheritedMembers
Whether to suppress inherited members that aren't explicitly overridden in a given class.

Note: This can suppress functions such as `equals` / `hashCode` / `toString`, but cannot suppress synthetic functions such as `dataClass.componentN` and `dataClass.copy`. Use `suppressObviousFunctions` for that.

Default: `false`

offlineMode
Whether to resolve remote files/links over your network.

This includes package-lists used for generating external documentation links. For example, to make classes from the standard library clickable.

Setting this to `true` can significantly speed up build times in certain cases, but can also worsen documentation quality and user experience. For example, by not resolving class/member links from your dependencies, including the standard library.

Note: You can cache fetched files locally and provide them to Dokka as local paths. See `externalDocumentationLinks` section.

Default: `false`

sourceDirectories
The source code roots to be analyzed and documented. Acceptable inputs are directories and individual `.kt` / `.java` files.

Default: `{project.compileSourceRoots}`

documentedVisibilities
The set of visibility modifiers that should be documented.

This can be used if you want to document `protected` / `internal` / `private` declarations, as well as if you want to exclude `public` declarations and only document internal API.

Can be configured on per-package basis.

Default: `PUBLIC`

reportUndocumented
Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

This can be overridden at package level.

Default: `false`

skipDeprecated
Whether to document declarations annotated with `@Deprecated`.

This can be overridden at package level.

Default: `false`

skipEmptyPackages
Whether to skip packages that contain no visible declarations after various filters have been applied.

For example, if `skipDeprecated` is set to `true` and your package contains only deprecated declarations, it is considered to be empty.

Default: `true`

suppressedFiles
The directories or individual files that should be suppressed, meaning that declarations from them are not documented.

suppressAnnotatedWith
A list of annotation fully qualified names (FQNs) to suppress declarations annotated with.

Any declaration annotated with one of these annotations is excluded from the generated documentation.

jdkVersion
The JDK version to use when generating external documentation links for Java types.

For example, if you use `java.util.UUID` in some public declaration signature, and this option is set to `8`, Dokka generates an external documentation link to JDK 8 Javadocs for it.

Default: JDK 8

languageVersion
The Kotlin language version used for setting up analysis and @sample environment.

By default, the latest language version available to Dokka's embedded compiler is used.

apiVersion
The Kotlin API version used for setting up analysis and @sample environment.

By default, it is deduced from `languageVersion`.

noStdlibLink
Whether to generate external documentation links that lead to the API reference documentation of Kotlin's standard library.

Note: Links are generated when `noStdLibLink` is set to `false`.

Default: `false`

noJdkLink

Whether to generate external documentation links to JDK's Javadocs.

The version of JDK Javadocs is determined by the `jdkVersion` option.

Note: Links are generated when `noJdkLink` is set to `false`.

Default: `false`

includes
A list of Markdown files that contain module and package documentation

The contents of specified files are parsed and embedded into documentation as module and package descriptions.

classpath
The classpath for analysis and interactive samples.

This is useful if some types that come from dependencies are not resolved/picked up automatically. This option accepts both `.jar` and `.klib` files.

Default: `{project.compileClasspathElements}`

samples
A list of directories or files that contain sample functions which are referenced via @sample KDoc tag.

Source link configuration

The `sourceLinks` configuration block allows you to add a `source` link to each signature that leads to the `url` with a specific line number. (The line number is configurable by setting `lineSuffix`).

This helps readers to find the source code for each declaration.

For an example, see the documentation for the `count()` function in `kotlinx.coroutines`.

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    <!--   ...   -->
    <configuration>
        <sourceLinks>
            <link>
                <path>src</path>
                <url>https://github.com/kotlin/dokka/tree/master/src</url>
                <lineSuffix>#L</lineSuffix>
            </link>
        </sourceLinks>
    </configuration>
</plugin>
```

path
The path to the local source directory. The path must be relative to the root of the current module.

Note: Only Unix based paths are allowed, Windows-style paths will throw an error.

url
The URL of the source code hosting service that can be accessed by documentation readers, like GitHub, GitLab, Bitbucket, etc. This URL is used to generate source code links of declarations.

lineSuffix
The suffix used to append source code line number to the URL. This helps readers navigate not only to the file, but to the specific line number of the declaration.

The number itself is appended to the specified suffix. For example, if this option is set to `#L` and the line number is 10, the resulting URL suffix is `#L10`.

Suffixes used by popular services:

- GitHub: `#L`
- GitLab: `#L`
- Bitbucket: `#lines-`

External documentation links configuration

The `externalDocumentationLinks` block allows the creation of links that lead to the externally hosted documentation of your dependencies.

For example, if you are using types from `kotlinx.serialization`, by default they are unclickable in your documentation, as if they are unresolved. However, since the API reference documentation for `kotlinx.serialization` is built by Dokka and is published on kotlinlang.org, you can configure external documentation links for it. Thus allowing Dokka to generate links for types from the library, making them resolve successfully and clickable.

By default, external documentation links for Kotlin standard library and JDK are configured.

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    <!-- ... -->
    <configuration>
        <externalDocumentationLinks>
            <link>
                <url>https://kotlinlang.org/api/kotlinx.serialization/</url>
                <packageListUrl>file:/${project.basedir}/serialization.package.list</packageListUrl>
            </link>
        </externalDocumentationLinks>
    </configuration>
</plugin>
```

url

The root URL of documentation to link to. It must contain a trailing slash.

Dokka does its best to automatically find the `package-list` for the given URL, and link declarations together.

If automatic resolution fails or if you want to use locally cached files instead, consider setting the `packageListUrl` option.

packageListUrl

The exact location of a `package-list`. This is an alternative to relying on Dokka automatically resolving it.

Package lists contain information about the documentation and the project itself, such as module and package names.

This can also be a locally cached file to avoid network calls.

Package options

The `perPackageOptions` configuration block allows setting some options for specific packages matched by `matchingRegex`.

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    <!-- ... -->
    <configuration>
        <perPackageOptions>
            <packageOptions>
                <matchingRegex>.*api.*</matchingRegex>
                <suppress>false</suppress>
                <reportUndocumented>false</reportUndocumented>
                <skipDeprecated>false</skipDeprecated>
                <documentedVisibilities>
                    <visibility>PUBLIC</visibility>
                    <visibility>PRIVATE</visibility>
                    <visibility>PROTECTED</visibility>
                    <visibility>INTERNAL</visibility>
                    <visibility>PACKAGE</visibility>
                </documentedVisibilities>
            </packageOptions>
        </perPackageOptions>
    </configuration>
</plugin>
```

matchingRegex

The regular expression that is used to match the package.

Default: `.*`

suppress

Whether this package should be skipped when generating documentation.

Default: `false`

documentedVisibilities

The set of visibility modifiers that should be documented.

This can be used if you want to document `protected` / `internal` / `private` declarations within this package, as well as if you want to exclude `public` declarations and only document internal API.

Default: `PUBLIC`

skipDeprecated

Whether to document declarations annotated with `@Deprecated`.

This can be set on project/module level.

Default: `false`

reportUndocumented

Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

Default: `false`

Complete configuration

Below you can see all the possible configuration options applied at the same time.

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    <!-- ... -->
    <configuration>
        <skip>false</skip>
        <moduleName>${project.artifactId}</moduleName>
        <outputDir>${project.basedir}/target/documentation</outputDir>
        <failOnWarning>false</failOnWarning>
        <suppressObviousFunctions>true</suppressObviousFunctions>
        <suppressInheritedMembers>false</suppressInheritedMembers>
        <offlineMode>false</offlineMode>
        <sourceDirectories>
            <dir>${project.basedir}/src</dir>
        </sourceDirectories>
        <documentedVisibilities>
            <visibility>PUBLIC</visibility>
            <visibility>PRIVATE</visibility>
            <visibility>PROTECTED</visibility>
            <visibility>INTERNAL</visibility>
            <visibility>PACKAGE</visibility>
        </documentedVisibilities>
        <reportUndocumented>false</reportUndocumented>
        <skipDeprecated>false</skipDeprecated>
        <skipEmptyPackages>true</skipEmptyPackages>
        <suppressedFiles>
            <file>/path/to/dir</file>
            <file>/path/to/file</file>
        </suppressedFiles>
        <jdkVersion>8</jdkVersion>
        <languageVersion>1.7</languageVersion>
        <apiVersion>1.7</apiVersion>
        <noStdlibLink>false</noStdlibLink>
        <noJdkLink>false</noJdkLink>
        <includes>
            <include>packages.md</include>
            <include>extra.md</include>
        </includes>
        <classpath>${project.compileClasspathElements}</classpath>
        <samples>
            <dir>${project.basedir}/samples</dir>
        </samples>
        <sourceLinks>
            <link>
                <path>src</path>
                <url>https://github.com/kotlin/dokka/tree/master/src</url>
                <lineSuffix>#L</lineSuffix>
            </link>
        </sourceLinks>
        <externalDocumentationLinks>
            <link>
                <url>https://kotlinlang.org/api/core/kotlin-stdlib/</url>
                <packageListUrl>file:/${project.basedir}/stdlib.package.list</packageListUrl>
            </link>
        </externalDocumentationLinks>
        <perPackageOptions>
            <packageOptions>
                <matchingRegex>.*api.*</matchingRegex>
                <suppress>false</suppress>
                <reportUndocumented>false</reportUndocumented>
                <skipDeprecated>false</skipDeprecated>
                <documentedVisibilities>
                    <visibility>PUBLIC</visibility>
```

```
                    <visibility>PRIVATE</visibility>
                    <visibility>PROTECTED</visibility>
                    <visibility>INTERNAL</visibility>
                    <visibility>PACKAGE</visibility>
                </documentedVisibilities>
            </packageOptions>
        </perPackageOptions>
    </configuration>
</plugin>
```

CLI

If for some reason you cannot use Gradle or Maven build tools, Dokka has a command line (CLI) runner for generating documentation.

In comparison, it has the same, if not more, capabilities as the Gradle plugin for Dokka. Although it is considerably more difficult to set up as there is no autoconfiguration, especially in multiplatform and multi-module environments.

Get started

The CLI runner is published to Maven Central as a separate runnable artifact.

You can find it on Maven Central or download it directly.

With the `dokka-cli-2.2.0.jar` file saved on your computer, run it with the `-help` option to see all available configuration options and their description:

```
java -jar dokka-cli-2.2.0.jar -help
```

It also works for some nested options, such as `-sourceSet`:

```
java -jar dokka-cli-2.2.0.jar -sourceSet -help
```

Generate documentation

Prerequisites

Since there is no build tool to manage dependencies, you have to provide dependency `.jar` files yourself.

Listed below are the dependencies that you need for any output format:

Group	Artifact	Version	Link
`org.jetbrains.dokka`	`dokka-base`	2.2.0	download
`org.jetbrains.dokka`	`analysis-kotlin-symbols`	2.2.0	download

Below are the additional dependencies that you need for HTML output format:

Group	Artifact	Version	Link
`org.jetbrains.kotlinx`	`kotlinx-html-jvm`	0.8.0	download
`org.freemarker`	`freemarker`	2.3.31	download

Run with command line options

You can pass command line options to configure the CLI runner.

At the very least you need to provide the following options:

- `-pluginsClasspath` - a list of absolute/relative paths to downloaded dependencies, separated by semi-colons `;`
- `-sourceSet` - an absolute path to code sources to generate documentation for
- `-outputDir` - an absolute/relative path of the documentation output directory

```
java -jar dokka-cli-2.2.0.jar \
     -pluginsClasspath "./dokka-base-2.2.0.jar;./analysis-kotlin-symbols-2.2.0.jar;./kotlinx-html-jvm-0.8.0.jar;./freemarker-2.3.31.jar" \
     -sourceSet "-src /home/myCoolProject/src/main/kotlin" \
     -outputDir "./dokka/html"
```

Executing the given example generates documentation in HTML output format.

See Command line options for more configuration details.

Run with JSON configuration

It's possible to configure the CLI runner with JSON. In this case, you need to provide an absolute/relative path to the JSON configuration file as the first and only argument. All other configuration options are parsed from it.

```
java -jar dokka-cli-2.2.0.jar dokka-configuration.json
```

At the very least, you need the following JSON configuration file:

```
{
  "outputDir": "./dokka/html",
  "sourceSets": [
    {
      "sourceSetID": {
        "scopeId": "moduleName",
        "sourceSetName": "main"
      },
      "sourceRoots": [
        "/home/myCoolProject/src/main/kotlin"
      ]
    }
  ],
  "pluginsClasspath": [
    "./dokka-base-2.2.0.jar",
    "./kotlinx-html-jvm-0.8.0.jar",
    "./analysis-kotlin-symbols-2.2.0.jar",
    "./freemarker-2.3.31.jar"
  ]
}
```

See JSON configuration options for more details.

Other output formats

By default, the `dokka-base` artifact contains the HTML output format only.

All other output formats are implemented as Dokka plugins. In order to use them, you have to put them on the plugins classpath.

For example, if you want to generate documentation in the experimental GFM output format, you need to download and pass gfm-plugin's JAR (download) into the `pluginsClasspath` configuration option.

Via command line options:

```
java -jar dokka-cli-2.2.0.jar \
     -pluginsClasspath "./dokka-base-2.2.0.jar;...;./gfm-plugin-2.2.0.jar" \
     ...
```

Via JSON configuration:

```
{
  ...
  "pluginsClasspath": [
    "./dokka-base-2.2.0.jar",
    "...",
    "./gfm-plugin-2.2.0.jar"
  ],
  ...
}
```

With the GFM plugin passed to `pluginsClasspath`, the CLI runner generates documentation in the GFM output format.

For more information, see GFM and Javadoc pages.

Command line options

To see the list of all possible command line options and their detailed description, run:

```
java -jar dokka-cli-2.2.0.jar -help
```

Short summary:

Option	Description
`moduleName`	Name of the project/module.
`moduleVersion`	Documented version.
`outputDir`	Output directory path, `./dokka` by default.
`sourceSet`	Configuration for a Dokka source set. Contains nested configuration options.
`pluginsConfiguration`	Configuration for Dokka plugins.
`pluginsClasspath`	List of jars with Dokka plugins and their dependencies. Accepts multiple paths separated by semicolons.
`offlineMode`	Whether to resolve remote files/links over network.
`failOnWarning`	Whether to fail documentation generation if Dokka has emitted a warning or an error.
`delayTemplateSubstitution`	Whether to delay substitution of some elements. Used in incremental builds of multi-module projects.
`noSuppressObviousFunctions`	Whether to suppress obvious functions such as those inherited from `kotlin.Any` and `java.lang.Object`.
`includes`	Markdown files that contain module and package documentation. Accepts multiple values separated by semicolons.
`suppressInheritedMembers`	Whether to suppress inherited members that aren't explicitly overridden in a given class.
`globalPackageOptions`	Global list of package configuration options in format `"matchingRegex,-deprecated,-privateApi,+warnUndocumented,+suppress;+visibility:PUBLIC;..."`. Accepts multiple values separated by semicolons.
`globalLinks`	Global external documentation links in format `{url}^{packageListUrl}`. Accepts multiple values separated by `^^`.

Option	Description
`globalSrcLink`	Global mapping between a source directory and a Web service for browsing the code. Accepts multiple paths separated by semicolons.
`helpSourceSet`	Prints help for the nested `-sourceSet` configuration.
`loggingLevel`	Logging level, possible values: `DEBUG, PROGRESS, INFO, WARN, ERROR`.
`help, h`	Usage info.

Source set options

To see the list of command line options for the nested `-sourceSet` configuration, run:

```
java -jar dokka-cli-2.2.0.jar -sourceSet -help
```

Short summary:

Option	Description
`sourceSetName`	Name of the source set.
`displayName`	Display name of the source set, used both internally and externally.
`classpath`	Classpath for analysis and interactive samples. Accepts multiple paths separated by semicolons.
`src`	Source code roots to be analyzed and documented. Accepts multiple paths separated by semicolons.
`dependentSourceSets`	Names of the dependent source sets in format `moduleName/sourceSetName`. Accepts multiple values separated by semicolons.
`samples`	List of directories or files that contain sample functions. Accepts multiple paths separated by semicolons.
`includes`	Markdown files that contain module and package documentation. Accepts multiple paths separated by semicolons.
`documentedVisibilities`	Visibilities to be documented. Accepts multiple values separated by semicolons. Possible values: `PUBLIC`, `PRIVATE`, `PROTECTED`, `INTERNAL`, `PACKAGE`.
`reportUndocumented`	Whether to report undocumented declarations.

Option	Description
`noSkipEmptyPackages`	Whether to create pages for empty packages.
`skipDeprecated`	Whether to skip deprecated declarations.
`jdkVersion`	Version of JDK to use for linking to JDK Javadocs.
`languageVersion`	Language version used for setting up analysis and samples.
`apiVersion`	Kotlin API version used for setting up analysis and samples.
`noStdlibLink`	Whether to generate links to the Kotlin standard library.
`noJdkLink`	Whether to generate links to JDK Javadocs.
`suppressedFiles`	Paths to files to be suppressed. Accepts multiple paths separated by semicolons.
`suppressAnnotatedWith`	Annotation fully qualified names (FQNs) to suppress declarations annotated with. Accepts multiple values separated by semicolons.
`analysisPlatform`	Platform used for setting up analysis.
`perPackageOptions`	List of package source set configurations in format `matchingRegexp,-deprecated,-privateApi,+warnUndocumented,+suppress;...`. Accepts multiple values separated by semicolons.
`externalDocumentationLinks`	External documentation links in format `{url}^{packageListUrl}`. Accepts multiple values separated by `^^`.
`srcLink`	Mapping between a source directory and a Web service for browsing the code. Accepts multiple paths separated by semicolons.

JSON configuration

Below are some examples and detailed descriptions for each configuration section. You can also find an example with all configuration options applied at the bottom of the page.

General configuration

```
{
  "moduleName": "Dokka Example",
  "moduleVersion": null,
  "outputDir": "./build/dokka/html",
  "failOnWarning": false,
  "suppressObviousFunctions": true,
  "suppressInheritedMembers": false,
  "offlineMode": false,
  "includes": [
    "module.md"
  ],
  "sourceLinks":  [
    { "_comment": "Options are described in a separate section" }
  ],
  "perPackageOptions": [
    { "_comment": "Options are described in a separate section" }
  ],
  "externalDocumentationLinks":  [
    { "_comment": "Options are described in a separate section" }
  ],
  "sourceSets": [
    { "_comment": "Options are described in a separate section" }
  ],
  "pluginsClasspath": [
    "./dokka-base-2.2.0.jar",
    "./kotlinx-html-jvm-0.8.0.jar",
    "./analysis-kotlin-symbols-2.2.0.jar",
    "./freemarker-2.3.31.jar"
  ]
}
```

moduleName
The display name used to refer to the module. It is used for the table of contents, navigation, logging, etc.

Default: `root`

moduleVersion
The module version.

Default: empty

outputDirectory
The directory to where documentation is generated, regardless of output format.

Default: `./dokka`

failOnWarning
Whether to fail documentation generation if Dokka has emitted a warning or an error. The process waits until all errors and warnings have been emitted first.

This setting works well with `reportUndocumented`

Default: `false`

suppressObviousFunctions
Whether to suppress obvious functions.

A function is considered to be obvious if it is:

- Inherited from `kotlin.Any`, `Kotlin.Enum`, `java.lang.Object` or `java.lang.Enum`, such as `equals`, `hashCode`, `toString`.

- Synthetic (generated by the compiler) and does not have any documentation, such as `dataClass.componentN` or `dataClass.copy`.

Default: `true`

suppressInheritedMembers
Whether to suppress inherited members that aren't explicitly overridden in a given class.

Note: This can suppress functions such as `equals` / `hashCode` / `toString`, but cannot suppress synthetic functions such as `dataClass.componentN` and `dataClass.copy`. Use `suppressObviousFunctions` for that.

Default: `false`

offlineMode
Whether to resolve remote files/links over your network.

This includes package-lists used for generating external documentation links. For example, to make classes from the standard library clickable.

Setting this to `true` can significantly speed up build times in certain cases, but can also worsen documentation quality and user experience. For example, by not resolving class/member links from your dependencies, including the standard library.

Note: You can cache fetched files locally and provide them to Dokka as local paths. See `externalDocumentationLinks` section.

Default: `false`

includes
A list of Markdown files that contain module and package documentation.

The contents of specified files are parsed and embedded into documentation as module and package descriptions.

This can be configured on per-package basis.

sourceSets
Individual and additional configuration of Kotlin source sets.

For a list of possible options, see source set configuration.

sourceLinks
The global configuration of source links that is applied for all source sets.

For a list of possible options, see source link configuration.

perPackageOptions
The global configuration of matched packages, regardless of the source set they are in.

For a list of possible options, see per-package configuration.

externalDocumentationLinks
The global configuration of external documentation links, regardless of the source set they are used in.

For a list of possible options, see external documentation links configuration.

pluginsClasspath
A list of JAR files with Dokka plugins and their dependencies.

Source set configuration

How to configure Kotlin source sets:

```
{
  "sourceSets": [
    {
      "displayName": "jvm",
      "sourceSetID": {
        "scopeId": "moduleName",
        "sourceSetName": "main"
      },
      "dependentSourceSets": [
        {
          "scopeId": "dependentSourceSetScopeId",
          "sourceSetName": "dependentSourceSetName"
        }
      ],
      "documentedVisibilities": ["PUBLIC", "PRIVATE", "PROTECTED", "INTERNAL", "PACKAGE"],
      "reportUndocumented": false,
      "skipEmptyPackages": true,
      "skipDeprecated": false,
      "jdkVersion": 8,
      "languageVersion": "1.7",
      "apiVersion": "1.7",
      "noStdlibLink": false,
      "noJdkLink": false,
      "includes": [
        "module.md"
      ],
      "analysisPlatform": "jvm",
      "sourceRoots": [
        "/home/ignat/IdeaProjects/dokka-debug-mvn/src/main/kotlin"
      ],
      "classpath": [
        "libs/kotlin-stdlib-2.4.20.jar",
        "libs/kotlin-stdlib-common-2.4.20.jar"
      ],
      "samples": [
        "samples/basic.kt"
      ],
      "suppressedFiles": [
        "src/main/kotlin/org/jetbrains/dokka/Suppressed.kt"
      ],
      "sourceLinks":  [
        { "_comment": "Options are described in a separate section" }
      ],
      "perPackageOptions": [
        { "_comment": "Options are described in a separate section" }
      ],
      "externalDocumentationLinks":  [
        { "_comment": "Options are described in a separate section" }
      ]
    }
  ]
}
```

displayName

The display name used to refer to this source set.

The name is used both externally (for example, the source set name is visible to documentation readers) and internally (for example, for logging messages of `reportUndocumented`).

The platform name can be used if you don't have a better alternative.

sourceSetID

The technical ID of the source set

documentedVisibilities
The set of visibility modifiers that should be documented.

This can be used if you want to document `protected` / `internal` / `private` declarations, as well as if you want to exclude `public` declarations and only document internal API.

This can be configured on per-package basis.

Possible values:

- `PUBLIC`
- `PRIVATE`
- `PROTECTED`
- `INTERNAL`
- `PACKAGE`

Default: `PUBLIC`

reportUndocumented
Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

This can be configured on per-package basis.

Default: `false`

skipEmptyPackages
Whether to skip packages that contain no visible declarations after various filters have been applied.

For example, if `skipDeprecated` is set to `true` and your package contains only deprecated declarations, it is considered to be empty.

Default for CLI runner is `false`.

skipDeprecated
Whether to document declarations annotated with `@Deprecated`.

This can be configured on per-package basis.

Default: `false`

jdkVersion
The JDK version to use when generating external documentation links for Java types.

For example, if you use `java.util.UUID` in some public declaration signature, and this option is set to `8`, Dokka generates an external documentation link to JDK 8 Javadocs for it.

languageVersion
The Kotlin language version used for setting up analysis and @sample environment.

apiVersion
The Kotlin API version used for setting up analysis and @sample environment.

noStdlibLink
Whether to generate external documentation links that lead to the API reference documentation of Kotlin's standard library.

Note: Links are generated when `noStdLibLink` is set to `false`.

Default: `false`

noJdkLink
Whether to generate external documentation links to JDK's Javadocs.

The version of JDK Javadocs is determined by the `jdkVersion` option.

Note: Links are generated when `noJdkLink` is set to `false`.

Default: `false`

includes
A list of Markdown files that contain module and package documentation.

The contents of the specified files are parsed and embedded into documentation as module and package descriptions.

analysisPlatform
Platform to be used for setting up code analysis and @sample environment.

Possible values:

- `jvm`
- `common`
- `js`
- `native`

sourceRoots
The source code roots to be analyzed and documented. Acceptable inputs are directories and individual `.kt` / `.java` files.

classpath
The classpath for analysis and interactive samples.

This is useful if some types that come from dependencies are not resolved/picked up automatically.

This option accepts both `.jar` and `.klib` files.

samples
A list of directories or files that contain sample functions which are referenced via the @sample KDoc tag.

suppressedFiles
The files to be suppressed when generating documentation.

suppressAnnotatedWith
A list of annotation fully qualified names (FQNs) to suppress declarations annotated with.

Any declaration annotated with one of these annotations is excluded from the generated documentation.

sourceLinks
A set of parameters for source links that is applied only for this source set.

For a list of possible options, see source link configuration.

perPackageOptions
A set of parameters specific to matched packages within this source set.

For a list of possible options, see per-package configuration.

externalDocumentationLinks
A set of parameters for external documentation links that is applied only for this source set.

For a list of possible options, see external documentation links configuration.

Source link configuration

The `sourceLinks` configuration block allows you to add a `source` link to each signature that leads to the `remoteUrl` with a specific line number. (The line number is configurable by setting `remoteLineSuffix`).

This helps readers to find the source code for each declaration.

For an example, see the documentation for the `count()` function in `kotlinx.coroutines`.

You can configure source links for all source sets together at the same time, or individually:

```
{
  "sourceLinks": [
    {
      "localDirectory": "src/main/kotlin",
      "remoteUrl": "https://github.com/Kotlin/dokka/tree/master/src/main/kotlin",
      "remoteLineSuffix": "#L"
    }
  ]
}
```

localDirectory

The path to the local source directory.

remoteUrl

The URL of the source code hosting service that can be accessed by documentation readers, like GitHub, GitLab, Bitbucket, etc. This URL is used to generate source code links of declarations.

remoteLineSuffix

The suffix used to append the source code line number to the URL. This helps readers navigate not only to the file, but to the specific line number of the declaration.

The number itself is appended to the specified suffix. For example, if this option is set to `#L` and the line number is 10, the resulting URL suffix is `#L10`.

Suffixes used by popular services:

- GitHub: `#L`
- GitLab: `#L`
- Bitbucket: `#lines-`

Default: empty (no suffix)

Per-package configuration

The `perPackageOptions` configuration block allows setting some options for specific packages matched by `matchingRegex`.

You can add package configurations for all source sets together at the same time, or individually:

```
{
  "perPackageOptions": [
    {
      "matchingRegex": ".*internal.*",
      "suppress": false,
      "skipDeprecated": false,
      "reportUndocumented": false,
      "documentedVisibilities": ["PUBLIC", "PRIVATE", "PROTECTED", "INTERNAL", "PACKAGE"]
    }
  ]
}
```

matchingRegex
The regular expression that is used to match the package.

suppress
Whether this package should be skipped when generating documentation.

Default: `false`

skipDeprecated
Whether to document declarations annotated with `@Deprecated`.

This can be set on project/module level.

Default: `false`

reportUndocumented
Whether to emit warnings about visible undocumented declarations, that is declarations without KDocs after they have been filtered by `documentedVisibilities` and other filters.

This setting works well with `failOnWarning`.

This can be configured on source set level.

Default: `false`

documentedVisibilities
The set of visibility modifiers that should be documented.

This can be used if you want to document `protected` / `internal` / `private` declarations within this package, as well as if you want to exclude `public` declarations and only document internal API.

Can be configured on source set level.

Default: `PUBLIC`

External documentation links configuration

The `externalDocumentationLinks` block allows the creation of links that lead to the externally hosted documentation of your dependencies.

For example, if you are using types from `kotlinx.serialization`, by default they are unclickable in your documentation, as if they are unresolved. However, since the API reference documentation for `kotlinx.serialization` is built by Dokka and is published on kotlinlang.org, you can configure external documentation links for it. Thus allowing Dokka to generate links for types from the library, making them resolve successfully and clickable.

You can configure external documentation links for all source sets together at the same time, or individually:

```
{
  "externalDocumentationLinks": [
    {
      "url": "https://kotlinlang.org/api/kotlinx.serialization/",
      "packageListUrl": "https://kotlinlang.org/api/kotlinx.serialization/package-list"
    }
  ]
}
```

url

The root URL of documentation to link to. It must contain a trailing slash.

Dokka does its best to automatically find `package-list` for the given URL, and link declarations together.

If automatic resolution fails or if you want to use locally cached files instead, consider setting the `packageListUrl` option.

packageListUrl

The exact location of a `package-list`. This is an alternative to relying on Dokka automatically resolving it.

Package lists contain information about the documentation and the project itself, such as module and package names.

This can also be a locally cached file to avoid network calls.

Complete configuration

Below you can see all possible configuration options applied at the same time.

```
{
  "moduleName": "Dokka Example",
  "moduleVersion": null,
  "outputDir": "./build/dokka/html",
  "failOnWarning": false,
  "suppressObviousFunctions": true,
  "suppressInheritedMembers": false,
  "offlineMode": false,
  "suppressAnnotatedWith": [
    "com.example.SuppressMe"
  ],
  "sourceLinks": [
    {
      "localDirectory": "src/main/kotlin",
      "remoteUrl": "https://github.com/Kotlin/dokka/tree/master/src/main/kotlin",
      "remoteLineSuffix": "#L"
    }
  ],
  "externalDocumentationLinks": [
    {
      "url": "https://docs.oracle.com/javase/8/docs/api/",
      "packageListUrl": "https://docs.oracle.com/javase/8/docs/api/package-list"
    },
    {
      "url": "https://kotlinlang.org/api/core/kotlin-stdlib/",
      "packageListUrl": "https://kotlinlang.org/api/core/kotlin-stdlib/package-list"
    }
  ],
  "perPackageOptions": [
    {
      "matchingRegex": ".*internal.*",

}
```

HTML

This guide applies to Dokka Gradle plugin (DGP) v2 mode. The DGP v1 mode is no longer supported. To upgrade from v1 to v2 mode, follow the Migration guide.

HTML is Dokka's default and recommended output format. It provides support for Kotlin Multiplatform, Android, and Java projects. Additionally, you can use the HTML format to document both single and multi-project builds.

For examples of the HTML output format, check the following docs:

- kotlinx.coroutines
- Bitmovin
- Hexagon
- Ktor
- OkHttp
- Gradle

Generate HTML documentation

HTML as an output format is supported by all runners. To generate HTML documentation, follow these steps depending on your build tool or runner:

- For Gradle, you can run the following tasks:
  - `dokkaGenerate` to generate documentation in all available formats based on the applied plugins. This is the recommended task for most users. When using this task in IntelliJ IDEA, it logs a clickable link to the output.
  - `dokkaGeneratePublicationHtml` to generate documentation only in HTML format. This task exposes the output directory as an `@OutputDirectory`. Use this task when you need to consume the generated files in other Gradle tasks, such as uploading them to a server, moving them into a GitHub Pages directory, or packaging them into a `javadoc.jar`. This task is intentionally not listed in Gradle task groups because it is not meant for everyday use.

    If you're using IntelliJ IDEA, you may see the `dokkaGenerateHtml` Gradle task. This task is simply an alias of `dokkaGeneratePublicationHtml`. Both tasks perform exactly the same operation.

- For Maven, run the `dokka:dokka` goal.
- For CLI runner, run with HTML dependencies set.

HTML pages generated by this format need to be hosted on a web server in order to render everything correctly.

You can use any free static site hosting service, such as GitHub Pages.

Locally, you can use the built-in IntelliJ web server.

Configuration

HTML format is Dokka's base format. You can configure it using the following options:

Gradle Kotlin DSL

```
// build.gradle.kts

dokka {
    pluginsConfiguration.html {
        customAssets.from("logo.png")
        customStyleSheets.from("styles.css")
        footerMessage.set("(c) Your Company")
        separateInheritedMembers.set(false)
        templatesDir.set(file("dokka/templates"))
        mergeImplicitExpectActualDeclarations.set(false)
    }
}
```

Gradle Groovy DSL

```
// build.gradle

dokka {
    pluginsConfiguration {
        html {
            customAssets.from("logo.png")
            customStyleSheets.from("styles.css")
            footerMessage.set("(c) Your Company")
            separateInheritedMembers.set(false)
            templatesDir.set(file("dokka/templates"))
            mergeImplicitExpectActualDeclarations.set(false)
        }
    }
}
```

Maven

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    ...
    <configuration>
        <pluginsConfiguration>
            <!-- Fully qualified plugin name -->
            <org.jetbrains.dokka.base.DokkaBase>
                <!-- Options by name -->
                <customAssets>
                    <asset>${project.basedir}/my-image.png</asset>
                </customAssets>
                <customStyleSheets>
                    <stylesheet>${project.basedir}/my-styles.css</stylesheet>
                </customStyleSheets>
                <footerMessage>(c) MyOrg 2022 Maven</footerMessage>
                <separateInheritedMembers>false</separateInheritedMembers>
                <templatesDir>${project.basedir}/dokka/templates</templatesDir>
                <mergeImplicitExpectActualDeclarations>false</mergeImplicitExpectActualDeclarations>
            </org.jetbrains.dokka.base.DokkaBase>
        </pluginsConfiguration>
    </configuration>
</plugin>
```

Via command line options:

CLI

```
java -jar dokka-cli-2.2.0.jar \
     ...
     -pluginsConfiguration "org.jetbrains.dokka.base.DokkaBase={\"customAssets\": [\"my-image.png\"],
\"customStyleSheets\": [\"my-styles.css\"], \"footerMessage\": \"(c) 2022 MyOrg\",
\"separateInheritedMembers\": false, \"templatesDir\": \"dokka/templates\",
\"mergeImplicitExpectActualDeclarations\": false}
"
```

Via JSON configuration:

```
{
  "moduleName": "Dokka Example",
  "pluginsConfiguration": [
    {
      "fqPluginName": "org.jetbrains.dokka.base.DokkaBase",
      "serializationFormat": "JSON",
      "values": "{\"customAssets\": [\"my-image.png\"], \"customStyleSheets\": [\"my-styles.css\"],
\"footerMessage\": \"(c) 2022 MyOrg\", \"separateInheritedMembers\": false, \"templatesDir\":
\"dokka/templates\", \"mergeImplicitExpectActualDeclarations\": false}"
    }
  ]
}
```

Configuration options

The table below contains all the possible configuration options and their purpose:

Option	Description
`customAssets`	List of paths for image assets to be bundled with documentation. The image assets can have any file extension. For more information, see Customizing assets.
`customStyleSheets`	List of paths for `.css` stylesheets to be bundled with documentation and used for rendering. For more information, see Customizing styles.
`templatesDir`	Path to the directory containing custom HTML templates. For more information, see Templates.
`footerMessage`	The text displayed in the footer.
`separateInheritedMembers`	This is a boolean option. If set to `true`, Dokka renders properties/functions and inherited properties/inherited functions separately. This is disabled by default.
`mergeImplicitExpectActualDeclarations`	This is a boolean option. If set to `true`, Dokka merges declarations that are not declared as expect/actual, but have the same fully qualified name. This can be useful for legacy codebases. This is disabled by default.

For more information about configuring Dokka plugins, see Configuring Dokka plugins.

Customization

To help you add your own look and feel to your documentation, the HTML format supports a number of customization options.

Customize styles

You can use your own stylesheets by using the `customStyleSheets` configuration option. These are applied to every page.

It's also possible to override Dokka's default stylesheets by providing files with the same name:

Stylesheet name	Description
`style.css`	Main stylesheet, contains most of the styles used across all pages
`logo-styles.css`	Header logo styling
`prism.css`	Styles for PrismJS syntax highlighter

The source code for all of Dokka's stylesheets is available on GitHub.

Customize assets

You can provide your own images to be bundled with documentation by using the `customAssets` configuration option.

These files are copied to the `<output>/images` directory.

You can use the `customAssets` property with collections of files (`FileCollection`):

```
customAssets.from("example.png", "example2.png")
```

It's possible to override Dokka's images and icons by providing files with the same name. The most useful and relevant one is `logo-icon.svg` , which is the image used in the header. The rest is mostly icons.

You can find all images used by Dokka on GitHub.

Change the logo

To customize the logo, you can begin by providing your own asset for `logo-icon.svg` .

If you don't like how it looks, or you want to use a `.png` file instead of the default `.svg` file, you can override the `logo-styles.css` stylesheet to customize it.

For an example of how to do this, see our custom format example project.

The maximum supported logo dimensions are 120 pixels in width and 36 pixels in height. If you use a larger image, it will be automatically resized.

Modify the footer

You can modify text in the footer by using the `footerMessage` configuration option.

Templates

Dokka provides the ability to modify FreeMarker templates used for generating documentation pages.

You can change the header completely, add your own banners/menus/search, load analytics, change body styling, and so on.

Dokka uses the following templates:

Template	Description
`base.ftl`	Defines the general design of all pages to be rendered.
`includes/header.ftl`	The page header that by default contains the logo, version, source set selector, light/dark theme switch, and search.
`includes/footer.ftl`	The page footer that contains the `footerMessage` configuration option and copyright.
`includes/page_metadata.ftl`	Metadata used within `<head>` container.

Template	Description
`includes/source_set_selector.ftl`	The source set selector in the header.

The base template is `base.ftl` and it includes all the remaining listed templates. You can find the source code for all of Dokka's templates on GitHub.

You can override any template by using the `templatesDir` configuration option. Dokka searches for the exact template names within the given directory. If it fails to find user-defined templates, it uses the default templates.

Variables

The following variables are available inside all templates:

Variable	Description
`${pageName}`	The page name
`${footerMessage}`	The text which is set by the `footerMessage` configuration option
`${sourceSets}`	A nullable list of source sets for multi-platform pages. Each item has `name`, `platform`, and `filter` properties.
`${projectName}`	The project name. It's available only within the `template_cmd` directive.
`${pathToRoot}`	The path to root from the current page. It's useful for locating assets and is available only within the `template_cmd` directive.

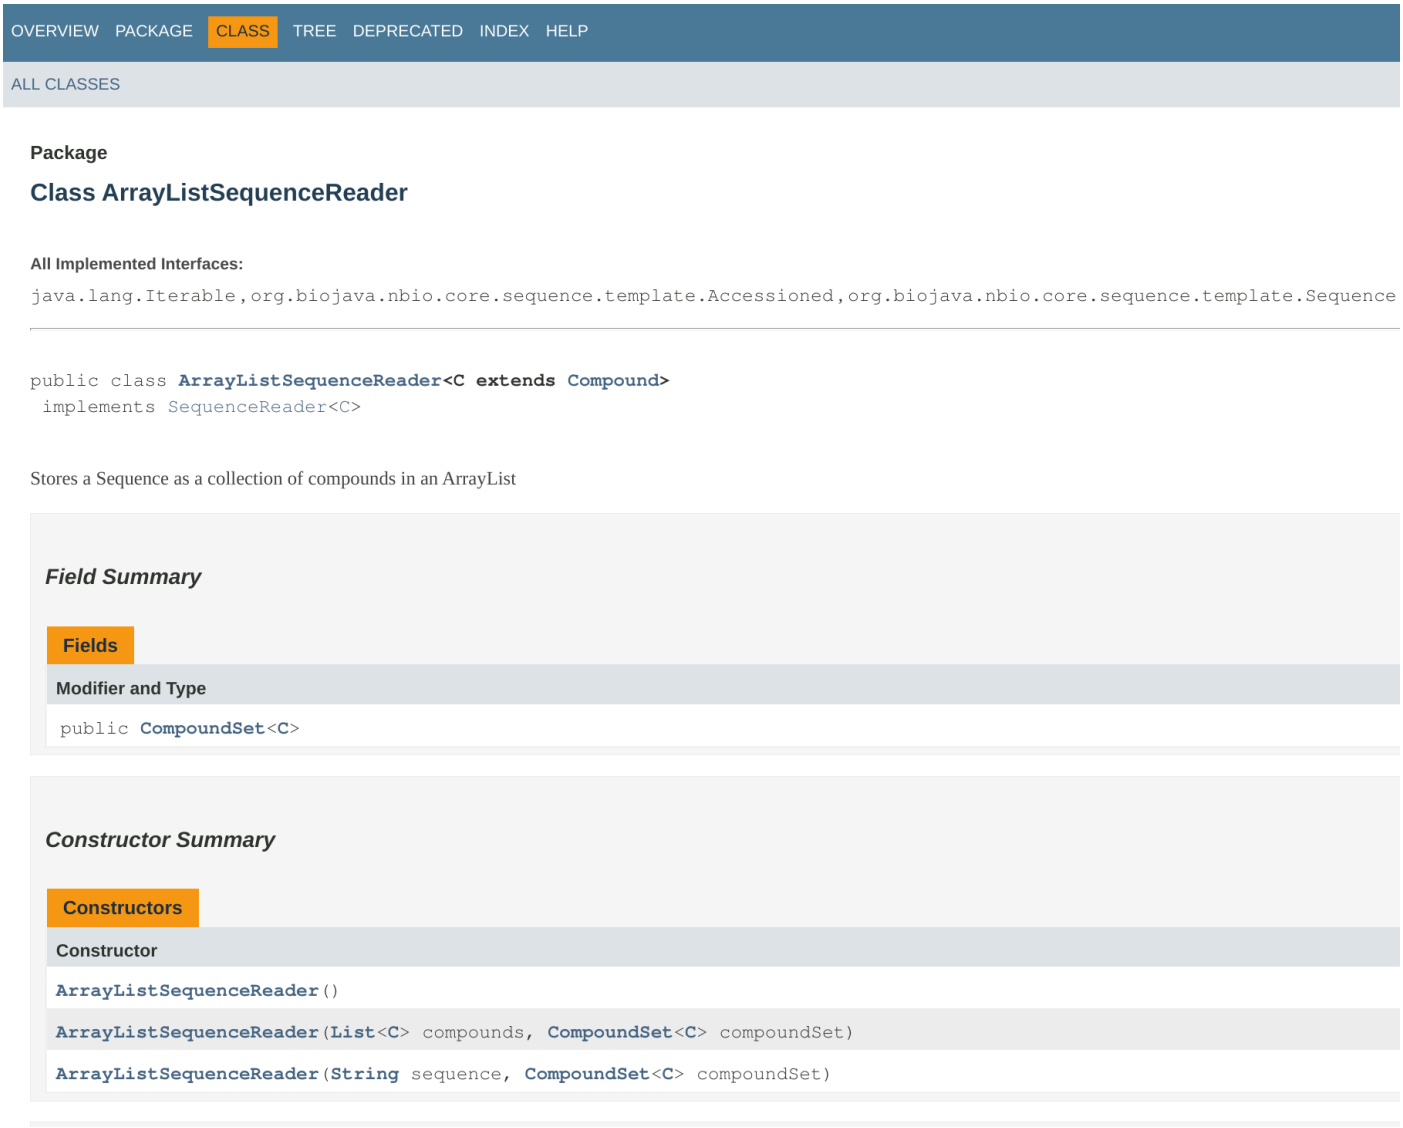
Variables `projectName` and `pathToRoot` are available only within the `template_cmd` directive as they require more context, and thus they need to be resolved at later stages:

```
<@template_cmd name="projectName">
    <span>${projectName}</span>
</@template_cmd>
```

Directives

You can also use the following Dokka-defined directives:

Variable	Description
`<@content/>`	The main page content.



Variable	Description
`<@resources/>`	Resources such as scripts and stylesheets.
`<@version/>`	The subproject version taken from configuration. If the versioning plugin is applied, it is replaced with a version navigator.

Javadoc

> This guide applies to Dokka Gradle plugin (DGP) v2 mode. The DGP v1 mode is no longer supported. To upgrade from v1 to v2 mode, follow the Migration guide.

Dokka's Javadoc output format is a lookalike of Java's Javadoc HTML format.

It tries to visually mimic HTML pages generated by the Javadoc tool, but it's not a direct implementation or an exact copy.

Screenshot of Javadoc output format

All Kotlin code and signatures are rendered as seen from Java's perspective. This is achieved with our Kotlin as Java Dokka plugin, which comes bundled and applied by default for this format.

The Javadoc output format is implemented as a Dokka plugin, and it is maintained by the Dokka team. It is open source, and you can find the source code on GitHub.

Generate Javadoc documentation

Dokka doesn't support the Javadoc format for multi-project builds or Kotlin Multiplatform projects.

The Gradle plugin for Dokka comes with the Javadoc output format included. You need to apply the corresponding plugin ID in the `plugins {}` block of your project's `build.gradle.kts` file:

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka-javadoc") version "2.2.0"
}
```

Once you applied the plugin, you can run the following tasks:

- `dokkaGenerate` to generate documentation in all available formats based on the applied plugins.
- `dokkaGeneratePublicationJavadoc` to generate documentation only in Javadoc format.

The `javadoc.jar` file can be generated separately. For more information, see Building `javadoc.jar` .

Maven

The Maven plugin for Dokka comes with the Javadoc output format built in. You can generate documentation by using the following goals:

Goal	Description
`dokka:javadoc`	Generates documentation in Javadoc format
`dokka:javadocJar`	Generates a `javadoc.jar` file that contains documentation in Javadoc format

Since the Javadoc output format is a Dokka plugin, you need to download the plugin's JAR file.

The Javadoc output format has two dependencies that you need to provide as additional JAR files:

- kotlin-as-java plugin
- korte-jvm

Via command line options:

CLI

```
java -jar dokka-cli-2.2.0.jar \
     -pluginsClasspath "./dokka-base-2.2.0.jar;...;./javadoc-plugin-2.2.0.jar" \
     ...
```

Via JSON configuration:

```
{
  ...
  "pluginsClasspath": [
    "./dokka-base-2.2.0.jar",
    "...",
    "./kotlin-as-java-plugin-2.2.0.jar",
    "./korte-jvm-3.3.0.jar",
    "./javadoc-plugin-2.2.0.jar"
  ],
  ...
}
```

For more information, see Other output formats in the CLI runner's documentation.

Dokka plugins

> This guide applies to Dokka Gradle plugin (DGP) v2 mode. The DGP v1 mode is no longer supported. To upgrade from v1 to v2 mode, follow the Migration guide.

Dokka was built from the ground up to be easily extensible and highly customizable, which allows the community to implement plugins for missing or very specific features that are not provided out of the box.

Dokka plugins range anywhere from supporting other programming language sources to exotic output formats. You can add support for your own KDoc tags or annotations, teach Dokka how to render different DSLs that are found in KDoc descriptions, visually redesign Dokka's pages to be seamlessly integrated into your company's website, integrate it with other tools and so much more.

If you want to learn how to create Dokka plugins, see Developer guides.

Apply Dokka plugins

Dokka plugins are published as separate artifacts, so to apply a Dokka plugin, you only need to add it as a dependency. From there, the plugin extends Dokka by itself – no further action is needed.

> Plugins that use the same extension points or work in a similar way can interfere with each other. This may lead to visual bugs, general undefined behavior or even failed builds. However, it should not lead to concurrency issues since Dokka does not expose any mutable data structures or objects.
>
> If you notice problems like this, it's a good idea to check which plugins are applied and what they do.

Let's have a look at how you can apply the mathjax plugin to your project:

Gradle Kotlin DSL

```
plugins {
    id("org.jetbrains.dokka") version "2.2.0"
}

dependencies {
    dokkaPlugin("org.jetbrains.dokka:mathjax-plugin")
}
```

- Built-in plugins (like HTML and Javadoc) are always applied automatically. You only configure them and do not need to declare dependencies on them.
- When documenting multi-module projects (multi-project builds), you need to share Dokka configuration and plugins across subprojects.

Gradle Groovy DSL

```
plugins {
    id 'org.jetbrains.dokka' version '2.2.0'
}

dependencies {
    dokkaPlugin 'org.jetbrains.dokka:mathjax-plugin'
}
```

When documenting multi-project builds, you need to share Dokka configuration across subprojects.

Maven

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    ...
    <configuration>
        <dokkaPlugins>
            <plugin>
                <groupId>org.jetbrains.dokka</groupId>
                <artifactId>mathjax-plugin</artifactId>
                <version>2.2.0</version>
            </plugin>
        </dokkaPlugins>
    </configuration>
</plugin>
```

If you are using the CLI runner with command line options, Dokka plugins should be passed as `.jar` files to `-pluginsClasspath`:

CLI

```
java -jar dokka-cli-2.2.0.jar \
     -pluginsClasspath "./dokka-base-2.2.0.jar;...;./mathjax-plugin-2.2.0.jar" \
     ...
```

If you are using JSON configuration, Dokka plugins should be specified under `pluginsClasspath`.

```
{
  ...
  "pluginsClasspath": [
    "./dokka-base-2.2.0.jar",
    "...",
    "./mathjax-plugin-2.2.0.jar"
  ],
  ...
}
```

Configure Dokka plugins

Dokka plugins can also have configuration options of their own. To see which options are available, consult the documentation of the plugins you are using.

Let's have a look at how you can configure the built-in HTML plugin by adding a custom image to the assets (`customAssets` option), custom style sheets (`customStyleSheets` option), and a modified footer message (`footerMessage` option):

To configure Dokka plugins in a type-safe way, use the `dokka.pluginsConfiguration {}` block:

Gradle Kotlin DSL

```
dokka {
    pluginsConfiguration.html {
        customAssets.from("logo.png")
        customStyleSheets.from("styles.css")
        footerMessage.set("(c) Your Company")
    }
}
```

For an example of Dokka plugins configuration, see the Dokka's versioning plugin.

Dokka allows you to extend its functionality and modify the documentation generation process by configuring custom plugins.

Gradle Groovy DSL

```
dokka {
    pluginsConfiguration {
        html {
            customAssets.from("logo.png")
            customStyleSheets.from("styles.css")
            footerMessage.set("(c) Your Company")
        }
    }
}
```

Maven

```
<plugin>
    <groupId>org.jetbrains.dokka</groupId>
    <artifactId>dokka-maven-plugin</artifactId>
    ...
    <configuration>
        <pluginsConfiguration>
            <!-- Fully qualified plugin name -->
            <org.jetbrains.dokka.base.DokkaBase>
                <!-- Options by name -->
                <customAssets>
                    <asset>${project.basedir}/my-image.png</asset>
                </customAssets>
                <customStyleSheets>
                    <stylesheet>${project.basedir}/my-styles.css</stylesheet>
                </customStyleSheets>
                <footerMessage>(c) MyOrg 2022 Maven</footerMessage>
            </org.jetbrains.dokka.base.DokkaBase>
        </pluginsConfiguration>
    </configuration>
</plugin>
```

If you are using the CLI runner with command line options, use the `-pluginsConfiguration` option that accepts JSON configuration in the form of `fullyQualifiedPluginName=json`.

If you need to configure multiple plugins, you can pass multiple values separated by `^^`.

CLI

```
java -jar dokka-cli-2.2.0.jar \
     ...
     -pluginsConfiguration "org.jetbrains.dokka.base.DokkaBase={\"customAssets\": [\"my-image.png\"],
\"customStyleSheets\": [\"my-styles.css\"], \"footerMessage\": \"(c) 2022 MyOrg CLI\"}"
```

If you are using JSON configuration, there exists a similar `pluginsConfiguration` array that accepts JSON configuration in `values`.

```
{
  "moduleName": "Dokka Example",
  "pluginsConfiguration": [
    {
      "fqPluginName": "org.jetbrains.dokka.base.DokkaBase",
      "serializationFormat": "JSON",
      "values": "{\"customAssets\": [\"my-image.png\"], \"customStyleSheets\": [\"my-styles.css\"],
\"footerMessage\": \"(c) 2022 MyOrg\"}"
    }
  ]
}
```

Notable plugins

Here are some notable Dokka plugins that you might find useful:

Name	Description
Android documentation plugin	Improves the documentation experience on Android
Versioning plugin	Adds version selector and helps to organize documentation for different versions of your application/library
MermaidJS HTML plugin	Renders MermaidJS diagrams and visualizations found in KDocs
Mathjax HTML plugin	Pretty prints mathematics found in KDocs
Kotlin as Java plugin	Renders Kotlin signatures as seen from Java's perspective
GFM plugin	Adds the ability to generate documentation in GitHub Flavoured Markdown format
Jekyll plugin	Adds the ability to generate documentation in Jekyll Flavoured Markdown format

If you are a Dokka plugin author and would like to add your plugin to this list, get in touch with maintainers via Slack or GitHub.

Module documentation

Documentation for a subproject as a whole, as well as packages in that subproject, can be provided as separate Markdown files.

File format

Inside the Markdown file, the documentation for the subproject as a whole and for individual packages is introduced by the corresponding first-level headings. The text of the heading **must** be **Module** `<module name>` for a subproject, and **Package** `<package qualified name>` for a package.

The file doesn't have to contain both subproject and package documentation. You can have files that contain only package or subproject documentation. You can even have a Markdown file per subproject or package.

Using Markdown syntax, you can add:

- Headings up to level 6
- Emphasis with bold or italic formatting
- Links
- Inline code
- Code blocks
- Blockquotes

Here's an example file containing both subproject and package documentation:

```
# Module kotlin-demo

This content appears under your subproject name.

# Package org.jetbrains.kotlin.demo

This content appears under your package name in the packages list.
It also appears under the first-level heading on your package's page.

## Level 2 heading for package org.jetbrains.kotlin.demo

Content after this heading is also part of documentation for `org.jetbrains.kotlin.demo`

# Package org.jetbrains.kotlin.demo2

This content appears under your package name in the packages list.
It also appears under the first-level heading on your package's page.

## Level 2 heading for package org.jetbrains.kotlin.demo2

Content after this heading is also part of documentation for `org.jetbrains.kotlin.demo2`
```

To explore an example project with Gradle, see Dokka gradle example.

Pass files to Dokka

To pass these files to Dokka, you need to use the relevant **includes** option for Gradle, Maven, or CLI:

Gradle

Use the `includes` option in General configuration.

Maven

Use the `includes` option in General configuration.

CLI

If you are using command line configuration, use the `includes` option in Source set options.

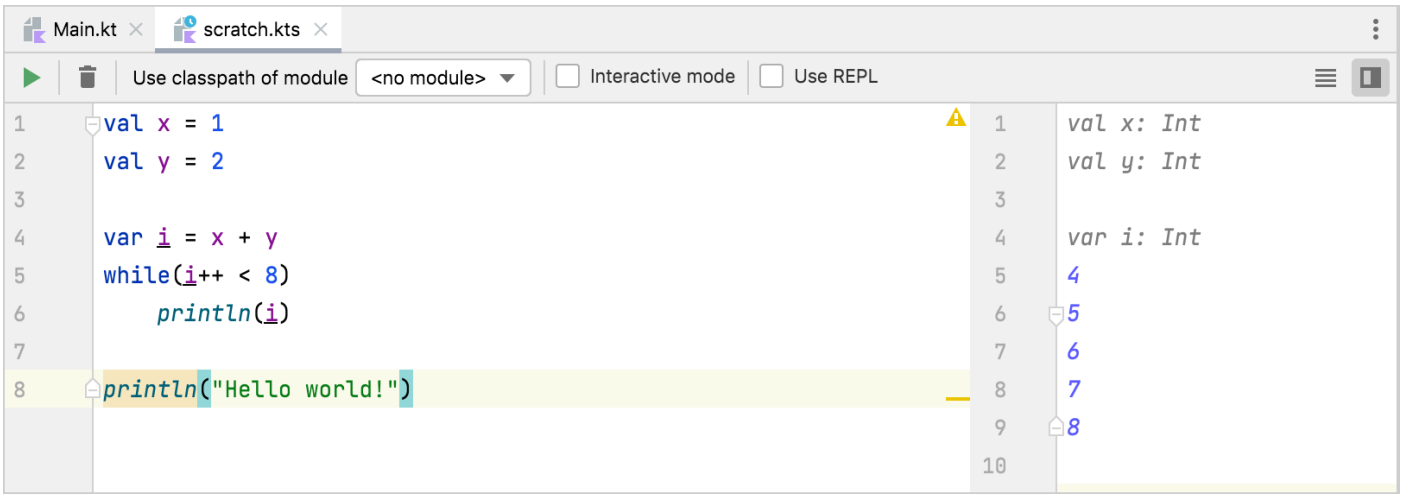
If you are using JSON configuration, use the `includes` option in General configuration.

Run code snippets

Kotlin code is typically organized into projects with which you work in an IDE, a text editor, or another tool. However, if you want to quickly see how a function works or find an expression's value, there's no need to create a new project and build it. Check out these three handy ways to run Kotlin code instantly in different environments:

- Scratch files in the IDE.
- Kotlin Playground in the browser.
- ki shell in the command line.

IDE: scratches

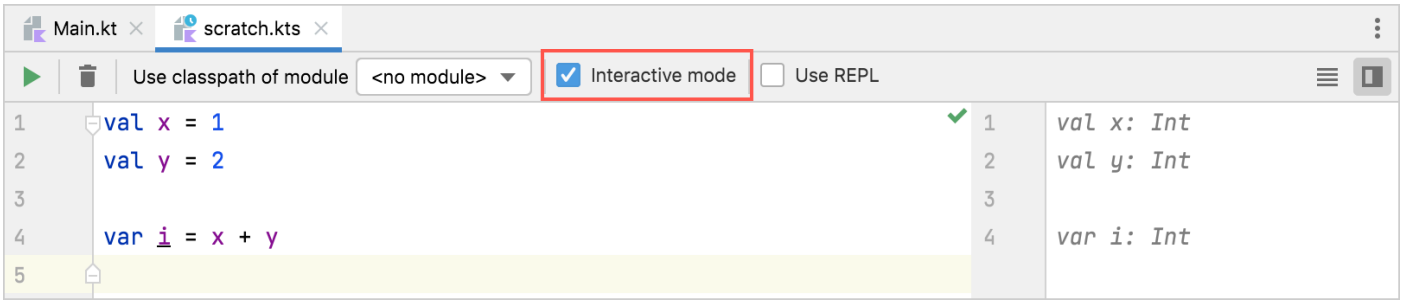


IntelliJ IDEA and Android Studio support Kotlin scratch files.

Scratch files (or just *scratches*) let you create code drafts in the same IDE window as your project and run them on the fly. Scratches are not tied to projects; you can access and run all your scratches from any IntelliJ IDEA window on your OS.

To create a Kotlin scratch, click **File** | **New** | **Scratch File** and select the **Kotlin** type.

Syntax highlighting, auto-completion, and other IntelliJ IDEA code editing features are supported in scratches. There's no need to declare the `main()` function – all the code you write is executed as if it were in the body of `main()`.

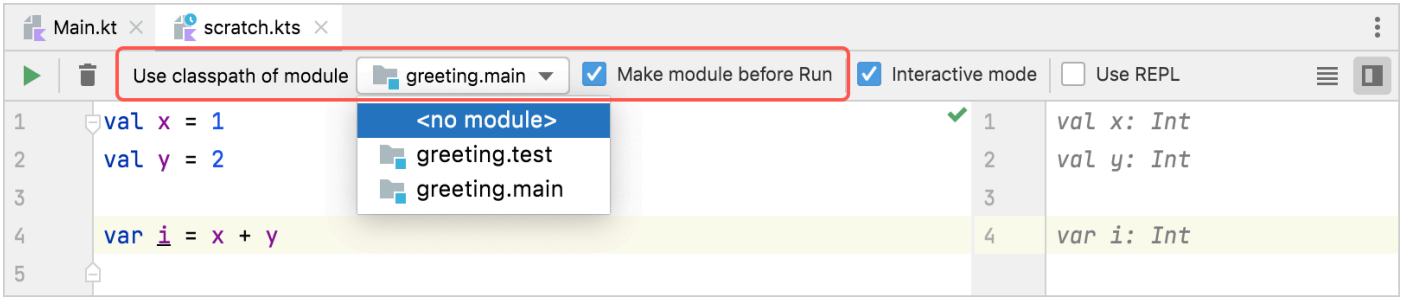


Once you have finished writing your code in a scratch, click **Run**. The execution results will appear in the lines opposite your code.

Run scratch

Interactive mode

The IDE can run code from scratches automatically. To get execution results as soon as you stop typing, switch on **Interactive mode**.



Scratch interactive mode

Use modules

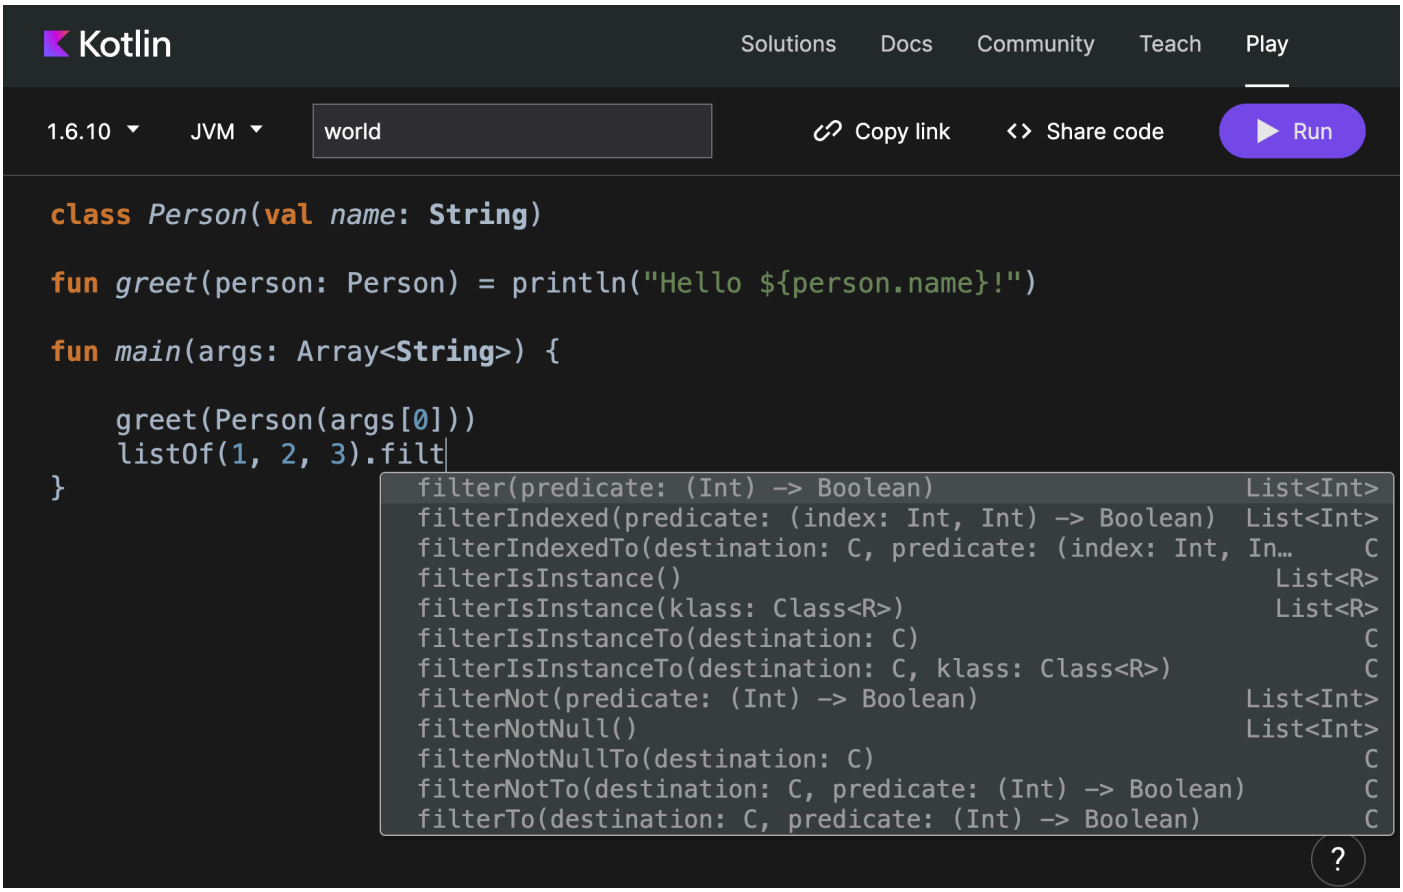
You can use classes or functions from a Kotlin project in your scratches.

To use classes or functions from a project in a scratch, import them into the scratch file with the `import` statement, as usual. Then write your code and run it with the appropriate module selected in the **Use classpath of module** list.

Scratches use the compiled versions of connected modules. So, if you modify a module's source files, the changes will propagate to scratches when you rebuild the module. To rebuild the module automatically before each run of a scratch, select **Make module before Run**.

Scratch select module

Browser: Kotlin Playground



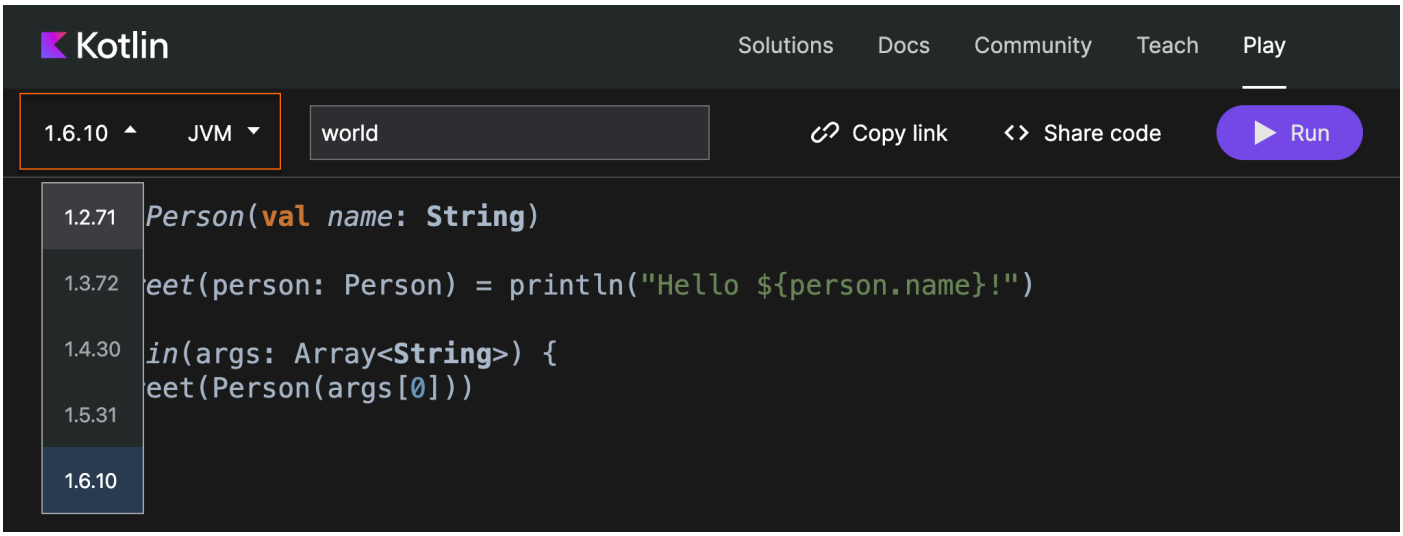
Kotlin Playground is an online application for writing, running, and sharing Kotlin code in your browser.

Write and edit code

In the Playground's editor area, you can write code just as you would in a source file:

- Add your own classes, functions, and top-level declarations in an arbitrary order.
- Write the executable part in the body of the `main()` function.

As in typical Kotlin projects, the `main()` function in the Playground can have the `args` parameter or no parameters at all. To pass program arguments upon execution, write them in the **Program arguments** field.



Playground: code completion

The Playground highlights the code and shows code completion options as you type. It automatically imports declarations from the standard library and `kotlinx.coroutines`.

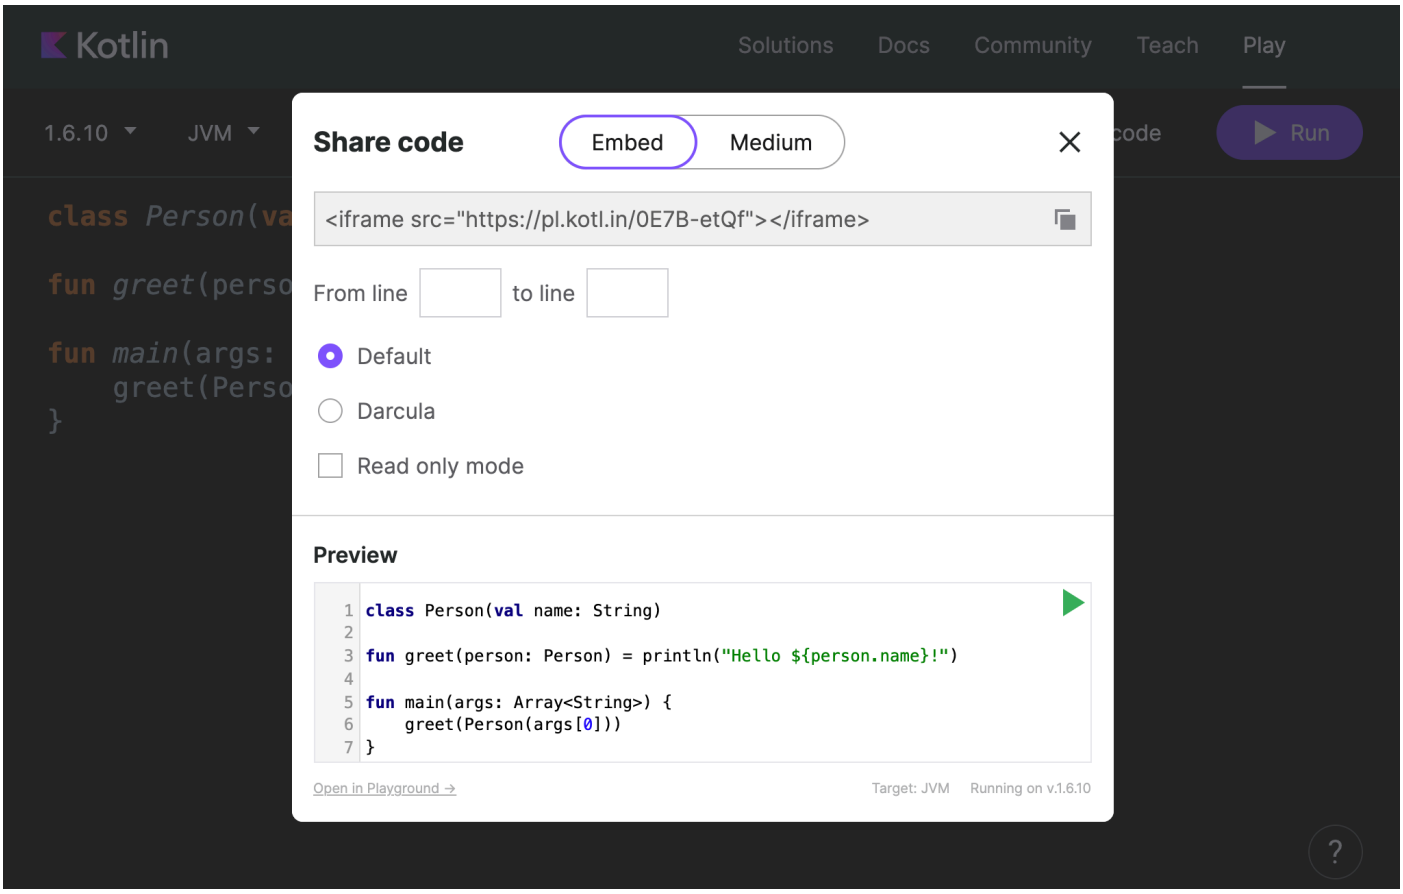
Choose execution environment

The Playground provides ways to customize the execution environment:

- Multiple Kotlin versions, including available previews of future versions.
- Multiple backends to run the code in: JVM, JS (legacy or IR compiler, or Canvas), or JUnit.

Playground: environment setup

For JS backends, you can also see the generated JS code.



Playground: generated JS

Share code online

Use the Playground to share your code with others – click **Copy link** and send it to anyone you want to show the code to.

You can also embed code snippets from the Playground into other websites and even make them runnable. Click **Share code** to embed your sample into any web page or into a Medium article.

Playground: share code

Command line: ki shell

The ki shell (*Kotlin Interactive Shell*) is a command-line utility for running Kotlin code in the terminal. It's available for Linux, macOS, and Windows.

The ki shell provides basic code evaluation capabilities, along with advanced features such as:

- code completion
- type checks
- external dependencies
- paste mode for code snippets
- scripting support

See the ki shell GitHub repository for more details.

Install and run ki shell

To install the ki shell, download the latest version of it from GitHub and unzip it in the directory of your choice.

On macOS, you can also install the ki shell with Homebrew by running the following command:

```
brew install ki
```

To start the ki shell, run `bin/ki.sh` on Linux and macOS (or just `ki` if the ki shell was installed with Homebrew) or `bin\ki.bat` on Windows.

Once the shell is running, you can immediately start writing Kotlin code in your terminal. Type `:help` (or `:h`) to see the commands that are available in the ki shell.

Code completion and highlighting

The ki shell shows code completion options when you press **Tab**. It also provides syntax highlighting as you type. You can disable this feature by entering `:syntax off`.

```
ki-shell 0.4.5/1.6.10
type :h for help
[0] val x = 1 + 2 + 3
[1] var greeting = "Hello"
[2] listOf(1, 2, 3).fil
file                filterIndexedTo(      filterIsInstanceTo(   filterNotNullTo(
filter {            filterIsInstance(     filterNot {           filterNotTo(
filterIndexed {     filterIsInstance()    filterNotNull()       filterTo(
```

ki shell highlighting and completion

When you press **Enter**, the ki shell evaluates the entered line and prints the result. Expression values are printed as variables with auto-generated names like `res*`. You can later use such variables in the code you run. If the construct entered is incomplete (for example, an `if` with a condition but without the body), the shell prints three dots and expects the remaining part.

```
ki-shell 0.4.5/1.6.10
type :h for help
[0] val greeting = "Hello"
[1] greeting + " world!"
res1: String = Hello world!
[2] println(res1)
Hello world!
[3] if (res1.length > 10)
...
```

ki shell results

Check an expression's type

For complex expressions or APIs that you don't know well, the ki shell provides the `:type` (or `:t`) command, which shows the type of an expression:

```
ki-shell 0.4.5/1.6.10
type :h for help
[0] :t sequenceOf("one", "two", "three").associateWith { it.length }
Map<String, Int>
[1]
```

ki shell type

Load code

If the code you need is stored somewhere else, there are two ways to load it and use it in the ki shell:

- Load a source file with the `:load` (or `:l`) command.
- Copy and paste the code snippet in paste mode with the `:paste` (or `:p`) command.

```
ki-shell 0.4.5/1.6.10
type :h for help
[0] :l Desktop/sourceFile.kt
[1] :ls
val variableFromFile: String
fun functionFromFile(): Unit
[2] println(variableFromFile)
Hello from file!
[3] functionFromFile()
Calling function from file
[4]
```

ki shell load file

The `ls` command shows available symbols (variables and functions).

Add external dependencies

Along with the standard library, the ki shell also supports external dependencies. This lets you try out third-party libraries in it without creating a whole project.

To add a third-party library in the ki shell, use the `:dependsOn` command. By default, the ki shell works with Maven Central, but you can use other repositories if you connect them using the `:repository` command:

```
ki-shell 0.4.5/1.6.10
type :h for help
[0] :repository https://maven.pkg.jetbrains.space/public/p/kotlinx-html/maven
[1] :dependsOn org.jetbrains.kotlinx:kotlinx-html-jvm:0.7.3
[2] import kotlinx.html.*
[3] import kotlinx.html.stream.*
[4] val html = createHTML().html {
...body {
...h1 { "Hello" }
...}
...}
[9] html
res5: String = <html>
  <body>
    <h1></h1>
  </body>
</html>

[10]
```

ki shell external dependency

Document Kotlin code: KDoc

The language used to document Kotlin code (the equivalent of Java's Javadoc) is called **KDoc**. In essence, KDoc combines Javadoc's syntax for block tags (extended to support Kotlin's specific constructs) and Markdown for inline markup.

Kotlin's documentation engine: Dokka, understands KDoc and can be used to generate documentation in various formats. For more information, read our Dokka documentation.

KDoc syntax

Just like with Javadoc, KDoc comments start with `/**` and end with `*/`. Every line of the comment may begin with an asterisk, which is not considered part of the contents of the comment.

By convention, the first paragraph of the documentation text (the block of text until the first blank line) is the summary description of the element, and the following text is the detailed description.

Every block tag begins on a new line and starts with the `@` character.

Here's an example of a class documented using KDoc:

```
/**
 * A group of *members*.
 *
 * This class has no useful logic; it's just a documentation example.
 *
 * @param T the type of a member in this group.
 * @property name the name of this group.
 * @constructor Creates an empty group.
 */
class Group<T>(val name: String) {
    /**
     * Adds a [member] to this group.
     * @return the new size of the group.
     */
    fun add(member: T): Int { ... }
}
```

Block tags

KDoc currently supports the following block tags:

@param *name*

Documents a value parameter of a function or a type parameter of a class, property, or function. To better separate the parameter name from the description, if you prefer, you can enclose the name of the parameter in brackets. The following two syntaxes are therefore equivalent:

```
@param name description.
@param[name] description.
```

@return

Documents the return value of a function.

@constructor

Documents the primary constructor of a class.

@receiver

Documents the receiver of an extension function.

@property *name*

Documents the property of a class which has the specified name. This tag can be used for documenting properties declared in the primary constructor, where putting a doc comment directly before the property definition would be awkward.

@throws *class*, @exception *class*

Documents an exception which can be thrown by a method. Since Kotlin does not have checked exceptions, there is also no expectation that all possible exceptions are documented, but you can still use this tag when it provides useful information for users of the class.

@sample *identifier*

Embeds the body of the function with the specified qualified name into the documentation for the current element, in order to show an example of how the element could be used.

@see *identifier*

Adds a link to the specified class or method to the **See also** block of the documentation.

@author

Specifies the author of the element being documented.

@since

Specifies the version of the software in which the element being documented was introduced.

@suppress

Excludes the element from the generated documentation. Can be used for elements which are not part of the official API of a module but still have to be visible externally.

KDoc does not support the `@deprecated` tag. Instead, please use the `@Deprecated` annotation.

Inline markup

For inline markup, KDoc uses the regular Markdown syntax, extended to support a shorthand syntax for linking to other elements in the code.

Links to elements

To link to another element (class, method, property, or parameter), simply put its name in square brackets:

```
Use the method [foo] for this purpose.
```

If you want to specify a custom label for the link, add it in another set of square brackets before the element link:

```
Use [this method][foo] for this purpose.
```

You can also use qualified names in the element links. Note that, unlike Javadoc, qualified names always use the dot character to separate the components, even before a method name:

```
Use [kotlin.reflect.KClass.properties] to enumerate the properties of the class.
```

Names in element links are resolved using the same rules as if the name was used inside the element being documented. In particular, this means that if you have imported a name into the current file, you don't need to fully qualify it when you use it in a KDoc comment.

Note that KDoc does not have any syntax for resolving overloaded members in links. Since Kotlin's documentation generation tool puts the documentation for all overloads of a function on the same page, identifying a specific overloaded function is not required for the link to work.

External links

To add an external link, use the typical Markdown syntax:

```
For more information about KDoc syntax, see [KDoc](<example-URL>).
```

What's next?

Learn how to use Kotlin's documentation generation tool: Dokka.

Kotlin and OSGi

To enable Kotlin OSGi support in your Kotlin project, include `kotlin-osgi-bundle` instead of the regular Kotlin libraries. It is recommended to remove `kotlin-runtime`, `kotlin-stdlib` and `kotlin-reflect` dependencies as `kotlin-osgi-bundle` already contains all of them. You also should pay attention in case when external Kotlin libraries are included. Most regular Kotlin dependencies are not OSGi-ready, so you shouldn't use them and should remove them from your project.

Maven

To include the Kotlin OSGi bundle to a Maven project:

```
<dependencies>
    <dependency>
        <groupId>org.jetbrains.kotlin</groupId>
        <artifactId>kotlin-osgi-bundle</artifactId>
        <version>${kotlin.version}</version>
    </dependency>
</dependencies>
```

To exclude the standard library from external libraries (notice that "star exclusion" works in Maven 3 only):

```
<dependency>
    <groupId>some.group.id</groupId>
    <artifactId>some.library</artifactId>
    <version>some.library.version</version>

    <exclusions>
        <exclusion>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>*</artifactId>
        </exclusion>
    </exclusions>
</dependency>
```

Gradle

To include `kotlin-osgi-bundle` to a Gradle project:

Kotlin

```
dependencies {
    implementation(kotlin("osgi-bundle"))
}
```

Groovy

```
dependencies {
    implementation "org.jetbrains.kotlin:kotlin-osgi-bundle:2.4.20"
}
```

To exclude default Kotlin libraries that come as transitive dependencies, you can use the following approach:

Kotlin

```
dependencies {
    implementation("some.group.id:some.library:someversion") {
        exclude(group = "org.jetbrains.kotlin")
    }
}
```

Groovy

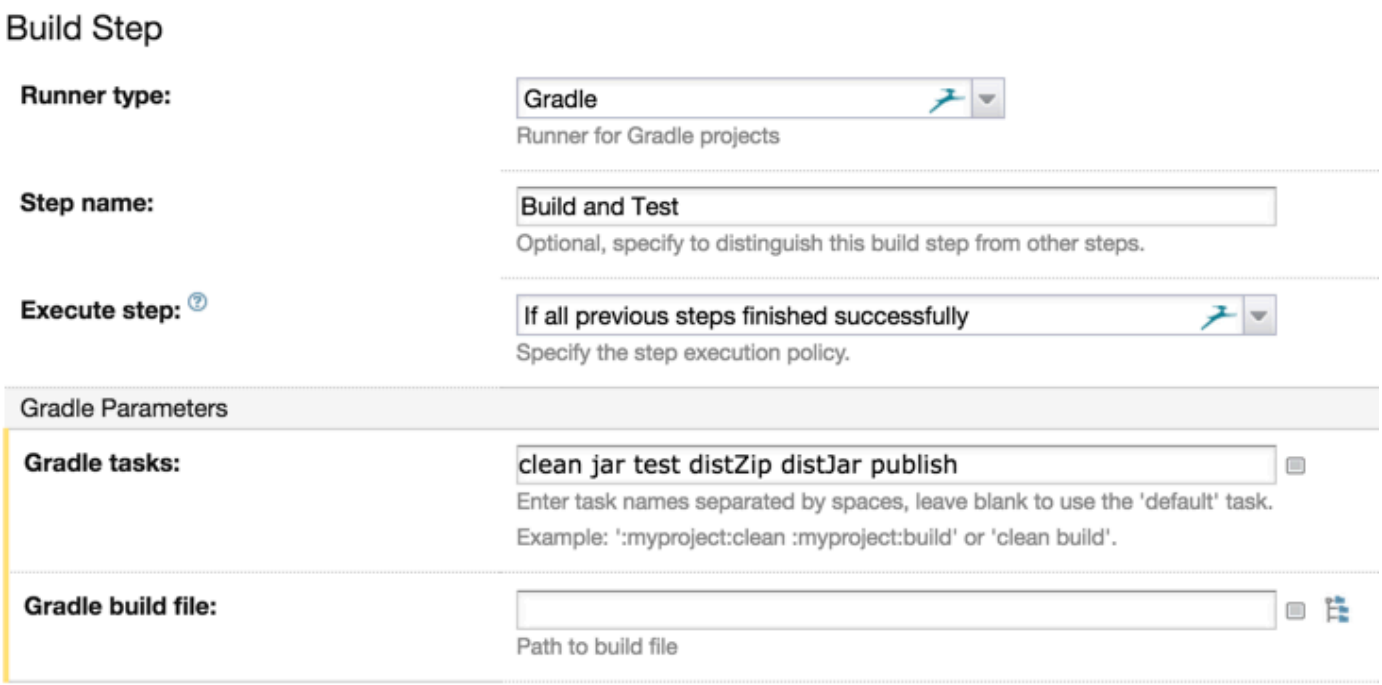
```
dependencies {
    implementation('some.group.id:some.library:someversion') {
        exclude group: 'org.jetbrains.kotlin'
    }
}
```

FAQ

Why not just add required manifest options to all Kotlin libraries

Even though it is the most preferred way to provide OSGi support, unfortunately it couldn't be done for now due to so-called "package split" issue that couldn't be easily eliminated and such a big change is not planned for now. There is `Require-Bundle` feature but it is not the best option too and not recommended to use. So it was decided to make a separate artifact for OSGi.

Kotlin and continuous integration with TeamCity



On this page, you'll learn how to set up TeamCity to build your Kotlin project. For more information and basics of TeamCity please check the Documentation page which contains information about installation, basic configuration, etc.

Kotlin works with different build tools, so if you're using a standard tool such as Maven or Gradle, the process for setting up a Kotlin project is no different to any other language or library that integrates with these tools. Where

there are some minor requirements and differences is when using the internal build system of IntelliJ IDEA, which is also supported on TeamCity.

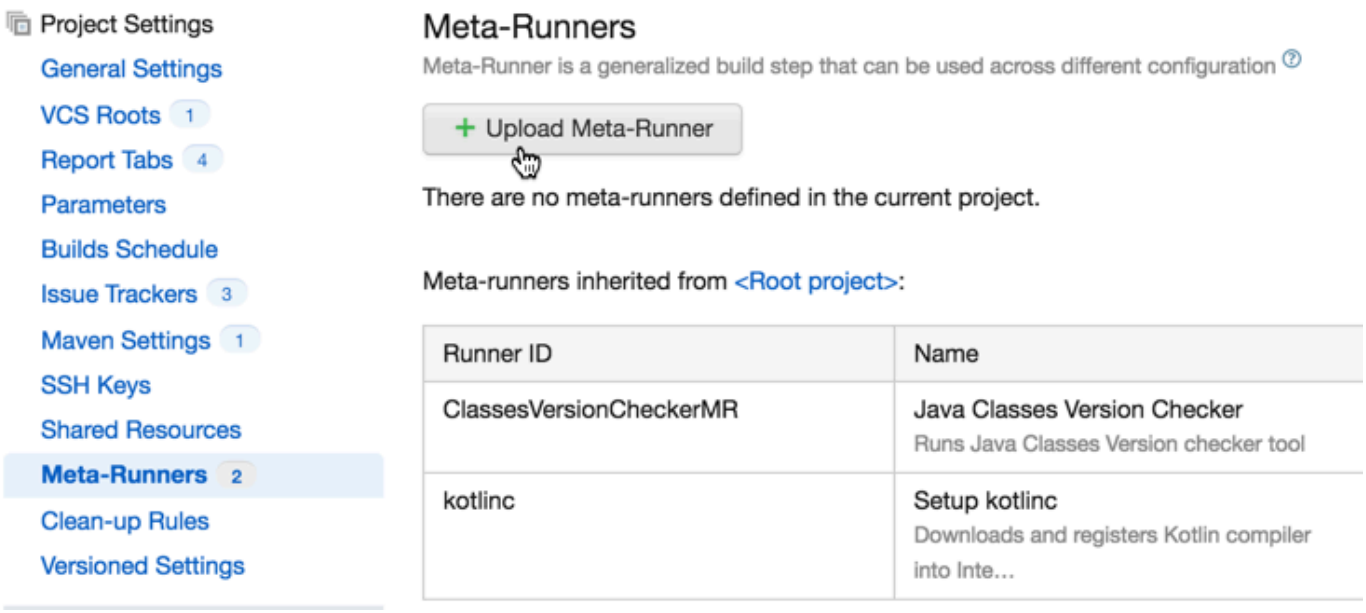
Gradle and Maven

If using Maven or Gradle, the setup process is straightforward. All that is needed is to define the Build Step. For example, if using Gradle, simply define the required parameters such as the Step Name and Gradle tasks that need executing for the Runner Type.

Gradle Build Step

Since all the dependencies required for Kotlin are defined in the Gradle file, nothing else needs to be configured specifically for Kotlin to run correctly.

If using Maven, the same configuration applies. The only difference is that the Runner Type would be Maven.

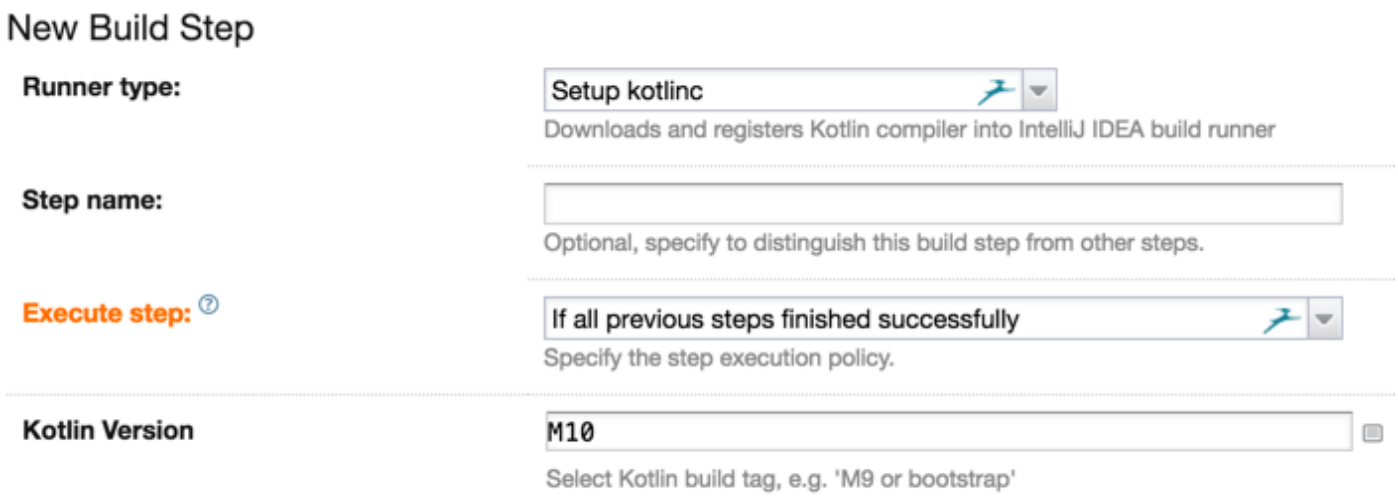


IntelliJ IDEA Build System

If using IntelliJ IDEA build system with TeamCity, make sure that the version of Kotlin being used by IntelliJ IDEA is the same as the one that TeamCity runs. You may need to download the specific version of the Kotlin plugin and install it on TeamCity.

Fortunately, there is a meta-runner already available that takes care of most of the manual work. If not familiar with the concept of TeamCity meta-runners, check the documentation. They are very easy and powerful way to introduce custom Runners without the need to write plugins.

Download and install the meta-runner

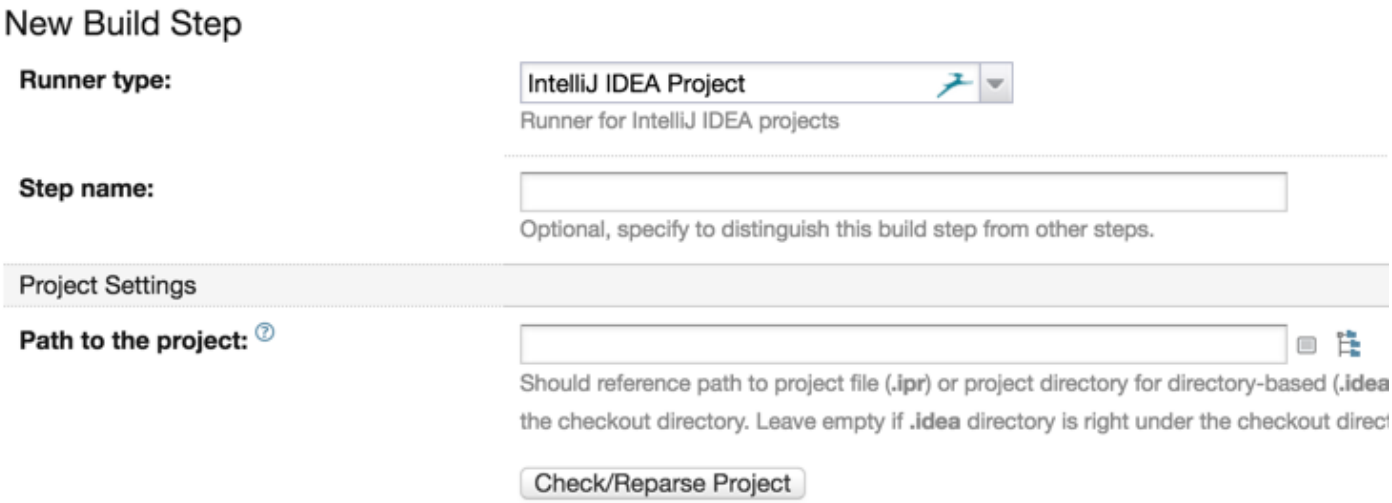


The meta-runner for Kotlin is available on GitHub. Download that meta-runner and import it from the TeamCity user interface

Meta-runner

Setup Kotlin compiler fetching step

Basically, this step is limited to defining the Step Name and the version of Kotlin you need. Tags can be used.



Setup Kotlin Compiler

The runner will set the value for the property `system.path.macro.KOTLIN.BUNDLED` to the correct one based on the path settings from the IntelliJ IDEA project. However, this value needs to be defined in TeamCity (and can be set to any value). Therefore, you need to define it as a system variable.

Setup Kotlin compilation step

The final step is to define the actual compilation of the project, which uses the standard IntelliJ IDEA Runner Type.

IntelliJ IDEA Runner

With that, our project should now build and produce the corresponding artifacts.

Other CI servers

If using a continuous integration tool different to TeamCity, as long as it supports any of the build tools, or calling command line tools, compiling Kotlin and automating things as part of a CI process should be possible.

Comparison to Java

Some Java issues addressed in Kotlin

Kotlin fixes a series of issues that Java suffers from:

- Null references are controlled by the type system.
- No raw types
- Arrays in Kotlin are invariant
- Kotlin has proper function types, as opposed to Java's SAM-conversions
- Use-site variance without wildcards
- Kotlin does not have checked exceptions
- Separate interfaces for read-only and mutable collections

What Java has that Kotlin does not

- Checked exceptions
- Primitive types that are not classes. The byte-code uses primitives where possible, but they are not explicitly available.
- Static members are replaced with companion objects, top-level functions, extension functions, or @JvmStatic.
- Wildcard-types are replaced with declaration-site variance and type projections.

- Ternary-operator `a ? b : c` is replaced with if expression.
- Records
- package-private visibility modifier

> Kotlin doesn't have pattern matching, but smart casts in Kotlin provide similar functionality to pattern Matching in Java.
>
> Learn more in this video on the official Kotlin by JetBrains channel.

What Kotlin has that Java does not

- Lambda expressions + Inline functions = performant custom control structures
- Extension functions
- Null-safety
- String templates
- Properties
- Primary constructors
- First-class delegation
- Type inference for variable and property types (**Java 10**: Local-Variable Type Inference)
- Singletons
- Declaration-site variance & Type projections
- Range expressions
- Operator overloading
- Companion objects
- Data classes
- Coroutines
- Top-level functions
- Parameters with default values
- Named parameters
- Infix functions
- Expect and actual declarations
- Explicit API mode and better control of API surface

> Java doesn't have smart casts, but pattern matching provides similar functionality to smart casts in Kotlin.

What's next?

Learn how to:

- Perform typical tasks with strings in Java and Kotlin.
- Perform typical tasks with collections in Java and Kotlin.
- Handle nullability in Java and Kotlin.

Calling Java from Kotlin

Kotlin is designed with Java interoperability in mind. Existing Java code can be called from Kotlin in a natural way, and Kotlin code can be used from Java rather smoothly as well. In this section, we describe some details about calling Java code from Kotlin.

Pretty much all Java code can be used without any issues:

```
import java.util.*

fun demo(source: List<Int>) {
    val list = ArrayList<Int>()
    // 'for'-loops work for Java collections:
    for (item in source) {
        list.add(item)
    }
    // Operator conventions work as well:
    for (i in 0..source.size - 1) {
        list[i] = source[i] // get and set are called
    }
}
```

Getters and setters

Methods that follow the Java conventions for getters and setters (no-argument methods with names starting with `get` and single-argument methods with names starting with `set`) are represented as properties in Kotlin. Such properties are also called *synthetic properties*. `Boolean` accessor methods (where the name of the getter starts with `is` and the name of the setter starts with `set`) are represented as properties which have the same name as the getter method.

```
import java.util.Calendar

fun calendarDemo() {
    val calendar = Calendar.getInstance()
    if (calendar.firstDayOfWeek == Calendar.SUNDAY) { // call getFirstDayOfWeek()
        calendar.firstDayOfWeek = Calendar.MONDAY // call setFirstDayOfWeek()
    }
    if (!calendar.isLenient) { // call isLenient()
        calendar.isLenient = true // call setLenient()
    }
}
```

`calendar.firstDayOfWeek` above is an example of a synthetic property.

Note that if the Java class only has a setter, it isn't visible as a property in Kotlin because Kotlin doesn't support set-only properties.

Java synthetic property references

This feature is Experimental. It may be dropped or changed at any time. We recommend that you use it only for evaluation purposes.

Starting from Kotlin 1.8.20, you can create references to Java synthetic properties. Consider the following Java code:

```
public class Person {
    private String name;
    private int age;

    public Person(String name, int age) {
        this.name = name;
        this.age = age;
    }

    public String getName() {
        return name;
    }

    public int getAge() {
        return age;
    }
}
```

Kotlin has always allowed you to write `person.age`, where `age` is a synthetic property. Now, you can also create references to `Person::age` and `person::age`. The same applies for `name`, as well.

```
val persons = listOf(Person("Jack", 11), Person("Sofie", 12), Person("Peter", 11))
    persons
         // Call a reference to Java synthetic property:
        .sortedBy(Person::age)
         // Call Java getter via the Kotlin property syntax:
        .forEach { person -> println(person.name) }
```

How to enable Java synthetic property references

To enable this feature, set the `-language-version 2.1` compiler option. In a Gradle project, you can do so by adding the following to your `build.gradle(.kts)`:

Kotlin

```
tasks
    .withType<org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask<*>>()
    .configureEach {
        compilerOptions
            .languageVersion
            .set(
                org.jetbrains.kotlin.gradle.dsl.KotlinVersion.KOTLIN_2_1
            )
    }
```

Groovy

```
tasks
    .withType(org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask.class)
    .configureEach {
        compilerOptions.languageVersion
            = org.jetbrains.kotlin.gradle.dsl.KotlinVersion.KOTLIN_2_1
}
```

Prior to Kotlin 1.9.0, to enable this feature you had to set the `-language-version 1.9` compiler option.

Methods returning void

If a Java method returns `void`, it will return `Unit` when called from Kotlin. If by any chance someone uses that return value, it will be assigned at the call site by the Kotlin compiler since the value itself is known in advance (being `Unit`).

Escaping for Java identifiers that are keywords in Kotlin

Some of the Kotlin keywords are valid identifiers in Java: `in`, `object`, `is`, and others. If a Java library uses a Kotlin keyword for a method, you can still call the method escaping it with the backtick (`) character:

```
foo.`is`(bar)
```

Null-safety and platform types

Any reference in Java may be `null`, which makes Kotlin's requirements of strict null-safety impractical for objects coming from Java. Types of Java declarations are treated in Kotlin as non-denotable and called *platform types*. You can't write the non-denotable types in the code explicitly. Therefore, when a platform value is assigned to a Kotlin variable, you can:

- Rely on the type inference. In this case, the variable has an inferred platform type.
- Choose the type you expect. Kotlin allows both nullable and non-nullable types.

Null-checks are relaxed for such types, so that safety guarantees for them are the same as in Java (see more below). Consider the following examples:

```
val list = ArrayList<String>() // non-null (constructor result)
list.add("Item")
val size = list.size // non-null (primitive int)
val item = list[0] // platform type inferred (ordinary Java object)
```

When you call methods on variables of platform types, Kotlin does not issue nullability errors at compile time, but the call may fail at runtime, because of a null-pointer exception or an assertion that Kotlin generates to prevent nulls from propagating:

```
item.substring(1) // allowed, throws an exception if item == null
```

You can assign a value of a platform type to a variable of both nullable and non-nullable Kotlin types. However, if you assign such a value to a variable of a non-nullable type and the value is actually `null` at runtime, Kotlin throws a `NullPointerException`. To avoid this, add explicit nullability to your Kotlin code:

```
val nullable: String? = item // allowed, always works
val notNull: String = item // allowed, may fail at runtime
```

If you choose a non-nullable type, the compiler will emit an assertion upon assignment. This prevents Kotlin's non-nullable variables from holding nulls. Assertions are also emitted when you pass platform values to Kotlin functions expecting non-null values and in other cases. Overall, the compiler does its best to prevent nulls from propagating far through the program, although sometimes this is impossible to eliminate entirely, because of generics.

Notation for platform types

As mentioned in the previous section, platform types can't be mentioned explicitly in the program, so there's no syntax for them in the language. Nevertheless, the compiler and IDE need to display them sometimes (for example, in error messages or parameter info), so there is a mnemonic notation for them:

- `T!` means "`T` or `T?`"
- `(Mutable)Collection<T>!` means "Java collection of `T` may be mutable or not, may be nullable or not"
- `Array<(out) T>!` means "Java array of `T` (or a subtype of `T`), nullable or not"

When you see this notation in an error message or IDE tooltip, add an explicit type annotation to your Kotlin variable to restore null-safety checks, or eliminate platform types at the source using nullability annotations.

Nullability annotations

Java types that have nullability annotations are represented not as platform types, but as actual nullable or non-nullable Kotlin types. The compiler supports several flavors of nullability annotations, including:

- JetBrains (`@Nullable` and `@NotNull` from the `org.jetbrains.annotations` package)
- JSpecify (`org.jspecify.annotations`)
- Android (`com.android.annotations` and `android.support.annotations`)
- JSR-305 (`javax.annotation`)
- FindBugs (`edu.umd.cs.findbugs.annotations`)
- Eclipse (`org.eclipse.jdt.annotation`)
- Lombok (`lombok.NonNull`)
- RxJava 3 (`io.reactivex.rxjava3.annotations`)
- Vert.x (`io.vertx.codegen.annotations`)

You can instruct the compiler to report nullability mismatches for specific nullability annotations with the following compiler option:

```
-Xnullability-annotations=@<package-name>:<report-level>
```

Specify the package name for the fully qualified nullability annotations and one of these report levels:

- `ignore` to ignore nullability mismatches

- `warn` to report warnings
- `strict` to report errors.

> JSpecify is the only supported flavor that uses `strict` report level by default. Use it to report errors on nullability annotations without additional configuration.

See the full list of supported nullability annotations in the Kotlin compiler source code.

Mutability annotations

You can annotate a Java declaration with a mutability annotation to specify whether a returned collection is read-only or mutable in Kotlin. If you assign the value to a collection type with different mutability, the compiler reports a type mismatch. The diagnostic severity depends on the specific mutability annotation.

The compiler supports several mutability annotations, including:

- `kotlin.annotations.jvm.ReadOnly`
- `kotlin.annotations.jvm.Mutable`
- `org.jetbrains.annotations.Unmodifiable`
- `org.jetbrains.annotations.UnmodifiableView`

See the full list of supported mutability annotations in the Kotlin compiler source code.

Annotating type arguments and type parameters

You can annotate the type arguments and type parameters of generic types to provide nullability information for them as well.

> All examples in the section use JetBrains nullability annotations from the `org.jetbrains.annotations` package.

Type arguments

Consider these annotations on a Java declaration:

```
@NotNull
Set<@NotNull String> toSet(@NotNull Collection<@NotNull String> elements) { ... }
```

They result in the following signature in Kotlin:

```
fun toSet(elements: (Mutable)Collection<String>) : (Mutable)Set<String> { ... }
```

When the `@NotNull` annotation is missing from a type argument, you get a platform type instead:

```
fun toSet(elements: (Mutable)Collection<String!>) : (Mutable)Set<String!> { ... }
```

Kotlin also takes into account nullability annotations on type arguments of base classes and interfaces. For example, there are two Java classes with the signatures provided below:

```
public class Base<T> {}
```

```
public class Derived extends Base<@Nullable String> {}
```

In the Kotlin code, passing the instance of `Derived` where the `Base<String>` is assumed produces the warning.

```
fun takeBaseOfNotNullStrings(x: Base<String>) {}

fun main() {
    takeBaseOfNotNullStrings(Derived()) // warning: nullability mismatch
}
```

The upper bound of `Derived` is set to `Base<String?>`, which is different from `Base<String>`.

Learn more about Java generics in Kotlin.

Type parameters

By default, the nullability of plain type parameters in both Kotlin and Java is undefined. In Java, you can specify it using nullability annotations. Let's annotate the type parameter of the `Base` class:

```
public class Base<@NotNull T> {}
```

When inheriting from `Base`, Kotlin expects a non-nullable type argument or type parameter. Thus, the following Kotlin code produces a warning:

```
class Derived<K> : Base<K> {} // warning: K has undefined nullability
```

You can fix it by specifying the upper bound `K : Any`.

Kotlin also supports nullability annotations on the bounds of Java type parameters. Let's add bounds to `Base`:

```
public class BaseWithBound<T extends @NotNull Number> {}
```

Kotlin translates this just as follows:

```
class BaseWithBound<T : Number> {}
```

So passing nullable type as a type argument or type parameter produces a warning.

Annotating type arguments and type parameters works with the Java 8 target or higher. The feature requires that the nullability annotations support the `TYPE_USE` target (`org.jetbrains.annotations` supports this in version 15 and above).

If a nullability annotation supports other targets that are applicable to a type in addition to the `TYPE_USE` target, `TYPE_USE` takes priority. For example, if `@Nullable` has both `TYPE_USE` and `METHOD` targets, the Java method signature `@Nullable String[] f()` becomes `fun f(): Array<String?>!` in Kotlin.

JSpecify support

Kotlin supports the JSpecify nullability annotations, which provide a unified set of annotations for Java nullability. JSpecify allows you to provide detailed nullability information for Java declarations, helping Kotlin maintain null-safety when working with Java code.

Kotlin supports the following annotations in the `org.jspecify.annotations` package:

- `@Nullable` marks a type as nullable.
- `@NonNull` marks a type as non-nullable.
- `@NullMarked` marks all types within a scope, for example a class or package, as non-nullable by default unless annotated otherwise.

  This annotation doesn't apply to local variables and type variables (generics). Type variables remain "null-agnostic" until a specific nullable or non-nullable type is provided.
- `@NullUnmarked` reverses the effect of `@NullMarked`, making all types within the scope as platform types.

Consider the following Java class with JSpecify annotations:

```
// Java
import org.jspecify.annotations.*;

@NullMarked
public class InventoryService {
    public String notNull() { return ""; }
    public @Nullable String nullable() { return null; }
}
```

In Kotlin, these are treated as regular nullable and non-nullable types rather than platform types:

```
// Kotlin
fun test(inventory: InventoryService) {
   inventory.notNull().length // OK
   inventory.nullable().length // Error: only safe (?.) or non-null asserted (!!) calls are allowed
}
```

By default, the Kotlin compiler reports nullability mismatches for JSpecify annotations as errors. You can customize the severity of JSpecify nullability diagnostics using the following compiler option:

```
-Xjspecify-annotations=<report-level>
```

Available report levels are:

Level	Description
`strict`	Reports errors for nullability mismatches (default).
`warn`	Reports warnings.
`ignore`	Ignores nullability mismatches.

For more information on JSpecify annotations, see the JSpecify user guide.

JSR-305 support

The `@Nonnull` annotation defined in JSR-305 is supported for denoting nullability of Java types.

If the `@Nonnull(when = ...)` value is `When.ALWAYS`, the annotated type is treated as non-nullable; `When.MAYBE` and `When.NEVER` denote a nullable type; and `When.UNKNOWN` forces the type to be platform one.

A library can be compiled against the JSR-305 annotations, but there's no need to make the annotations artifact (e.g. `jsr305.jar`) a compile dependency for the library consumers. The Kotlin compiler can read the JSR-305 annotations from a library without the annotations present on the classpath.

Custom nullability qualifiers (KEEP-79) are also supported (see below).

Type qualifier nicknames

If an annotation type is annotated with both `@TypeQualifierNickname` and JSR-305 `@Nonnull` (or its another nickname, such as `@CheckForNull`), then the annotation type is itself used for retrieving precise nullability and has the same meaning as that nullability annotation:

```
@TypeQualifierNickname
@Nonnull(when = When.ALWAYS)
@Retention(RetentionPolicy.RUNTIME)
public @interface MyNonnull {
}

@TypeQualifierNickname
@CheckForNull // a nickname to another type qualifier nickname
@Retention(RetentionPolicy.RUNTIME)
public @interface MyNullable {
}

interface A {
    @MyNullable String foo(@MyNonnull String x);
    // in Kotlin (strict mode): `fun foo(x: String): String?`

    String bar(List<@MyNonnull String> x);
    // in Kotlin (strict mode): `fun bar(x: List<String>!): String!`
}
```

Type qualifier defaults

`@TypeQualifierDefault` allows introducing annotations that, when being applied, define the default nullability within the scope of the annotated element.

Such annotation type should itself be annotated with both `@Nonnull` (or its nickname) and `@TypeQualifierDefault(...)` with one or more `ElementType` values:

- `ElementType.METHOD` for return types of methods
- `ElementType.PARAMETER` for value parameters
- `ElementType.FIELD` for fields
- `ElementType.TYPE_USE` for any type including type arguments, upper bounds of type parameters and wildcard types

The default nullability is used when a type itself is not annotated by a nullability annotation, and the default is determined by the innermost enclosing element annotated with a type qualifier default annotation with the `ElementType` matching the type usage.

```java
@Nonnull
@TypeQualifierDefault({ElementType.METHOD, ElementType.PARAMETER})
public @interface NonNullApi {
}

@Nonnull(when = When.MAYBE)
@TypeQualifierDefault({ElementType.METHOD, ElementType.PARAMETER, ElementType.TYPE_USE})
public @interface NullableApi {
}

@NullableApi
interface A {
    String foo(String x); // fun foo(x: String?): String?

    @NotNullApi // overriding default from the interface
    String bar(String x, @Nullable String y); // fun bar(x: String, y: String?): String

    // The List<String> type argument is seen as nullable because of `@NullableApi`
    // having the `TYPE_USE` element type:
    String baz(List<String> x); // fun baz(List<String?>?): String?

    // The type of `x` parameter remains platform because there's an explicit
    // UNKNOWN-marked nullability annotation:
    String qux(@Nonnull(when = When.UNKNOWN) String x); // fun baz(x: String!): String?
}
```

The types in this example only take place with the strict mode enabled; otherwise, the platform types remain. See the `@UnderMigration` annotation and Compiler configuration sections.

Package-level default nullability is also supported:

```java
// FILE: test/package-info.java
@NonNullApi // declaring all types in package 'test' as non-nullable by default
package test;
```

@UnderMigration annotation

The `@UnderMigration` annotation (provided in a separate artifact `kotlin-annotations-jvm`) can be used by library maintainers to define the migration status for the nullability type qualifiers.

The status value in `@UnderMigration(status = ...)` specifies how the compiler treats inappropriate usages of the annotated types in Kotlin (e.g. using a `@MyNullable`-annotated type value as non-null):

- `MigrationStatus.STRICT` makes annotation work as any plain nullability annotation, i.e. report errors for the inappropriate usages and affect the types in the annotated declarations as they are seen in Kotlin
- `MigrationStatus.WARN`: the inappropriate usages are reported as compilation warnings instead of errors, but the types in the annotated declarations remain platform
- `MigrationStatus.IGNORE` makes the compiler ignore the nullability annotation completely

A library maintainer can add `@UnderMigration` status to both type qualifier nicknames and type qualifier defaults:

```
@Nonnull(when = When.ALWAYS)
@TypeQualifierDefault({ElementType.METHOD, ElementType.PARAMETER})
@UnderMigration(status = MigrationStatus.WARN)
public @interface NonNullApi {
}

// The types in the class are non-nullable, but only warnings are reported
// because `@NonNullApi` is annotated `@UnderMigration(status = MigrationStatus.WARN)`
@NonNullApi
public class Test {}
```

The migration status of a nullability annotation is not inherited by its type qualifier nicknames but is applied to its usages in default type qualifiers.

If a default type qualifier uses a type qualifier nickname and they are both `@UnderMigration`, the status from the default type qualifier is used.

Compiler configuration

The JSR-305 checks can be configured by adding the `-Xjsr305` compiler flag with the following options (and their combination):

- `-Xjsr305={strict|warn|ignore}` to set up the behavior for non-`@UnderMigration` annotations. Custom nullability qualifiers, especially `@TypeQualifierDefault`, are already spread among many well-known libraries, and users may need to migrate smoothly when updating to the Kotlin version containing JSR-305 support. Since Kotlin 1.1.60, this flag only affects non-`@UnderMigration` annotations.
- `-Xjsr305=under-migration:{strict|warn|ignore}` to override the behavior for the `@UnderMigration` annotations. Users may have different view on the migration status for the libraries: they may want to have errors while the official migration status is `WARN`, or vice versa, they may wish to postpone errors reporting for some until they complete their migration.
- `-Xjsr305=@<fq.name>:{strict|warn|ignore}` to override the behavior for a single annotation, where `<fq.name>` is the fully qualified class name of the annotation. May appear several times for different annotations. This is useful for managing the migration state for a particular library.

The `strict`, `warn` and `ignore` values have the same meaning as those of `MigrationStatus`, and only the `strict` mode affects the types in the annotated declarations as they are seen in Kotlin.

Note: the built-in JSR-305 annotations `@Nonnull`, `@Nullable` and `@CheckForNull` are always enabled and affect the types of the annotated declarations in Kotlin, regardless of compiler configuration with the `-Xjsr305` flag.

For example, adding `-Xjsr305=ignore -Xjsr305=under-migration:ignore -Xjsr305=@org.library.MyNullable:warn` to the compiler arguments makes the compiler generate warnings for inappropriate usages of types annotated by `@org.library.MyNullable` and ignore all other JSR-305 annotations.

The default behavior is the same to `-Xjsr305=warn`. The `strict` value should be considered experimental (more checks may be added to it in the future).

Mapped types

Kotlin treats some Java types specifically. Such types are not loaded from Java "as is", but are *mapped* to corresponding Kotlin types. The mapping only matters at compile time, the runtime representation remains unchanged. Java's primitive types are mapped to corresponding Kotlin types (keeping platform types in mind):

Java type	Kotlin type
`byte`	`kotlin.Byte`
`short`	`kotlin.Short`
`int`	`kotlin.Int`
`long`	`kotlin.Long`
`char`	`kotlin.Char`
`float`	`kotlin.Float`
`double`	`kotlin.Double`
`boolean`	`kotlin.Boolean`

Some non-primitive built-in classes are also mapped:

Java type	Kotlin type
`java.lang.Object`	`kotlin.Any!`
`java.lang.Cloneable`	`kotlin.Cloneable!`
`java.lang.Comparable`	`kotlin.Comparable!`
`java.lang.Enum`	`kotlin.Enum!`
`java.lang.annotation.Annotation`	`kotlin.Annotation!`
`java.lang.CharSequence`	`kotlin.CharSequence!`
`java.lang.String`	`kotlin.String!`
`java.lang.Number`	`kotlin.Number!`

Java type	Kotlin type
`java.lang.Throwable`	`kotlin.Throwable!`

Java's boxed primitive types are mapped to nullable Kotlin types:

Java type	Kotlin type
`java.lang.Byte`	`kotlin.Byte?`
`java.lang.Short`	`kotlin.Short?`
`java.lang.Integer`	`kotlin.Int?`
`java.lang.Long`	`kotlin.Long?`
`java.lang.Character`	`kotlin.Char?`
`java.lang.Float`	`kotlin.Float?`
`java.lang.Double`	`kotlin.Double?`
`java.lang.Boolean`	`kotlin.Boolean?`

Note that a boxed primitive type used as a type parameter is mapped to a platform type: for example, `List<java.lang.Integer>` becomes a `List<Int!>` in Kotlin.

Collection types may be read-only or mutable in Kotlin, so Java's collections are mapped as follows (all Kotlin types in this table reside in the package `kotlin.collections`):

Java type	Kotlin read-only type	Kotlin mutable type	Loaded platform type
`Iterator<T>`	`Iterator<T>`	`MutableIterator<T>`	`(Mutable)Iterator<T>!`
`Iterable<T>`	`Iterable<T>`	`MutableIterable<T>`	`(Mutable)Iterable<T>!`
`Collection<T>`	`Collection<T>`	`MutableCollection<T>`	`(Mutable)Collection<T>!`
`Set<T>`	`Set<T>`	`MutableSet<T>`	`(Mutable)Set<T>!`
`List<T>`	`List<T>`	`MutableList<T>`	`(Mutable)List<T>!`

Java type	Kotlin read-only type	Kotlin mutable type	Loaded platform type
`ListIterator<T>`	`ListIterator<T>`	`MutableListIterator<T>`	`(Mutable)ListIterator<T>!`
`Map<K, V>`	`Map<K, V>`	`MutableMap<K, V>`	`(Mutable)Map<K, V>!`
`Map.Entry<K, V>`	`Map.Entry<K, V>`	`MutableMap.MutableEntry<K, V>`	`(Mutable)Map.(Mutable)Entry<K, V>!`

Java's arrays are mapped as mentioned below:

Java type	Kotlin type
`int[]`	`kotlin.IntArray!`
`String[]`	`kotlin.Array<(out) String!>!`

The static members of these Java types are not directly accessible on the companion objects of the Kotlin types. To call them, use the full qualified names of the Java types, e.g. `java.lang.Integer.toHexString(foo)`.

Java generics in Kotlin

Kotlin's generics are a little different from Java's (see Generics). When importing Java types to Kotlin, the following conversions are done:

- Java's wildcards are converted into type projections:
  - `Foo<? extends Bar>` becomes `Foo<out Bar!>!`
  - `Foo<? super Bar>` becomes `Foo<in Bar!>!`
- Java's raw types are converted into star projections:
  - `List` becomes `List<*>!` that is `List<out Any?>!`

Like Java's, Kotlin's generics are not retained at runtime: objects do not carry information about actual type arguments passed to their constructors. For example, `ArrayList<Integer>()` is indistinguishable from `ArrayList<Character>()`. This makes it impossible to perform `is`-checks that take generics into account. Kotlin only allows `is`-checks for star-projected generic types:

```
if (a is List<Int>) // Error: cannot check if it is really a List of Ints
// but
if (a is List<*>) // OK: no guarantees about the contents of the list
```

Java arrays

Arrays in Kotlin are invariant, unlike Java. This means that Kotlin won't let you assign an `Array<String>` to an `Array<Any>`, which prevents a possible runtime failure. Passing an array of a subclass as an array of superclass to a Kotlin method is also prohibited, but for Java methods this is allowed through platform types of the form `Array<(out) String>!`.

Arrays are used with primitive datatypes on the Java platform to avoid the cost of boxing/unboxing operations. As Kotlin hides those implementation details, a workaround is required to interface with Java code. There are specialized classes for every type of primitive array (`IntArray`, `DoubleArray`, `CharArray`, and so on) to handle this case. They are not related to the `Array` class and are compiled down to Java's primitive arrays for maximum performance.

Suppose there is a Java method that accepts an int array of indices:

```
public class JavaArrayExample {
    public void removeIndices(int[] indices) {
        // code here...
    }
}
```

To pass an array of primitive values, you can do the following in Kotlin:

```
val javaObj = JavaArrayExample()
val array = intArrayOf(0, 1, 2, 3)
javaObj.removeIndices(array)  // passes int[] to method
```

When compiling to the JVM bytecode, the compiler optimizes access to arrays so that there's no overhead introduced:

```
val array = arrayOf(1, 2, 3, 4)
array[1] = array[1] * 2 // no actual calls to get() and set() generated
for (x in array) { // no iterator created
    print(x)
}
```

Even when you navigate with an index, it does not introduce any overhead:

```
for (i in array.indices) { // no iterator created
    array[i] += 2
}
```

Finally, `in`-checks have no overhead either:

```
if (i in array.indices) { // same as (i ≥ 0 && i < array.size)
    print(array[i])
}
```

Java varargs

Java classes sometimes use a method declaration for the indices with a variable number of arguments (varargs):

```
public class JavaArrayExample {

    public void removeIndicesVarArg(int... indices) {
        // code here...
    }
}
```

In that case, you need to use the spread operator `*` to pass the `IntArray`:

```
val javaObj = JavaArrayExample()
val array = intArrayOf(0, 1, 2, 3)
javaObj.removeIndicesVarArg(*array)
```

Operators

Since Java has no way of marking methods for which it makes sense to use the operator syntax, Kotlin allows using any Java methods with the right name and signature as operator overloads and other conventions (`invoke()` etc.) Calling Java methods using the infix call syntax is not allowed.

Checked exceptions

In Kotlin, all exceptions are unchecked, meaning that the compiler does not force you to catch any of them. So, when you call a Java method that declares a checked exception, Kotlin does not force you to do anything:

```
fun render(list: List<*>, to: Appendable) {
    for (item in list) {
        to.append(item.toString()) // Java would require us to catch IOException here
    }
}
```

Object methods

When Java types are imported into Kotlin, all the references of the type `java.lang.Object` are turned into `Any`. Since `Any` is not platform-specific, it only declares `toString()`, `hashCode()` and `equals()` as its members, so to make other members of `java.lang.Object` available, Kotlin uses extension functions.

`wait()` and `notify()`

Methods `wait()` and `notify()` are not available on references of type `Any`. Their usage is generally discouraged in favor of `java.util.concurrent`.

If you have to call these methods, access them through Java objects and suppress the `PLATFORM_CLASS_MAPPED_TO_KOTLIN` warning:

```
import java.util.LinkedList

class SimpleBlockingQueue<T>(private val capacity: Int) {
    private val queue = LinkedList<T>()

    // java.lang.Object is used specifically to access wait() and notify()
    // In Kotlin, the standard 'Any' type does not expose these methods.
    @Suppress("PLATFORM_CLASS_MAPPED_TO_KOTLIN")
    private val lock = Object()

    fun put(item: T) {
        synchronized(lock) {
            while (queue.size >= capacity) {
                lock.wait()
            }
            queue.add(item)
            println("Produced: $item")

            lock.notifyAll()
        }
    }

    fun take(): T {
        synchronized(lock) {
            while (queue.isEmpty()) {
                lock.wait()
            }
            val item = queue.removeFirst()
            println("Consumed: $item")

            lock.notifyAll()
            return item
        }
    }
}
```

Or explicitly cast to `java.lang.Object` and suppress the `PLATFORM_CLASS_MAPPED_TO_KOTLIN` warning:

```
@Suppress("PLATFORM_CLASS_MAPPED_TO_KOTLIN")
(foo as java.lang.Object).wait()
```

`getClass()`

To retrieve the Java class of an object, use the `java` extension property on a class reference:

```
val fooClass = foo::class.java
```

The code above uses a bound class reference. You can also use the `javaClass` extension property:

```
val fooClass = foo.javaClass
```

`clone()`

To override `clone()`, your class needs to extend `kotlin.Cloneable`:

```
class Example : Cloneable {
    override fun clone(): Any { ... }
}
```

Don't forget about Effective Java, 3rd Edition, Item 13: *Override clone judiciously*.

`finalize()`

To override `finalize()`, all you need to do is simply declare it, without using the `override` keyword:

```
class C {
    protected fun finalize() {
        // finalization logic
    }
}
```

According to Java's rules, `finalize()` must not be `private`.

Inheritance from Java classes

At most one Java class (and as many Java interfaces as you like) can be a supertype for a class in Kotlin.

Accessing static members

Static members of Java classes form "companion objects" for these classes. You can't pass such a "companion object" around as a value but can access the members explicitly, for example:

```
if (Character.isLetter(a)) { ... }
```

To access static members of a Java type that is mapped to a Kotlin type, use the full qualified name of the Java type: `java.lang.Integer.bitCount(foo)`.

Java reflection

Java reflection works on Kotlin classes and vice versa. As mentioned above, you can use `instance::class.java`, `ClassName::class.java` or `instance.javaClass` to enter Java reflection through `java.lang.Class`. Do not use `ClassName.javaClass` for this purpose because it refers to `ClassName`'s companion object class, which is the same as `ClassName.Companion::class.java` and not `ClassName::class.java`.

For each primitive type, there are two different Java classes, and Kotlin provides ways to get both. For example, `Int::class.java` will return the class instance representing the primitive type itself, corresponding to `Integer.TYPE` in Java. To get the class of the corresponding wrapper type, use `Int::class.javaObjectType`, which is equivalent of Java's `Integer.class`.

Other supported cases include acquiring a Java getter/setter method or a backing field for a Kotlin property, a `KProperty` for a Java field, a Java method or constructor for a `KFunction` and vice versa.

SAM conversions

Kotlin supports SAM conversions for both Java and Kotlin interfaces. This support for Java means that Kotlin function literals can be automatically converted into implementations of Java interfaces with a single non-default method, as long as the parameter types of the interface method match the parameter types of the Kotlin function.

You can use this for creating instances of SAM interfaces:

```
val runnable = Runnable { println("This runs in a runnable") }
```

...and in method calls:

```
val executor = ThreadPoolExecutor()
// Java signature: void execute(Runnable command)
executor.execute { println("This runs in a thread pool") }
```

If the Java class has multiple methods taking functional interfaces, you can choose the one you need to call by using an adapter function that converts a lambda to a specific SAM type. Those adapter functions are also generated by the compiler when needed:

```
executor.execute(Runnable { println("This runs in a thread pool") })
```

SAM conversions only work for interfaces, not for abstract classes, even if those also have just a single abstract method.

Using JNI with Kotlin

To declare a function that is implemented in native (C or C++) code, you need to mark it with the `external` modifier:

```
external fun foo(x: Int): Double
```

The rest of the procedure works in exactly the same way as in Java.

You can also mark property getters and setters as `external`:

```
var myProperty: String
    external get
    external set
```

Behind the scenes, this will create two functions `getMyProperty` and `setMyProperty`, both marked as `external`.

Using Lombok-generated declarations in Kotlin

You can use Java's Lombok-generated declarations in Kotlin code. If you need to generate and use these declarations in the same mixed Java/Kotlin module, you can learn how to do this on the Lombok compiler plugin's page. If you call such declarations from another module, then you don't need to use this plugin to compile that module.

Calling Kotlin from Java

Kotlin code can be easily called from Java. For example, instances of a Kotlin class can be seamlessly created and operated in Java methods. However, there are certain differences between Java and Kotlin that require attention when integrating Kotlin code into Java. On this page, we'll describe the ways to tailor the interop of your Kotlin code with its Java clients.

Properties

A Kotlin property is compiled to the following Java elements:

- a getter method, with the name calculated by prepending the `get` prefix.
- a setter method, with the name calculated by prepending the `set` prefix (only for `var` properties).
- a private field, with the same name as the property name (only for properties with backing fields).

For example, `var firstName: String` compiles to the following Java declarations:

```
private String firstName;

public String getFirstName() {
    return firstName;
}

public void setFirstName(String firstName) {
    this.firstName = firstName;
}
```

If the name of the property starts with `is`, a different name mapping rule is used: the name of the getter is the same as the property name, and the name of the setter is obtained by replacing `is` with `set`. For example, for a property `isOpen`, the getter is called `isOpen()` and the setter is called `setOpen()`. This rule applies for properties of any type, not just `Boolean`.

Package-level functions

All the functions and properties declared in a file `app.kt` inside a package `org.example`, including extension functions, are compiled into static methods of a Java class named `org.example.AppKt`.

```
// app.kt
package org.example

class Util

fun getTime() { /*...*/ }
```

```
// Java
new org.example.Util();
org.example.AppKt.getTime();
```

To set a custom name to the generated Java class, use the `@JvmName` annotation:

```
@file:JvmName("DemoUtils")

package org.example

class Util

fun getTime() { /*...*/ }
```

```
// Java
new org.example.Util();
org.example.DemoUtils.getTime();
```

Having multiple files with the same generated Java class name (the same package and the same name or the same `@JvmName` annotation) is normally an error. However, the compiler can generate a single Java facade class which has the specified name and contains all the declarations from all the files which have that name. To enable the generation of such a facade, use the `@JvmMultifileClass` annotation in all such files.

```
// oldutils.kt
@file:JvmName("Utils")
@file:JvmMultifileClass

package org.example

fun getTime() { /*...*/ }
```

```
// newutils.kt
@file:JvmName("Utils")
@file:JvmMultifileClass

package org.example

fun getDate() { /*...*/ }
```

```
// Java
org.example.Utils.getTime();
org.example.Utils.getDate();
```

Instance fields

If you need to expose a Kotlin property as a field in Java, annotate it with the `@JvmField` annotation. The field has the same visibility as the underlying property. You can annotate a property with `@JvmField` if it:

- has a backing field
- is not private
- does not have `open`, `override` or `const` modifiers
- is not a delegated property

```
class User(id: String) {
    @JvmField val ID = id
}
```

```
// Java
class JavaClient {
    public String getID(User user) {
        return user.ID;
    }
}
```

Late-Initialized properties are also exposed as fields. The visibility of the field is the same as the visibility of the `lateinit` property setter.

Static fields

Kotlin properties declared in a named object or a companion object have static backing fields either in that named object or in the class containing the companion object.

Usually these fields are private, but they can be exposed in one of the following ways:

- `@JvmField` annotation
- `lateinit` modifier
- `const` modifier

Annotating such a property with `@JvmField` makes it a static field with the same visibility as the property itself.

```
class Key(val value: Int) {
    companion object {
        @JvmField
        val COMPARATOR: Comparator<Key> = compareBy<Key> { it.value }
    }
}
```

```
// Java
Key.COMPARATOR.compare(key1, key2);
// public static final field in Key class
```

A late-initialized property in an object or a companion object has a static backing field with the same visibility as the property setter.

```
object Singleton {
    lateinit var provider: Provider
}
```

```
// Java
Singleton.provider = new Provider();
// public static non-final field in Singleton class
```

Properties declared as `const` (in classes as well as at the top level) are turned into static fields in Java:

```
// file example.kt

object Obj {
    const val CONST = 1
}

class C {
    companion object {
        const val VERSION = 9
    }
}

const val MAX = 239
```

In Java:

```
int constant = Obj.CONST;
int max = ExampleKt.MAX;
int version = C.VERSION;
```

Static methods

Kotlin represents package-level functions as static methods. You can also generate static methods for functions defined in named objects or companion objects if you annotate such functions with the `@JvmStatic` annotation.

If you use `@JvmStatic` on a function in a companion object, the compiler generates both a static method in the enclosing class and an instance method in the companion object:

```
// Kotlin
class C {
    companion object {
        @JvmStatic fun callStatic() {}
        fun callNonStatic() {}
    }
}
```

In Java, you can call `callStatic()` on both the enclosing class and the companion object, while `callNonStatic()` is only available through the companion object:

```
// Java
C.callStatic();              // Success
C.callNonStatic();           // Error: not a static method
C.Companion.callStatic();    // Instance method remains
C.Companion.callNonStatic(); // Success
```

For a named object (a singleton), `@JvmStatic` turns the function into a static method of the object's class but doesn't generate a separate instance method:

```
// Kotlin
object Obj {
    @JvmStatic fun callStatic() {}
    fun callNonStatic() {}
}
```

In Java, you can call the `callStatic()` method on the named object, while `callNonStatic()` is only available through the singleton instance:

```
// Java
Obj.callStatic();              // Success
Obj.callNonStatic();           // Error: not a static method
Obj.INSTANCE.callNonStatic(); // Success, the call passed through the singleton instance
```

You can also annotate a function in an interface's companion object with `@JvmStatic`. Such functions compile to static methods in interfaces:

```
interface ChatBot {
    companion object {
        @JvmStatic fun greet(username: String) {
            println("Hello, $username")
        }
    }
}
```

You can also apply the `@JvmStatic` annotation to the property of an object or a companion object, making its getter and setter methods static members in that object or the class containing the companion object.

Default methods in interfaces

When targeting the JVM, Kotlin compiles functions declared in interfaces to default methods unless configured otherwise. These are concrete methods in interfaces that Java classes can inherit directly, without reimplementation.

Here is an example of a Kotlin interface with a default method:

```
interface Robot {
    fun move() { println("~walking~") }  // will be default in the Java interface
    fun speak(): Unit
}
```

The default implementation is available for Java classes implementing the interface.

```
//Java implementation
public class C3PO implements Robot {
    // move() implementation from Robot is available implicitly
    @Override
    public void speak() {
        System.out.println("I beg your pardon, sir");
    }
}
```

```
C3PO c3po = new C3PO();
c3po.move(); // default implementation from the Robot interface
c3po.speak();
```

Implementations of the interface can override default methods.

```java
//Java
public class BB8 implements Robot {
    //own implementation of the default method
    @Override
    public void move() {
        System.out.println("~rolling~");
    }

    @Override
    public void speak() {
        System.out.println("Beep-beep");
    }
}
```

Compatibility modes for default methods

Kotlin provides three modes for controlling how functions in interfaces are compiled to JVM default methods. These modes determine whether the compiler generates compatibility bridges and static methods in `DefaultImpls` classes.

You can control this behavior using the `-jvm-default` compiler option:

> The `-jvm-default` compiler option replaces the deprecated `-Xjvm-default` option.

Learn more about compatibility modes:

enable

Default behavior. Generates default implementations in interfaces and includes compatibility bridges and `DefaultImpls` classes. This mode maintains compatibility with older compiled Kotlin code.

no-compatibility

Generates only default implementations in interfaces. Skips compatibility bridges and `DefaultImpls` classes. Use this mode for new codebases that don't interact with code that relies on `DefaultImpls` classes. This can break binary compatibility with older Kotlin code.

> If interface delegation is used, all interface methods are delegated.

disable

Disables default implementations in interfaces. Only compatibility bridges and `DefaultImpls` classes are generated.

Visibility

The Kotlin maps visibility modifiers to Java as follows:

- `private` members remain `private`.
- `private` top-level declarations become `private` top-level declarations in Java. Package-private accessors are also included if accessed from within a class.

- `protected` members remain `protected`.

  Note that Java allows accessing protected members from other classes in the same package, and Kotlin doesn't.

- `internal` declarations become `public` in Java.

  The Kotlin compiler mangles the names of `internal` members in bytecode. This prevents accidental overrides across modules, for example, when extending a Kotlin class from Java, and allows overloading for members with the same signature.

  Note that the names of public members of `internal` classes aren't mangled and remain callable from Java.

- `public` members remain `public`.

KClass

Sometimes you need to call a Kotlin method with a parameter of type `KClass`. There is no automatic conversion from `Class` to `KClass`, so you have to do it manually by invoking the equivalent of the `Class<T>.kotlin` extension property:

```
kotlin.jvm.JvmClassMappingKt.getKotlinClass(MainView.class)
```

Handling signature clashes with @JvmName

Sometimes we have a named function in Kotlin, for which we need a different JVM name in bytecode. The most prominent example happens due to *type erasure*:

```
fun List<String>.filterValid(): List<String>
fun List<Int>.filterValid(): List<Int>
```

These two functions can not be defined side-by-side, because their JVM signatures are the same: `filterValid(Ljava/util/List;)Ljava/util/List;`. If we really want them to have the same name in Kotlin, we can annotate one (or both) of them with `@JvmName` and specify a different name as an argument:

```
fun List<String>.filterValid(): List<String>

@JvmName("filterValidInt")
fun List<Int>.filterValid(): List<Int>
```

From Kotlin, they are accessible by the same name `filterValid`, but from Java it is `filterValid` and `filterValidInt`.

The same trick applies when we need to have a property `x` along with a function `getX()`:

```
val x: Int
    @JvmName("getX_prop")
    get() = 15

fun getX() = 10
```

To change the names of generated accessor methods for properties without explicitly implemented getters and setters, you can use `@get:JvmName` and `@set:JvmName`:

```
@get:JvmName("x")
@set:JvmName("changeX")
var x: Int = 23
```

Overloads generation

Normally, if you write a Kotlin function with default parameter values, it's visible in Java only as a full signature, with all parameters present.

You can use the `@IntroducedAt` annotation or the `@JvmOverloads` annotation to generate overloads for optional parameters.

Use `@IntroducedAt` when you add new optional parameters to published APIs and want the generated overloads to reflect the version in which each parameter was introduced. The compiler uses this information to automatically generate the corresponding hidden overloads.

This gives you version-based overload generation and helps preserve binary compatibility for callers compiled against older versions of your library.

> The `@IntroducedAt` annotation is Experimental. To opt in, use the `@OptIn(ExperimentalVersionOverloading::class)` annotation.

Here's an example where the `Button()` function receives multiple optional parameters over several API versions:

```
@OptIn(ExperimentalVersionOverloading::class)
fun Button(
    label: String = "",
    color: Color = DefaultColor,
    @IntroducedAt("1.1") borderColor: Color = DefaultBorderColor,
    @IntroducedAt("1.2") borderStyle: Style = DefaultBorderStyle,
    @IntroducedAt("1.2") borderWidth: Int = 1,
    onClick: () -> Unit
) {
    // Function body
}
```

Based on these versions, the compiler generates hidden overloads for the original API and for each API version that introduced new optional parameters:

```
// Original API
Button(
    label: String,
    color: Color,
    onClick: () -> Unit
)

// Version 1.1
Button(
    label: String,
    color: Color,
    borderColor: Color,
    onClick: () -> Unit
)

// Version 1.2
Button(
    label: String,
    color: Color,
    borderColor: Color,
    borderStyle: Style,
    borderWidth: Int,
    onClick: () -> Unit
)
```

If you want to expose multiple overloads to Java callers, you can also use the `@JvmOverloads` annotation.

The annotation also works for constructors, static methods, and so on. It can't be used on abstract methods, including methods defined in interfaces. For example, consider a `Circle` class with default parameter values:

```
class Circle @JvmOverloads constructor(centerX: Int, centerY: Int, radius: Double = 1.0) {
    @JvmOverloads fun draw(label: String, lineWidth: Int = 1, color: String = "red") { /*...*/ }
}
```

For every parameter with a default value, this generates one additional overload, which has this parameter and all parameters to the right of it in the parameter list removed. In this example, the following is generated:

```
// Constructors:
Circle(int centerX, int centerY, double radius)
Circle(int centerX, int centerY)

// Methods
void draw(String label, int lineWidth, String color) { }
void draw(String label, int lineWidth) { }
void draw(String label) { }
```

Since both `@IntroducedAt` and `@JvmOverloads` annotations generate overloads, using them together can create conflicting overloads. If you use both annotations, the compiler reports a warning. If you suppress the warning, the compiler prioritizes overloads generated from the `@IntroducedAt` annotation.

Note that, as described in Secondary constructors, if a class has default values for all constructor parameters, a public constructor with no arguments is generated for it. This works even if the `@JvmOverloads` annotation is not specified.

Checked exceptions

Kotlin does not have checked exceptions. So, normally the Java signatures of Kotlin functions do not declare exceptions thrown. Thus, if you have a function in Kotlin like this:

```kotlin
// example.kt
package demo

fun writeToFile() {
    /*...*/
    throw IOException()
}
```

And you want to call it from Java and catch the exception:

```java
// Java
try {
    demo.Example.writeToFile();
} catch (IOException e) {
    // error: writeToFile() does not declare IOException in the throws list
    // ...
}
```

You get an error message from the Java compiler, because `writeToFile()` does not declare `IOException`. To work around this problem, use the `@Throws` annotation in Kotlin:

```kotlin
@Throws(IOException::class)
fun writeToFile() {
    /*...*/
    throw IOException()
}
```

Null-safety

When calling Kotlin functions from Java, nobody prevents us from passing `null` as a non-nullable parameter. That's why Kotlin generates runtime checks for all public functions that expect non-nulls. This way we get a `NullPointerException` in the Java code immediately.

Variant generics

When Kotlin classes make use of declaration-site variance, there are two options of how their usages are seen from the Java code. For example, imagine you have the following class and two functions that use it:

```kotlin
class Box<out T>(val value: T)

interface Base
class Derived : Base

fun boxDerived(value: Derived): Box<Derived> = Box(value)
fun unboxBase(box: Box<Base>): Base = box.value
```

A naive way of translating these functions into Java would be this:

```java
Box<Derived> boxDerived(Derived value) { ... }
Base unboxBase(Box<Base> box) { ... }
```

The problem is that in Kotlin you can write `unboxBase(boxDerived(Derived()))` but in Java that would be impossible because in Java the class `Box` is *invariant* in its parameter `T`, and thus `Box<Derived>` is not a subtype of `Box<Base>`. To make this work in Java, you would have to define `unboxBase` as follows:

```
Base unboxBase(Box<? extends Base> box) { ... }
```

This declaration uses Java's *wildcards types* (`? extends Base`) to emulate declaration-site variance through use-site variance, because it is all Java has.

To make Kotlin APIs work in Java, the compiler generates `Box<Super>` as `Box<? extends Super>` for covariantly defined `Box` (or `Foo<? super Bar>` for contravariantly defined `Foo`) when it appears *as a parameter*. When it's a return value, wildcards are not generated, because otherwise Java clients will have to deal with them (and it's against the common Java coding style). Therefore, the functions from our example are actually translated as follows:

```
// return type - no wildcards
Box<Derived> boxDerived(Derived value) { ... }

// parameter - wildcards
Base unboxBase(Box<? extends Base> box) { ... }
```

When the argument type is final, there's usually no point in generating the wildcard, so `Box<String>` is always `Box<String>` , no matter what position it takes.

If you need wildcards where they are not generated by default, use the `@JvmWildcard` annotation:

```
fun boxDerived(value: Derived): Box<@JvmWildcard Derived> = Box(value)
// is translated to
// Box<? extends Derived> boxDerived(Derived value) { ... }
```

In the opposite case, if you don't need wildcards where they are generated, use `@JvmSuppressWildcards` :

```
fun unboxBase(box: Box<@JvmSuppressWildcards Base>): Base = box.value
// is translated to
// Base unboxBase(Box<Base> box) { ... }
```

`@JvmSuppressWildcards` can be used not only on individual type arguments, but on entire declarations, such as functions or classes, causing all wildcards inside them to be suppressed.

Translation of type Nothing

The type `Nothing` is special, because it has no natural counterpart in Java. Indeed, every Java reference type, including `java.lang.Void` , accepts `null` as a value, and `Nothing` doesn't accept even that. So, this type cannot be accurately represented in the Java world. This is why Kotlin generates a raw type where an argument of type `Nothing` is used:

```
fun emptyList(): List<Nothing> = listOf()
// is translated to
// List emptyList() { ... }
```

Experimental

Inline value classes

If you want Java code to work smoothly with Kotlin's inline value classes, you can use the `@JvmExposeBoxed` annotation or the `-Xjvm-expose-boxed` compiler option. These approaches ensure Kotlin generates the necessary boxed representations for Java interoperability.

By default, Kotlin compiles inline value classes to use **unboxed representations**, which are often inaccessible from Java. For example, you can't call the constructor for the `MyInt` class from Java:

```
@JvmInline
value class MyInt(val value: Int)
```

So the following Java code fails:

```
MyInt input = new MyInt(5);
```

You can use the `@JvmExposeBoxed` annotation so that Kotlin generates a public constructor that you can call from Java directly. You can apply the annotation at the following levels to ensure fine-grained control over what's exposed to Java:

- Class
- Constructor
- Function

Before using the `@JvmExposeBoxed` annotation in your code, you must opt in by using `@OptIn(ExperimentalStdlibApi::class)`. For example:

```
@OptIn(ExperimentalStdlibApi::class)
@JvmExposeBoxed
@JvmInline
value class MyInt(val value: Int)

@OptIn(ExperimentalStdlibApi::class)
@JvmExposeBoxed
fun MyInt.timesTwoBoxed(): MyInt = MyInt(this.value * 2)
```

With these annotations, Kotlin generates a Java-accessible constructor for the `MyInt` class **and** a variant for the extension function that uses the boxed form of the value class. So the following Java code runs successfully:

```
MyInt input = new MyInt(5);
MyInt output = ExampleKt.timesTwoBoxed(input);
```

To apply this behavior to all inline value classes and the functions that use them within a module, compile it with the `-Xjvm-expose-boxed` option. Compiling with this option has the same effect as if every declaration in the module has the `@JvmExposeBoxed` annotation.

Inherited functions

The `@JvmExposeBoxed` annotation doesn't automatically generate boxed representations for inherited functions.

To generate the necessary representation for an inherited function, override it in the implementing or extending class:

```
interface IdTransformer {
    fun transformId(rawId: UInt): UInt = rawId
}

// Doesn't generate a boxed representation for the transformId() function
@OptIn(ExperimentalStdlibApi::class)
@JvmExposeBoxed
class LightweightTransformer : IdTransformer

// Generates a boxed representation for the transformId() function
@OptIn(ExperimentalStdlibApi::class)
@JvmExposeBoxed
class DefaultTransformer : IdTransformer {
    override fun transformId(rawId: UInt): UInt = super.transformId(rawId)
}
```

To learn how inheritance works in Kotlin and how to call superclass implementations using the `super` keyword, see Inheritance.

Using Java records in Kotlin

Records are classes in Java for storing immutable data. Records carry a fixed set of values – the *records components*. They have a concise syntax in Java and save you from having to write boilerplate code:

```
// Java
public record Person (String name, int age) {}
```

The compiler automatically generates a final class inherited from `java.lang.Record` with the following members:

- a private final field for each record component
- a public constructor with parameters for all fields
- a set of methods to implement structural equality: `equals()`, `hashCode()`, `toString()`
- a public method for reading each record component

Records are very similar to Kotlin data classes.

Using Java records from Kotlin code

You can use record classes with components that are declared in Java the same way you would use classes with properties in Kotlin. To access the record component, just use its name like you do for Kotlin properties:

```
val newPerson = Person("Kotlin", 10)
val firstName = newPerson.name
```

Declare records in Kotlin

Kotlin supports record declaration only for data classes, and the data class must meet the requirements.

To declare a record class in Kotlin, use the `@JvmRecord` annotation:

Applying `@JvmRecord` to an existing class is not a binary compatible change. It alters the naming convention of the class property accessors.

```
@JvmRecord
data class Person(val name: String, val age: Int)
```

This JVM-specific annotation enables generating:

- the record components corresponding to the class properties in the class file
- the property accessor methods named according to the Java record naming convention

The data class provides `equals()`, `hashCode()`, and `toString()` method implementations.

Requirements

To declare a data class with the `@JvmRecord` annotation, it must meet the following requirements:

- The class must be in a module that targets JVM 16 bytecode (or 15 if the `-Xjvm-enable-preview` compiler option is enabled).
- The class cannot explicitly inherit any other class (including `Any`) because all JVM records implicitly inherit `java.lang.Record`. However, the class can implement interfaces.
- The class cannot declare any properties with backing fields – except those initialized from the corresponding primary constructor parameters.
- The class cannot declare any mutable properties with backing fields.
- The class cannot be local.
- The primary constructor of the class must be as visible as the class itself.

Enable JVM records

JVM records require the `16` target version or higher of the generated JVM bytecode.

To specify it explicitly, use the `jvmTarget` compiler option in Gradle or Maven.

Experimental

Annotate record components in Kotlin

In Java, annotations on a record component are automatically propagated to the backing field, getter, setter, and constructor parameter. You can replicate this behavior in Kotlin by using the `all` use-site target.

For example:

```
@JvmRecord
data class Person(val name: String, @all:Positive val age: Int)
```

When you use `@JvmRecord` with `@all:`, Kotlin:

- Propagates the annotation to the property, backing field, constructor parameter, getter, and setter.
- Applies the annotation to the record component as well, if the annotation supports Java's `RECORD_COMPONENT`.

Make annotations work with record components

To make an annotation available for both Kotlin properties **and** Java record components, add the following meta-annotations to your annotation declaration:

- For Kotlin: `@Target`
- For Java record components: `@java.lang.annotation.Target`

For example:

```
@Target(AnnotationTarget.CLASS, AnnotationTarget.PROPERTY)
@java.lang.annotation.Target(ElementType.CLASS, ElementType.RECORD_COMPONENT)
annotation class ExampleClass
```

You can now apply `@ExampleClass` to Kotlin classes and properties, as well as Java classes and record components.

Further discussion

See this language proposal for JVM records for further technical details and discussion.

Strings in Java and Kotlin

This guide contains examples of how to perform typical tasks with strings in Java and Kotlin. It will help you migrate from Java to Kotlin and write your code in the authentically Kotlin way.

Concatenate strings

In Java, you can do this in the following way:

```
// Java
String name = "Joe";
System.out.println("Hello, " + name);
System.out.println("Your name is " + name.length() + " characters long");
```

In Kotlin, use the dollar sign (`$`) before the variable name to interpolate the value of this variable into your string:

```
fun main() {
    // Kotlin
    val name = "Joe"
    println("Hello, $name")
    println("Your name is ${name.length} characters long")
}
```

You can interpolate the value of a complicated expression by surrounding it with curly braces, like in `${name.length}`. See string templates for more information.

Build a string

In Java, you can use the StringBuilder:

```java
// Java
StringBuilder countDown = new StringBuilder();
for (int i = 5; i > 0; i--) {
    countDown.append(i);
    countDown.append("\n");
}
System.out.println(countDown);
```

In Kotlin, use buildString() – an inline function that takes logic to construct a string as a lambda argument:

```kotlin
fun main() {
       // Kotlin
       val countDown = buildString {
           for (i in 5 downTo 1) {
               append(i)
               appendLine()
           }
       }
       println(countDown)
}
```

Under the hood, the `buildString` uses the same `StringBuilder` class as in Java, and you access it via an implicit `this` inside the lambda.

Learn more about lambda coding conventions.

Create a string from collection items

In Java, you use the Stream API to filter, map, and then collect the items:

```java
// Java
List<Integer> numbers = List.of(1, 2, 3, 4, 5, 6);
String invertedOddNumbers = numbers
        .stream()
        .filter(it -> it % 2 != 0)
        .map(it -> -it)
        .map(Object::toString)
        .collect(Collectors.joining("; "));
System.out.println(invertedOddNumbers);
```

In Kotlin, use the joinToString() function, which Kotlin defines for every List:

```kotlin
fun main() {
    // Kotlin
    val numbers = listOf(1, 2, 3, 4, 5, 6)
    val invertedOddNumbers = numbers
        .filter { it % 2 != 0 }
        .joinToString(separator = ";") {"${-it}"}
    println(invertedOddNumbers)
}
```

> In Java, if you want spaces between your delimiters and following items, you need to add a space to the delimiter explicitly.

Learn more about joinToString() usage.

Set default value if the string is blank

In Java, you can use the ternary operator:

```
// Java
public void defaultValueIfStringIsBlank() {
    String nameValue = getName();
    String name = nameValue.isBlank() ? "John Doe" : nameValue;
    System.out.println(name);
}

public String getName() {
    Random rand = new Random();
    return rand.nextBoolean() ? "" : "David";
}
```

Kotlin provides the inline function ifBlank() that accepts the default value as an argument:

```
// Kotlin
import kotlin.random.Random

fun main() {
    val name = getName().ifBlank { "John Doe" }
    println(name)
}

fun getName(): String =
    if (Random.nextBoolean()) "" else "David"
```

Replace characters at the beginning and end of a string

In Java, you can use the replaceAll() function. The `replaceAll()` function in this case accepts regular expressions `^##` and `##$`, which define strings starting and ending with `##` respectively:

```
// Java
String input = "##place##holder##";
String result = input.replaceAll("^##|##$", "");
System.out.println(result);
```

In Kotlin, use the removeSurrounding() function with the string delimiter `##`:

```
fun main() {
    // Kotlin
    val input = "##place##holder##"
    val result = input.removeSurrounding("##")
    println(result)
}
```

Replace occurrences

In Java, you can use the Pattern and the Matcher classes, for example, to obfuscate some data:

```java
// Java
String input = "login: Pokemon5, password: 1q2w3e4r5t";
Pattern pattern = Pattern.compile("\\w*\\d+\\w*");
Matcher matcher = pattern.matcher(input);
String replacementResult = matcher.replaceAll(it -> "xxx");
System.out.println("Initial input: '" + input + "'");
System.out.println("Anonymized input: '" + replacementResult + "'");
```

In Kotlin, you use the Regex class that simplifies working with regular expressions. Additionally, use multiline strings to simplify a regex pattern by reducing the count of backslashes:

```kotlin
fun main() {
    // Kotlin
    val regex = Regex("""\w*\d+\w*""") // multiline string
    val input = "login: Pokemon5, password: 1q2w3e4r5t"
    val replacementResult = regex.replace(input, replacement = "xxx")
    println("Initial input: '$input'")
    println("Anonymized input: '$replacementResult'")
}
```

Split a string

In Java, to split a string with the period character (`.`), you need to use shielding (`\\`). This happens because the split() function of the `String` class accepts a regular expression as an argument:

```java
// Java
System.out.println(Arrays.toString("Sometimes.text.should.be.split".split("\\.")));
```

In Kotlin, use the Kotlin function split(), which accepts varargs of delimiters as input parameters:

```kotlin
fun main() {
    // Kotlin
    println("Sometimes.text.should.be.split".split("."))
}
```

If you need to split with a regular expression, use the overloaded `split()` version that accepts the `Regex` as a parameter.

Take a substring

In Java, you can use the substring() function, which accepts an inclusive beginning index of a character to start taking the substring from. To take a substring after this character, you need to increment the index:

```java
// Java
String input = "What is the answer to the Ultimate Question of Life, the Universe, and Everything?
42";
String answer = input.substring(input.indexOf("?") + 1);
System.out.println(answer);
```

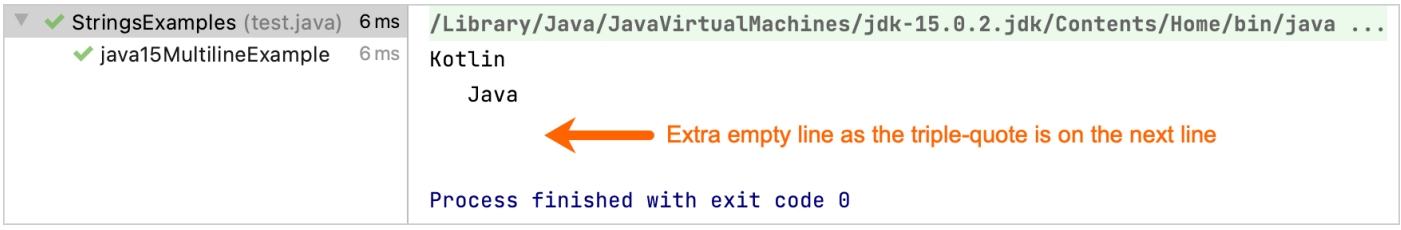
In Kotlin, you use the substringAfter() function and don't need to calculate the index of the character you want to take a substring after:

```kotlin
fun main() {
    // Kotlin
    val input = "What is the answer to the Ultimate Question of Life, the Universe, and Everything?
42"
    val answer = input.substringAfter("?")
    println(answer)
}
```

Additionally, you can take a substring after the last occurrence of a character:

```kotlin
fun main() {
    // Kotlin
    val input = "To be, or not to be, that is the question."
    val question = input.substringAfterLast(",")
    println(question)
}
```

Use multiline strings



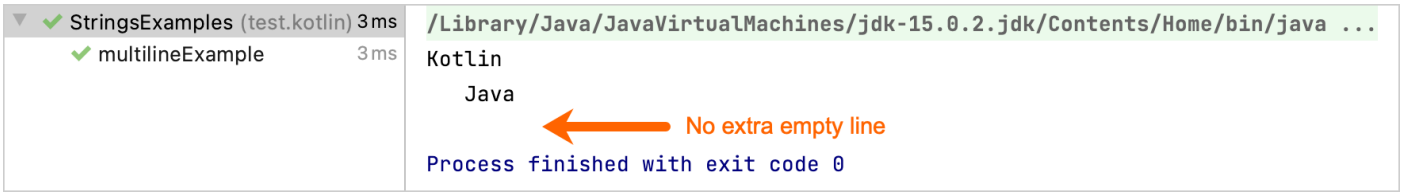
Before Java 15, there were several ways to create a multiline string. For example, using the join() function of the `String` class:

```java
// Java
String lineSeparator = System.getProperty("line.separator");
String result = String.join(lineSeparator,
       "Kotlin",
       "Java");
System.out.println(result);
```

In Java 15, text blocks appeared. There is one thing to keep in mind: if you print a multiline string and the triple-quote is on the next line, there will be an extra empty line:

```java
// Java
String result = """
    Kotlin
       Java
    """;
System.out.println(result);
```

The output:



Java 15 multiline output

If you put the triple-quote on the same line as the last word, this difference in behavior disappears.

In Kotlin, you can format your line with the quotes on the new line, and there will be no extra empty line in the output. The left-most character of any line identifies the beginning of the line. The difference with Java is that Java automatically trims indents, and in Kotlin you should do it explicitly:

```kotlin
fun main() {
    // Kotlin
    val result = """
        Kotlin
           Java
    """.trimIndent()
    println(result)
}
```

The output:

Kotlin multiline output

To have an extra empty line, you should add this empty line to your multiline string explicitly.

In Kotlin, you can also use the trimMargin() function to customize the indents:

```kotlin
// Kotlin
fun main() {
    val result = """
       #  Kotlin
       #  Java
   """.trimMargin("#")
    println(result)
}
```

Collections in Java and Kotlin

Collections are groups of a variable number of items (possibly zero) that are significant to the problem being solved and are commonly operated on. This guide explains and compares collection concepts and operations in Java and Kotlin. It will help you migrate from Java to Kotlin and write your code in the authentically Kotlin way.

The first part of this guide contains a quick glossary of operations on the same collections in Java and Kotlin. It is divided into operations that are the same and operations that exist only in Kotlin. The second part of the guide, starting from Mutability, explains some of the differences by looking at specific cases.

For an introduction to collections, see the Collections overview or watch this video by Sebastian Aigner, Kotlin Developer Advocate.

All of the examples below use Java and Kotlin standard library APIs only.

Operations that are the same in Java and Kotlin

In Kotlin, there are many operations on collections that look exactly the same as their counterparts in Java.

Operations on lists, sets, queues, and deques

Description	Common operations	More Kotlin alternatives
Add an element or elements	`add()`, `addAll()`	Use the `plusAssign` (`+=`) operator: `collection += element`, `collection += anotherCollection`.
Check whether a collection contains an element or elements	`contains()`, `containsAll()`	Use the `in` keyword to call `contains()` in the operator form: `element in collection`.
Check whether a collection is empty	`isEmpty()`	Use `isNotEmpty()` to check whether a collection is not empty.
Remove under a certain condition	`removeIf()`	
Leave only selected elements	`retainAll()`	
Remove all elements from a collection	`clear()`	
Get a stream from a collection	`stream()`	Kotlin has its own way to process streams: sequences and methods like `map()` and `filter()`.
Get an iterator from a collection	`iterator()`	

Operations on maps

Description	Common operations	More Kotlin alternatives
Add an element or elements	`put()`, `putAll()`, `putIfAbsent()`	In Kotlin, the assignment `map[key] = value` behaves the same as `put(key, value)`. Also, you may use the `plusAssign` (`+=`) operator: `map += Pair(key, value)` or `map += anotherMap`.

Description	Common operations	More Kotlin alternatives
Replace an element or elements	`put()`, `replace()`, `replaceAll()`	Use the indexing operator `map[key] = value` instead of `put()` and `replace()`.
Get an element	`get()`	Use the indexing operator to get an element: `map[index]`.
Check whether a map contains an element or elements	`containsKey()`, `containsValue()`	Use the `in` keyword to call `contains()` in the operator form: `element in map`.
Check whether a map is empty	`isEmpty()`	Use `isNotEmpty()` to check whether a map is not empty.
Remove an element	`remove(key)`, `remove(key, value)`	Use the `minusAssign` (`-=`) operator: `map -= key`.
Remove all elements from a map	`clear()`	
Get a stream from a map	`stream()` on entries, keys, or values	

Operations that exist only for lists

Description	Common operations	More Kotlin alternatives
Get an index of an element	`indexOf()`	
Get the last index of an element	`lastIndexOf()`	
Get an element	`get()`	Use the indexing operator to get an element: `list[index]`.
Take a sublist	`subList()`	
Replace an element or elements	`set()`, `replaceAll()`	Use the indexing operator instead of `set()`: `list[index] = value`.

Operations that differ a bit

Operations on any collection type

Description	Java	Kotlin
Get a collection's size	`size()`	`count()`, `size`
Get flat access to nested collection elements	`collectionOfCollections.forEach(flatCollection::addAll)` or `collectionOfCollections.stream().flatMap().collect()`	`flatten()` or `flatMap()`
Apply the given function to every element	`stream().map().collect()`	`map()`
Apply the provided operation to collection elements sequentially and return the accumulated result	`stream().reduce()`	`reduce()`, `fold()`
Group elements by a classifier and count them	`stream().collect(Collectors.groupingBy(classifier, counting()))`	`eachCount()`
Filter by a condition	`stream().filter().collect()`	`filter()`
Check whether collection elements satisfy a condition	`stream().noneMatch()`, `stream().anyMatch()`, `stream().allMatch()`	`none()`, `any()`, `all()`
Sort elements	`stream().sorted().collect()`	`sorted()`
Take the first N elements	`stream().limit(N).collect()`	`take(N)`
Take elements with a predicate	`stream().takeWhile().collect()`	`takeWhile()`
Skip the first N elements	`stream().skip(N).collect()`	`drop(N)`
Skip elements with a predicate	`stream().dropWhile().collect()`	`dropWhile()`
Build maps from collection elements and certain values associated with them	`stream().collect(toMap(keyMapper, valueMapper))`	`associate()`

To perform all of the operations listed above on maps, you first need to get an `entrySet` of a map.

Operations on lists

Description	Java	Kotlin
Sort a list into natural order	`sort(null)`	`sort()`
Sort a list into descending order	`sort(comparator)`	`sortDescending()`
Remove an element from a list	`remove(index)`, `remove(element)`	`removeAt(index)`, `remove(element)` or `collection -= element`
Fill all elements of a list with a certain value	`Collections.fill()`	`fill()`
Get unique elements from a list	`stream().distinct().toList()`	`distinct()`

Operations that don't exist in Java's standard library

- `zip()`, `unzip()` – transform a collection.
- `aggregate()` – group by a condition.
- `takeLast()`, `takeLastWhile()`, `dropLast()`, `dropLastWhile()` – take or drop elements by a predicate.
- `slice()`, `chunked()`, `windowed()` – retrieve collection parts.
- Plus (`+`) and minus (`-`) operators – add or remove elements.

If you want to take a deep dive into `zip()`, `chunked()`, `windowed()`, and some other operations, watch this video by Sebastian Aigner about advanced collection operations in Kotlin:

Watch video online.

Mutability

In Java, there are mutable collections:

```
// Java
// This list is mutable!
public List<Customer> getCustomers() { ... }
```

Partially mutable ones:

```
// Java
List<String> numbers = Arrays.asList("one", "two", "three", "four");
numbers.add("five"); // Fails in runtime with `UnsupportedOperationException`
```

And immutable ones:

```java
// Java
List<String> numbers = new LinkedList<>();
// This list is immutable!
List<String> immutableCollection = Collections.unmodifiableList(numbers);
immutableCollection.add("five"); // Fails in runtime with `UnsupportedOperationException`
```

If you write the last two pieces of code in IntelliJ IDEA, the IDE will warn you that you're trying to modify an immutable object. This code will compile and fail in runtime with `UnsupportedOperationException`. You can't tell whether a collection is mutable by looking at its type.

Unlike in Java, in Kotlin you explicitly declare mutable or read-only collections depending on your needs. If you try to modify a read-only collection, the code won't compile:

```kotlin
// Kotlin
val numbers = mutableListOf("one", "two", "three", "four")
numbers.add("five")            // This is OK
val immutableNumbers = listOf("one", "two")
//immutableNumbers.add("five") // Compilation error - Unresolved reference: add
```

Read more about immutability on the Kotlin coding conventions page.

Covariance

In Java, you can't pass a collection with a descendant type to a function that takes a collection of the ancestor type. For example, if `Rectangle` extends `Shape`, you can't pass a collection of `Rectangle` elements to a function that takes a collection of `Shape` elements. To make the code compilable, use the `? extends Shape` type so the function can take collections with any inheritors of `Shape`:

```java
// Java
class Shape {}

class Rectangle extends Shape {}

public void doSthWithShapes(List<? extends Shape> shapes) {
/* If using just List<Shape>, the code won't compile when calling
this function with the List<Rectangle> as the argument as below */
}

public void main() {
    var rectangles = List.of(new Rectangle(), new Rectangle());
    doSthWithShapes(rectangles);
}
```

In Kotlin, read-only collection types are covariant. This means that if a `Rectangle` class inherits from the `Shape` class, you can use the type `List<Rectangle>` anywhere the `List<Shape>` type is required. In other words, the collection types have the same subtyping relationship as the element types. Maps are covariant on the value type, but not on the key type. Mutable collections aren't covariant – this would lead to runtime failures.

```kotlin
// Kotlin
open class Shape(val name: String)

class Rectangle(private val rectangleName: String) : Shape(rectangleName)

fun doSthWithShapes(shapes: List<Shape>) {
    println("The shapes are: ${shapes.joinToString { it.name }}")
}

fun main() {
    val rectangles = listOf(Rectangle("rhombus"), Rectangle("parallelepiped"))
    doSthWithShapes(rectangles)
}
```

Read more about collection types here.

Ranges and progressions

In Kotlin, you can create intervals using ranges. For example, `Version(1, 11)..Version(1, 30)` includes all of the versions from `1.11` to `1.30`. You can check that your version is in the range by using the `in` operator: `Version(0, 9) in versionRange`.

In Java, you need to manually check whether a `Version` fits both bounds:

```java
// Java
class Version implements Comparable<Version> {

    int major;
    int minor;

    Version(int major, int minor) {
        this.major = major;
        this.minor = minor;
    }

    @Override
    public int compareTo(Version o) {
        if (this.major != o.major) {
            return this.major - o.major;
        }
        return this.minor - o.minor;
    }
}

public void compareVersions() {
    var minVersion = new Version(1, 11);
    var maxVersion = new Version(1, 31);

   System.out.println(
           versionIsInRange(new Version(0, 9), minVersion, maxVersion));
   System.out.println(
           versionIsInRange(new Version(1, 20), minVersion, maxVersion));
}

public Boolean versionIsInRange(Version versionToCheck, Version minVersion,
                                Version maxVersion) {
    return versionToCheck.compareTo(minVersion) >= 0
            && versionToCheck.compareTo(maxVersion) <= 0;
}
```

In Kotlin, you operate with a range as a whole object. You don't need to create two variables and compare a `Version` with them:

```
// Kotlin
class Version(val major: Int, val minor: Int): Comparable<Version> {
    override fun compareTo(other: Version): Int {
        if (this.major != other.major) {
            return this.major - other.major
        }
        return this.minor - other.minor
    }
}

fun main() {
    val versionRange = Version(1, 11)..Version(1, 30)

    println(Version(0, 9) in versionRange)
    println(Version(1, 20) in versionRange)
}
```

As soon as you need to exclude one of the bounds, like to check whether a version is greater than or equal to (`>=`) the minimum version and less than (`<`) the maximum version, these inclusive ranges won't help.

Comparison by several criteria

In Java, to compare objects by several criteria, you may use the `comparing()` and `thenComparingX()` functions from the `Comparator` interface. For example, to compare people by their name and age:

```
class Person implements Comparable<Person> {
    String name;
    int age;

    public String getName() {
        return name;
    }

    public int getAge() {
        return age;
    }

    Person(String name, int age) {
        this.name = name;
        this.age = age;
    }

    @Override
    public String toString() {
        return this.name + " " + age;
    }
}

public void comparePersons() {
    var persons = List.of(new Person("Jack", 35), new Person("David", 30),
            new Person("Jack", 25));
    System.out.println(persons.stream().sorted(Comparator
            .comparing(Person::getName)
            .thenComparingInt(Person::getAge)).collect(toList()));
}
```

In Kotlin, you just enumerate which fields you want to compare:

```
data class Person(
    val name: String,
    val age: Int
)

fun main() {
    val persons = listOf(Person("Jack", 35), Person("David", 30),
        Person("Jack", 25))
    println(persons.sortedWith(compareBy(Person::name, Person::age)))
}
```

Sequences

In Java, you can generate a sequence of numbers this way:

```
// Java
int sum = IntStream.iterate(1, e -> e + 3)
    .limit(10).sum();
System.out.println(sum); // Prints 145
```

In Kotlin, use *sequences*. Multistep processing of sequences is executed lazily when possible – actual computing happens only when the result of the whole processing chain is requested.

```
fun main() {
    // Kotlin
    val sum = generateSequence(1) {
        it + 3
    }.take(10).sum()
    println(sum) // Prints 145
}
```

Sequences may reduce the number of steps that are needed to perform some filtering operations. See the sequence processing example, which shows the difference between `Iterable` and `Sequence`.

Removal of elements from a list

In Java, the `remove()` function accepts an index of an element to remove.

When removing an integer element, use the `Integer.valueOf()` function as the argument for the `remove()` function:

```
// Java
public void remove() {
    var numbers = new ArrayList<>();
    numbers.add(1);
    numbers.add(2);
    numbers.add(3);
    numbers.add(1);
    numbers.remove(1); // This removes by index
    System.out.println(numbers); // [1, 3, 1]
    numbers.remove(Integer.valueOf(1));
    System.out.println(numbers); // [3, 1]
}
```

In Kotlin, there are two types of element removal: by index with `removeAt()` and by value with `remove()`.

```
fun main() {
    // Kotlin
    val numbers = mutableListOf(1, 2, 3, 1)
    numbers.removeAt(0)
    println(numbers) // [2, 3, 1]
    numbers.remove(1)
    println(numbers) // [2, 3]
}
```

Traverse a map

In Java, you can traverse a map via `forEach`:

```
// Java
numbers.forEach((k,v) -> System.out.println("Key = " + k + ", Value = " + v));
```

In Kotlin, use a `for` loop or a `forEach`, similar to Java's `forEach`, to traverse a map:

```
// Kotlin
for ((k, v) in numbers) {
    println("Key = $k, Value = $v")
}
// Or
numbers.forEach { (k, v) -> println("Key = $k, Value = $v") }
```

Get the first and the last items of a possibly empty collection

In Java, you can safely get the first and the last items by checking the size of the collection and using indices:

```
// Java
var list = new ArrayList<>();
// ...
if (list.size() > 0) {
    System.out.println(list.get(0));
    System.out.println(list.get(list.size() - 1));
}
```

In JDK 21 and later, you can also use the `getFirst()` and `getLast()` methods available on all `SequencedCollection` implementations. This includes all `List` implementations as well as other collections like `LinkedHashSet`. For example, with `ArrayList`:

```
// Java
var list = new ArrayList<>();
// ...
if (!list.isEmpty()) {
    System.out.println(list.getFirst());
    System.out.println(list.getLast());
}
```

In Kotlin, there are the special functions `firstOrNull()` and `lastOrNull()`. Using the `Elvis operator`, you can perform further actions right away depending on the result of a function. For example, `firstOrNull()`:

```kotlin
// Kotlin
val emails = listOf<String>() // Might be empty
val theOldestEmail = emails.firstOrNull() ?: ""
val theFreshestEmail = emails.lastOrNull() ?: ""
```

Create a set from a list

In Java, to create a `Set` from a `List`, you can use the `Set.copyOf` function:

```java
// Java
public void listToSet() {
    var sourceList = List.of(1, 2, 3, 1);
    var copySet = Set.copyOf(sourceList);
    System.out.println(copySet);
}
```

In Kotlin, use the function `toSet()`:

```kotlin
fun main() {
    // Kotlin
    val sourceList = listOf(1, 2, 3, 1)
    val copySet = sourceList.toSet()
    println(copySet)
}
```

Group elements

In Java, you can group elements with the Collectors function `groupingBy()`:

```java
// Java
public void analyzeLogs() {
    var requests = List.of(
        new Request("https://kotlinlang.org/docs/home.html", 200),
        new Request("https://kotlinlang.org/docs/home.html", 400),
        new Request("https://kotlinlang.org/docs/comparison-to-java.html", 200)
    );
    var urlsAndRequests = requests.stream().collect(
            Collectors.groupingBy(Request::getUrl));
    System.out.println(urlsAndRequests);
}
```

In Kotlin, use the function `groupBy()`:

```kotlin
data class Request(
    val url: String,
    val responseCode: Int
)

fun main() {
    // Kotlin
    val requests = listOf(
        Request("https://kotlinlang.org/docs/home.html", 200),
        Request("https://kotlinlang.org/docs/home.html", 400),
        Request("https://kotlinlang.org/docs/comparison-to-java.html", 200)
    )
    println(requests.groupBy(Request::url))
}
```

Filter elements

In Java, to filter elements from a collection, you need to use the Stream API. The Stream API has `intermediate` and `terminal` operations. `filter()` is an intermediate operation, which returns a stream. To receive a collection as the output, you need to use a terminal operation, like `collect()`. For example, to leave only those pairs whose keys end with `1` and whose values are greater than `10`:

```java
// Java
public void filterEndsWith() {
    var numbers = Map.of("key1", 1, "key2", 2, "key3", 3, "key11", 11);
    var filteredNumbers = numbers.entrySet().stream()
        .filter(entry -> entry.getKey().endsWith("1") && entry.getValue() > 10)
        .collect(Collectors.toMap(Map.Entry::getKey, Map.Entry::getValue));
    System.out.println(filteredNumbers);
}
```

In Kotlin, filtering is built into collections, and `filter()` returns the same collection type that was filtered. So, all you need to write is the `filter()` and its predicate:

```kotlin
fun main() {
    // Kotlin
    val numbers = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key11" to 11)
    val filteredNumbers = numbers.filter { (key, value) -> key.endsWith("1") && value > 10 }
    println(filteredNumbers)
}
```

Learn more about filtering maps here.

Filter elements by type

In Java, to filter elements by type and perform actions on them, you need to check their types with the `instanceof` operator and then do the type cast:

```java
// Java
public void objectIsInstance() {
    var numbers = new ArrayList<>();
    numbers.add(null);
    numbers.add(1);
    numbers.add("two");
    numbers.add(3.0);
    numbers.add("four");
    System.out.println("All String elements in upper case:");
    numbers.stream().filter(it -> it instanceof String)
        .forEach( it -> System.out.println(((String) it).toUpperCase()));
}
```

In Kotlin, you just call `filterIsInstance<NEEDED_TYPE>()` on your collection, and the type cast is done by Smart casts:

```kotlin
// Kotlin
fun main() {
    // Kotlin
    val numbers = listOf(null, 1, "two", 3.0, "four")
    println("All String elements in upper case:")
    numbers.filterIsInstance<String>().forEach {
        println(it.uppercase())
    }
}
```

Test predicates

Some tasks require you to check whether all, none, or any elements satisfy a condition. In Java, you can do all of these checks via the Stream API functions `allMatch()`, `noneMatch()`, and `anyMatch()`:

```java
// Java
public void testPredicates() {
    var numbers = List.of("one", "two", "three", "four");
    System.out.println(numbers.stream().noneMatch(it -> it.endsWith("e"))); // false
    System.out.println(numbers.stream().anyMatch(it -> it.endsWith("e"))); // true
    System.out.println(numbers.stream().allMatch(it -> it.endsWith("e"))); // false
}
```

In Kotlin, the extension functions `none()`, `any()`, and `all()` are available for every Iterable object:

```kotlin
fun main() {
// Kotlin
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.none { it.endsWith("e") })
    println(numbers.any { it.endsWith("e") })
    println(numbers.all { it.endsWith("e") })
}
```

Learn more about test predicates.

Collection transformation operations

Zip elements

In Java, you can make pairs from elements with the same positions in two collections by iterating simultaneously over them:

```
// Java
public void zip() {
    var colors = List.of("red", "brown");
    var animals = List.of("fox", "bear", "wolf");

    for (int i = 0; i < Math.min(colors.size(), animals.size()); i++) {
        String animal = animals.get(i);
        System.out.println("The " + animal.substring(0, 1).toUpperCase()
               + animal.substring(1) + " is " + colors.get(i));
    }
}
```

If you want to do something more complex than just printing pairs of elements into the output, you can use Records. In the example above, the record would be `record AnimalDescription(String animal, String color) {}`.

In Kotlin, use the `zip()` function to do the same thing:

```
fun main() {
    // Kotlin
    val colors = listOf("red", "brown")
    val animals = listOf("fox", "bear", "wolf")

    println(colors.zip(animals) { color, animal ->
        "The ${animal.replaceFirstChar { it.uppercase() }} is $color" })
}
```

`zip()` returns the List of Pair objects.

> If collections have different sizes, the result of `zip()` is the smaller size. The last elements of the larger collection are not included in the result.

Associate elements

In Java, you can use the Stream API to associate elements with characteristics:

```
// Java
public void associate() {
    var numbers = List.of("one", "two", "three", "four");
    var wordAndLength = numbers.stream()
        .collect(toMap(number -> number, String::length));
    System.out.println(wordAndLength);
}
```

In Kotlin, use the `associate()` function:

```
fun main() {
    // Kotlin
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.associateWith { it.length })
}
```

Nullability in Java and Kotlin

Nullability is the ability of a variable to hold a `null` value. When a variable contains `null`, an attempt to dereference the variable leads to a `NullPointerException`. There are many ways to write code in order to minimize the probability of receiving null pointer exceptions.

This guide covers differences between Java's and Kotlin's approaches to handling possibly nullable variables. It will help you migrate from Java to Kotlin and write your code in authentic Kotlin style.

The first part of this guide covers the most important difference – support for nullable types in Kotlin and how Kotlin processes types from Java code. The second part, starting from Checking the result of a function call, examines several specific cases to explain certain differences.

Learn more about null safety in Kotlin.

Support for nullable types

The most important difference between Kotlin's and Java's type systems is Kotlin's explicit support for nullable types. It is a way to indicate which variables can possibly hold a `null` value. If a variable can be `null`, it's not safe to call a method on the variable because this can cause a `NullPointerException`. Kotlin prohibits such calls at compile time and thereby prevents lots of possible exceptions. At runtime, objects of nullable types and objects of non-nullable types are treated the same: A nullable type isn't a wrapper for a non-nullable type. All checks are performed at compile time. That means there's almost no runtime overhead for working with nullable types in Kotlin.

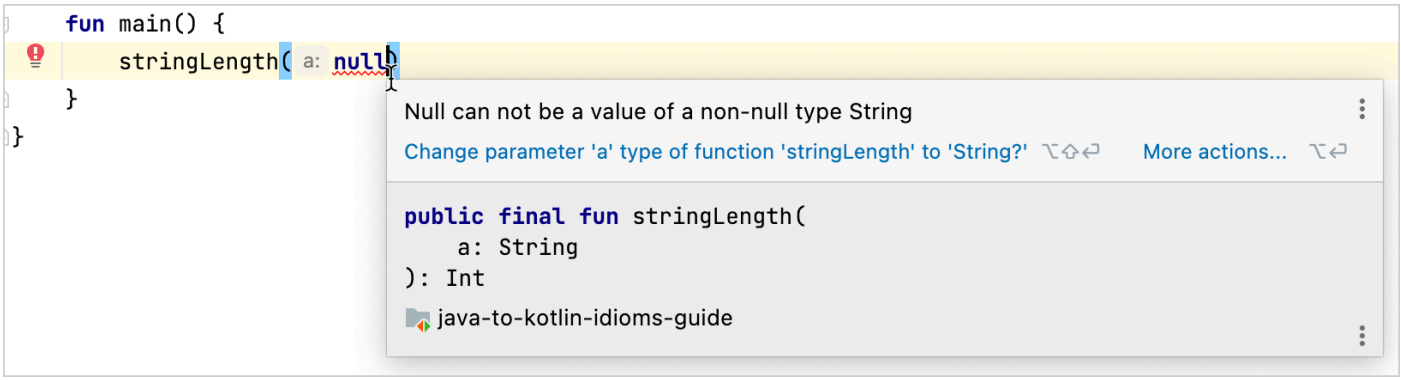
We say "almost" because, even though intrinsic checks *are* generated, their overhead is minimal.

In Java, if you don't write null checks, methods may throw a `NullPointerException`:

```java
// Java
int stringLength(String a) {
    return a.length();
}

void main() {
    stringLength(null); // Throws a `NullPointerException`
}
```

This call will have the following output:



```
java.lang.NullPointerException: Cannot invoke "String.length()" because "a" is null
    at test.java.Nullability.stringLength(Nullability.java:8)
    at test.java.Nullability.main(Nullability.java:12)
    at java.base/java.util.ArrayList.forEach(ArrayList.java:1511)
    at java.base/java.util.ArrayList.forEach(ArrayList.java:1511)
```

In Kotlin, all regular types are non-nullable by default unless you explicitly mark them as nullable. If you don't expect `a` to be `null`, declare the `stringLength()` function as follows:

```kotlin
// Kotlin
fun stringLength(a: String) = a.length
```

The parameter `a` has the `String` type, which in Kotlin means it must always contain a `String` instance and it cannot contain `null`. Nullable types in Kotlin are marked with a question mark `?`, for example, `String?`. The situation with a `NullPointerException` at runtime is impossible if `a` is `String` because the compiler enforces the rule that all arguments of `stringLength()` not be `null`.

An attempt to pass a `null` value to the `stringLength(a: String)` function will result in a compile-time error, "Null can not be a value of a non-null type String":

Passing null to a non-nullable function error

If you want to use this function with any arguments, including `null`, use a question mark after the argument type `String?` and check inside the function body to ensure that the value of the argument is not `null`:

```kotlin
// Kotlin
fun stringLength(a: String?): Int = if (a != null) a.length else 0
```

After the check is passed successfully, the compiler treats the variable as if it were of the non-nullable type `String` in the scope where the compiler performs the check.

If you don't perform this check, the code will fail to compile with the following message: "Only safe (?.) or non-nullable asserted (!!.) calls are allowed on a nullable receiver of type String?".

You can write the same shorter – use the safe-call operator ?. (If-not-null shorthand), which allows you to combine a null check and a method call into a single operation:

```
// Kotlin
fun stringLength(a: String?): Int = a?.length ?: 0
```

Platform types

In Java, you can use annotations showing whether a variable can or cannot be `null`. Such annotations aren't part of the standard library, but you can add them separately. For example, you can use JetBrains annotations `@Nullable` and `@NotNull` (from the `org.jetbrains.annotations` package), annotations from JSpecify (`org.jspecify.annotations`), or from Eclipse (`org.eclipse.jdt.annotation`). Kotlin can recognize such annotations when you're calling Java code from Kotlin code and will treat types according to their annotations.

If your Java code doesn't have these annotations, then Kotlin will treat Java types as *platform types*. But since Kotlin doesn't have nullability information for such types, its compiler will allow all operations on them. You will need to decide whether to perform null checks, because:

- Just as in Java, you'll get a `NullPointerException` if you try to perform an operation on `null`.
- The compiler won't highlight any redundant null checks, which it normally does when you perform a null-safe operation on a value of a non-nullable type.

Learn more about calling Java from Kotlin in regard to null-safety and platform types.

Support for definitely non-nullable types

In Kotlin, if you want to override a Java method that contains `@NotNull` as an argument, you need Kotlin's definitely non-nullable types.

For example, consider this `load()` method in Java:

```
import org.jetbrains.annotations.*;

public interface Game<T> {
  public T save(T x) {}
  @NotNull
  public T load(@NotNull T x) {}
}
```

To override the `load()` method in Kotlin successfully, you need `T1` to be declared as definitely non-nullable (`T1 & Any`):

```
interface ArcadeGame<T1> : Game<T1> {
  override fun save(x: T1): T1
  // T1 is definitely non-nullable
  override fun load(x: T1 & Any): T1 & Any
}
```

Learn more about generic types that are definitely non-nullable.

Checking the result of a function call

One of the most common situations where you need to check for `null` is when you obtain a result from a function call.

In the following example, there are two classes, `Order` and `Customer`. `Order` has a reference to an instance of `Customer`. The `findOrder()` function returns an instance of the `Order` class, or `null` if it can't find the order. The objective is to process the customer instance of the retrieved order.

Here are the classes in Java:

```
//Java
record Order (Customer customer) {}

record Customer (String name) {}
```

In Java, call the function and do an if-not-null check on the result to proceed with the dereferencing of the required property:

```
// Java
Order order = findOrder();

if (order ≠ null) {
    processCustomer(order.getCustomer());
}
```

Converting the Java code above to Kotlin code directly results in the following:

```
// Kotlin
data class Order(val customer: Customer)

data class Customer(val name: String)

val order = findOrder()

// Direct conversion
if (order ≠ null){
    processCustomer(order.customer)
}
```

Use the safe-call operator `?.` (If-not-null shorthand) in combination with any of the scope functions from the standard library. The `let` function is usually used for this:

```
// Kotlin
val order = findOrder()

order?.let {
    processCustomer(it.customer)
}
```

Here is a shorter version of the same:

```
// Kotlin
findOrder()?.customer?.let(::processCustomer)
```

Default values instead of null

Checking for `null` is often used in combination with setting the default value in case the null check is successful.

The Java code with a null check:

```
// Java
Order order = findOrder();
if (order == null) {
    order = new Order(new Customer("Antonio"))
}
```

To express the same in Kotlin, use the Elvis operator (If-not-null-else shorthand):

```
// Kotlin
val order = findOrder() ?: Order(Customer("Antonio"))
```

Functions returning a value or null

In Java, you need to be careful when working with list elements. You should always check whether an element exists at an index before you attempt to use the element:

```
// Java
var numbers = new ArrayList<Integer>();
numbers.add(1);
numbers.add(2);

System.out.println(numbers.get(0));
//numbers.get(5) // Exception!
```

The Kotlin standard library often provides functions whose names indicate whether they can possibly return a `null` value. This is especially common in the collections API:

```
fun main() {
    // Kotlin
    // The same code as in Java:
    val numbers = listOf(1, 2)

    println(numbers[0])  // Can throw IndexOutOfBoundsException if the collection is empty
    //numbers.get(5)     // Exception!

    // More abilities:
    println(numbers.firstOrNull())
    println(numbers.getOrNull(5)) // null
}
```

Aggregate operations

When you need to get the biggest element or `null` if there are no elements, in Java you would use the Stream API:

```java
// Java
var numbers = new ArrayList<Integer>();
var max = numbers.stream().max(Comparator.naturalOrder()).orElse(null);
System.out.println("Max: " + max);
```

In Kotlin, use aggregate operations:

```kotlin
// Kotlin
val numbers = listOf<Int>()
println("Max: ${numbers.maxOrNull()}")
```

Learn more about collections in Java and Kotlin.

Casting types safely

When you need to safely cast a type, in Java you would use the `instanceof` operator and then check how well it worked:

```java
// Java
int getStringLength(Object y) {
    return y instanceof String x ? x.length() : -1;
}

void main() {
    System.out.println(getStringLength(1)); // Prints `-1`
}
```

To avoid exceptions in Kotlin, use the safe cast operator `as?`, which returns `null` on failure:

```kotlin
// Kotlin
fun main() {
    println(getStringLength(1)) // Prints `-1`
}

fun getStringLength(y: Any): Int {
    val x: String? = y as? String // null
    return x?.length ?: -1 // Returns -1 because `x` is null
}
```

In the Java example above, the function `getStringLength()` returns a result of the primitive type `int`. To make it return `null`, you can use the *boxed* type `Integer`. However, it's more resource-efficient to make such functions return a negative value and then check the value – you would do the check anyway, but no additional boxing is performed this way.

When migrating Java code to Kotlin, you may want to initially use the regular cast operator `as` with a nullable type to preserve the original semantics of your code. However, we recommend adapting your code to use the safe cast operator `as?` for a safer and more idiomatic approach. For example, if you have the following Java code:

```java
public class UserProfile {
    Object data;

    public static String getUsername(UserProfile profile) {
        if (profile == null) {
            return null;
        }
        return (String) profile.data;
    }
}
```

Migrating this directly with the `as` operator gives you:

```kotlin
class UserProfile(var data: Any? = null)

fun getUsername(profile: UserProfile?): String? {
    if (profile == null) {
        return null
    }
    return profile.data as String?
}
```

Here, `profile.data` is cast to a nullable string using `as String?`.

We recommend going one step further and using `as? String` to safely cast the value. This approach returns `null` on failure instead of throwing a `ClassCastException`:

```kotlin
class UserProfile(var data: Any? = null)

fun getUsername(profile: UserProfile?): String? =
  profile?.data as? String
```

This version replaces the `if` expression with the safe call operator `?.`, which safely accesses the data property before attempting the cast.

Standard input

Java Scanner is a slow tool. Use it only when you need the specific functionalities it offers. Otherwise, it's generally preferable to use Kotlin's `readln()` function to read standard input.

To read from the standard input, Java provides the `Scanner` class. Kotlin offers two main ways to read from the standard input: the `Scanner` class, similar to Java, and the `readln()` function.

Read from the standard input with Java Scanner

In Java, the standard input is typically accessed through the `System.in` object. You need to import the `Scanner` class, create an object, and use methods like `.nextLine()` and `.nextInt()` to read different data types:

```
//Java implementation
import java.util.Scanner;

public class Main {
    public static void main(String[] args) {
        Scanner scanner = new Scanner(System.in);

        // Reads a single line of input. For example: Hi there!
        System.out.print("Enter a line: ");
        String line = scanner.nextLine();
        System.out.println("You entered: " + line);
        // You entered: Hi there!

        // Reads an integer. For example: 08081990
        System.out.print("Enter an integer: ");
        int number = scanner.nextInt();
        System.out.println("You entered: " + number);
        // You entered: 08081990

        scanner.close();
    }
}
```

Use Java Scanner in Kotlin

Due to Kotlin's interoperability with Java libraries, you can access Java Scanner from Kotlin code out of the box.

To use Java Scanner in Kotlin, you need to import the `Scanner` class and initialize it by passing a `System.in` object that represents the standard input stream and dictates how to read the data. You can use the available reading methods for reading values different from strings, such as `.nextLine()`, `.next()`, and `.nextInt()`:

```
// Imports Java Scanner
import java.util.Scanner

fun main() {
    // Initializes the Scanner
    val scanner = Scanner(System.`in`)

    // Reads a whole string line. For example: "Hello, Kotlin"
    val line = scanner.nextLine()
    print(line)
    // Hello, Kotlin

    // Reads a string. For example: "Hello"
    val string = scanner.next()
    print(string)
    // Hello

    // Reads a number. For example: 123
    val num = scanner.nextInt()
    print(num)
    // 123
}
```

Other useful methods for reading input with Java Scanner are `.hasNext()`, `.useDelimiter()`, and `.close()`:

- The `.hasNext()` method checks if there's more data available in the input. It returns the boolean value `true` if there are remaining elements to iterate and `false` if no more elements are left in the input.
- The `.useDelimiter()` method sets the delimiter for reading input elements. The delimiter is whitespaces by default, but you can specify other characters. For example, `.useDelimiter(",")` reads the input elements separated by commas.
- The `.close()` method closes the input stream associated with the Scanner, preventing further use of the Scanner for reading input.

Always use the `.close()` method when you're finished using Java Scanner. Closing the Java Scanner releases the resources it consumes and ensures proper program behavior.

Read from the standard input with readln()

In Kotlin, apart from the Java Scanner, you have the `readln()` function. It is the most straightforward way to read input. This function reads a line of text from the standard input and returns it as a string:

```
// Reads a string. For example: Charlotte
val name = readln()

// Reads a string and converts it into an integer. For example: 43
val age = readln().toInt()

println("Hello, $name! You are $age years old.")
// Hello, Charlotte! You are 43 years old.
```

For more information, see Read standard input.

Browser and DOM API

The `kotlinx-browser` library lets you access browser-specific functionality. It includes common top-level objects such as `document` and `window` and, where possible, provides typesafe wrappers for their functionality.

As a fallback, the `dynamic` type provides access to functions that do not map well into the Kotlin type system.

To use the browser and DOM API, add the `kotlinx-browser` library as a dependency to your project's `build.gradle(.kts)` file:

Kotlin

```
repositories {
    mavenCentral()
}

kotlin {
    js {
        browser()
    }

    sourceSets {
        commonMain {
            dependencies {
                implementation("org.jetbrains.kotlinx:kotlinx-browser:0.5.0")
            }
        }
    }
}
```

Groovy

```
repositories {
    mavenCentral()
}

kotlin {
    js {
        browser()
    }

    sourceSets {
        commonMain {
            dependencies {
                implementation 'org.jetbrains.kotlinx:kotlinx-browser:0.5.0'
            }
        }
    }
}
```

Interaction with the DOM

For interaction with the Document Object Model (DOM), you can use the variable `document`. For example, you can set the background color of our website through this object:

```
document.bgColor = "FFAA12"
```

The `document` object also provides you a way to retrieve a specific element by ID, name, class name, tag name and so on. All returned elements have the `Element?` type. To access their properties, you need to cast them to their appropriate type. For example, assume that you have an HTML page with an email `<input>` field:

```
<body>
    <input type="text" name="email" id="email"/>

    <script type="text/javascript" src="tutorial.js"></script>
</body>
```

Note that your script is included at the bottom of the `body` tag. This ensures that the DOM is fully available before the script is loaded.

With this setup, you can access elements of the DOM. To access the properties of the `input` field, invoke `getElementById` and cast it to `HTMLInputElement`. You can then safely access its properties, such as `value`:

```
val email = document.getElementById("email") as HTMLInputElement
email.value = "hadi@jetbrains.com"
```

Much like you reference this `input` element, you can access other elements on the page, casting them to the appropriate types.

What's next?

To see how to create and structure elements in the DOM in a concise way, check out the Typesafe HTML DSL.

Use JavaScript code from Kotlin

Kotlin was first designed for easy interoperation with the Java platform: it sees Java classes as Kotlin classes, and Java sees Kotlin classes as Java classes.

However, JavaScript is a dynamically typed language, which means it does not check types at compile time. You can freely talk to JavaScript from Kotlin via dynamic types. If you want to use the full power of the Kotlin type system, you can create external declarations for JavaScript libraries which will be understood by the Kotlin compiler and the surrounding tooling.

Inline JavaScript

You can inline JavaScript code into your Kotlin code using the `js()` function:

```
fun jsTypeOf(o: Any): String {
    return js("typeof o")
}
```

JavaScript code inlining has full support for ES2015 features, including:

- `const` and `let` variable declarations
- ES classes
- Generators

- Lambdas (arrow functions)
- Spread and rest operators
- Template strings

Because the parameter of `js` is parsed at compile time and translated to JavaScript code "as-is", it must be a string constant. So, the following code is incorrect:

```
fun jsTypeOf(o: Any): String {
    return js(getTypeof() + " o") // Error: Argument must be a string constant
    // The compiler cannot evaluate string concatenations
}

fun getTypeof() = "typeof"
```

Instead, for example to inline the rest operator, use a string constant:

```
fun runSumExample() {
    val sum = js("(...nums) => nums.reduce((a, b) => a + b, 0)")
    println(sum(1, 2, 3, 4))
}
```

Invoking `js()` returns a result of `dynamic` type, which doesn't provide type safety at compile time.

`external` modifier

To tell Kotlin that a certain declaration is written in pure JavaScript, you should mark it with the `external` modifier. When the compiler sees such a declaration, it assumes that the implementation for the corresponding class, function or property is provided externally (by the developer or via an npm dependency), and therefore does not try to generate any JavaScript code from the declaration. This is also why `external` declarations can't have a body. For example:

```
external fun alert(message: Any?): Unit

external class Node {
    val firstChild: Node

    fun append(child: Node): Node

    fun removeChild(child: Node): Node

    // etc
}

external val window: Window
```

Note that the `external` modifier is inherited by nested declarations. This is why in the example `Node` class, there is no `external` modifier before member functions and properties.

The `external` modifier is only allowed on package-level declarations. You can't declare an `external` member of a non-`external` class.

Declare (static) members of a class

In JavaScript, you can define members either on a prototype or a class itself:

```
function MyClass() { ... }
MyClass.sharedMember = function() { /* implementation */ };
MyClass.prototype.ownMember = function() { /* implementation */ };
```

There is no such syntax in Kotlin. However, in Kotlin we have `companion` objects. Kotlin treats companion objects of `external` classes in a special way: instead of expecting an object, it assumes members of companion objects to be members of the class itself. `MyClass` from the example above can be described as follows:

```
external class MyClass {
    companion object {
        fun sharedMember()
    }

    fun ownMember()
}
```

Declare parameters with default values

If you are writing an external declaration for a JavaScript function which has a parameter with a default value, use `definedExternally`. This delegates the generation of the default values to the JavaScript function itself:

```
external fun myFunWithOptionalArgs(
    x: Int,
    y: String = definedExternally,
    z: String = definedExternally
)
```

With this external declaration, you can call `myFunWithOptionalArgs` with one required argument and two optional arguments, where the default values are calculated by the JavaScript implementation of `myFunWithOptionalArgs`.

Extend JavaScript classes

You can easily extend JavaScript classes as if they were Kotlin classes. Just define an `external open` class and extend it by a non-`external` class. For example:

```
open external class Foo {
    open fun run()
    fun stop()
}

class Bar : Foo() {
    override fun run() {
        window.alert("Running!")
    }

    fun restart() {
        window.alert("Restarting")
    }
}
```

There are some limitations:

- When a function of an external base class is overloaded by signature, you can't override it in a derived class.
- You can't override a function including parameters with default values.
- Non-external classes can't be extended by external classes.

external interfaces

JavaScript does not have the concept of interfaces. When a function expects its parameter to support two methods `foo` and `bar`, you would just pass in an object that actually has these methods.

You can use interfaces to express this concept in statically typed Kotlin:

```
external interface HasFooAndBar {
    fun foo()

    fun bar()
}

external fun myFunction(p: HasFooAndBar)
```

A typical use case for external interfaces is to describe settings objects. For example:

```
external interface JQueryAjaxSettings {
    var async: Boolean

    var cache: Boolean

    var complete: (JQueryXHR, String) -> Unit

    // etc
}

fun JQueryAjaxSettings(): JQueryAjaxSettings = js("{}")

external class JQuery {
    companion object {
        fun get(settings: JQueryAjaxSettings): JQueryXHR
    }
}

fun sendQuery() {
    JQuery.get(JQueryAjaxSettings().apply {
        complete = { (xhr, data) ->
            window.alert("Request complete")
        }
    })
}
```

External interfaces have some restrictions:

- They can't be used on the right-hand side of `is` checks.
- They can't be passed as reified type arguments.
- They can't be used in class literal expressions (such as `I::class`).
- `as` casts to external interfaces always succeed. Casting to external interfaces produces the "Unchecked cast to external interface" compile time warning. The warning can be suppressed with the `@Suppress("UNCHECKED_CAST_TO_EXTERNAL_INTERFACE")` annotation.

IntelliJ IDEA can also automatically generate the `@Suppress` annotation. Open the intentions menu via the light bulb icon or Alt-Enter, and click the small arrow next to the "Unchecked cast to external interface" inspection. Here, you can select the suppression scope, and your IDE will add the annotation to your file accordingly.

Casts

In addition to the "unsafe" cast operator `as`, which throws a `ClassCastException` in case a cast is not possible, Kotlin/JS also provides `unsafeCast<T>()`. When using `unsafeCast`, *no type checking is done at all* during runtime. For example, consider the following two methods:

```
fun usingUnsafeCast(s: Any) = s.unsafeCast<String>()
fun usingAsOperator(s: Any) = s as String
```

They will be compiled accordingly:

```
function usingUnsafeCast(s) {
    return s;
}

function usingAsOperator(s) {
    var tmp$;
    return typeof (tmp$ = s) === 'string' ? tmp$ : throwCCE();
}
```

Equality

Kotlin/JS has particular semantics for equality checks compared to other platforms.

In Kotlin/JS, the Kotlin referential equality operator (`===`) always translates to the JavaScript strict equality operator (`===`).

The JavaScript `===` operator checks not only that two values are equal but also that the types of these two values are equal:

```
fun main() {
   val name = "kotlin"
   val value1 = name.substring(0, 1)
   val value2 = name.substring(0, 1)

   println(value1 === value2)
   // Prints 'true' on Kotlin/JS
   // Prints 'false' on other platforms
}
```

Also, in Kotlin/JS, the `Byte`, `Short`, `Int`, `Float`, and `Double` numeric types are all represented with the `Number` JavaScript type in runtime. Therefore, the values of these five types are indistinguishable:

```
fun main() {
   println(1.0 as Any === 1 as Any)
   // Prints 'true' on Kotlin/JS
   // Prints 'false' on other platforms
}
```

For more information about equality in Kotlin, see the Equality documentation.

Dynamic type

The dynamic type is not supported in code targeting the JVM.

Being a statically typed language, Kotlin still has to interoperate with untyped or loosely typed environments, such as the JavaScript ecosystem. To facilitate these use cases, the `dynamic` type is available in the language:

```
val dyn: dynamic = ...
```

The `dynamic` type basically turns off Kotlin's type checker:

- A value of the `dynamic` type can be assigned to any variable or passed anywhere as a parameter.
- Any value can be assigned to a variable of the `dynamic` type or passed to a function that takes `dynamic` as a parameter.
- `null` -checks are disabled for the `dynamic` type values.

The most peculiar feature of `dynamic` is that we are allowed to call **any** property or function with any parameters on a `dynamic` variable:

```
dyn.whatever(1, "foo", dyn) // 'whatever' is not defined anywhere
dyn.whatever(*arrayOf(1, 2, 3))
```

On the JavaScript platform this code will be compiled "as is": `dyn.whatever(1)` in Kotlin becomes `dyn.whatever(1)` in the generated JavaScript code.

When calling functions written in Kotlin on values of `dynamic` type, keep in mind the name mangling performed by the Kotlin to JavaScript compiler. You may need to use the @JsName annotation to assign well-defined names to the functions that you need to call.

A dynamic call always returns `dynamic` as a result, so you can chain such calls freely:

```
dyn.foo().bar.baz()
```

When you pass a lambda to a dynamic call, all of its parameters by default have the type `dynamic`:

```
dyn.foo {
    x → x.bar() // x is dynamic
}
```

Expressions using values of `dynamic` type are translated to JavaScript "as is", and do not use the Kotlin operator conventions. The following operators are supported:

- binary: `+`, `-`, `*`, `/`, `%`, `>`, `<`, `>=`, `<=`, `==`, `!=`, `===`, `!==`, `&&`, `||`
- unary
  - prefix: `-`, `+`, `!`
  - prefix and postfix: `++`, `--`
- assignments: `+=`, `-=`, `*=`, `/=`, `%=`
- indexed access:
  - read: `d[a]`, more than one argument is an error

- write: `d[a1] = a2`, more than one argument in `[]` is an error

`in`, `!in` and `..` operations with values of type `dynamic` are forbidden.

For a more technical description, see the spec document.

Use dependencies from npm

In Kotlin/JS projects, all dependencies can be managed through the Gradle plugin. This includes Kotlin/Multiplatform libraries such as `kotlinx.coroutines`, `kotlinx.serialization`, or `ktor-client`.

For depending on JavaScript packages from npm, the Gradle DSL exposes an `npm` function that lets you specify packages you want to import from npm. Let's consider the import of an NPM package called `is-sorted`.

The corresponding part in the Gradle build file looks as follows:

```
dependencies {
    // ...
    implementation(npm("is-sorted", "1.0.5"))
}
```

Because JavaScript modules are usually dynamically typed and Kotlin is a statically typed language, you need to provide a kind of adapter. In Kotlin, such adapters are called *external declarations*. For the `is-sorted` package which offers only one function, this declaration is small to write. Inside the source folder, create a new file called `is-sorted.kt`, and fill it with these contents:

```
@JsModule("is-sorted")
@JsNonModule
external fun <T> sorted(a: Array<T>): Boolean
```

Please note that if you're using CommonJS as a target, the `@JsModule` and `@JsNonModule` annotations need to be adjusted accordingly.

This JavaScript function can now be used just like a regular Kotlin function. Because we provided type information in the header file (as opposed to simply defining parameter and return type to be `dynamic`), proper compiler support and type-checking is also available.

```
console.log("Hello, Kotlin/JS!")
console.log(sorted(arrayOf(1,2,3)))
console.log(sorted(arrayOf(3,1,2)))
```

Running these three lines either in the browser or Node.js, the output shows that the call to `sorted` was properly mapped to the function exported by the `is-sorted` package:

```
Hello, Kotlin/JS!
true
false
```

Because the JavaScript ecosystem has multiple ways of exposing functions in a package (for example, through named or default exports), other npm packages might need a slightly altered structure for their external declarations.

To learn more about how to write declarations, please refer to Calling JavaScript from Kotlin.

Use Kotlin code from JavaScript

Depending on the selected JavaScript Module system, the Kotlin/JS compiler generates different output. But in general, the Kotlin compiler generates normal JavaScript classes, functions, and properties, which you can freely use from JavaScript code. There are some subtle things you should remember, though.

Isolating declarations in a separate JavaScript object in plain mode

If you have explicitly set your module kind to be `plain`, Kotlin creates an object that contains all Kotlin declarations from the current module. This is done to prevent spoiling the global object. This means that for a module `myModule`, all declarations are available to JavaScript via the `myModule` object. For example:

```
fun foo() = "Hello"
```

This function can be called from JavaScript like this:

```
alert(myModule.foo());
```

Calling the function directly like this is not applicable when you compile your Kotlin module to JavaScript modules like UMD (the default setting for both `browser` and `nodejs` targets), ESM, CommonJS, or AMD. In these cases, your declarations are exposed according to the chosen JavaScript module system. For example, when using UMD, ESM, or CommonJS, your call site would look like this:

```
alert(require('myModule').foo());
```

For more information about JavaScript module systems, see JavaScript Modules.

Package structure

For most of the module systems (CommonJS, Plain, and UMD), Kotlin exposes its package structure to JavaScript. Unless you define your declarations in the root package, you have to use fully qualified names in JavaScript. For example:

```
package my.qualified.packagename

fun foo() = "Hello"
```

For example, when using UMD or CommonJS, your call site could look like this:

```
alert(require('myModule').my.qualified.packagename.foo())
```

When using `plain` as a module system setting, the call site would be:

```
alert(myModule.my.qualified.packagename.foo());
```

When targeting ECMAScript Modules (ESM), package information is not preserved to improve the application bundle size and match the typical layout of ESM packages. In this case, the consumption of the Kotlin declarations with ES modules looks like this:

```
import { foo } from 'myModule';

alert(foo());
```

`@JsName` annotation

In some cases (for example, to support overloads), the Kotlin compiler mangles the names of generated functions and attributes in JavaScript code. To control the generated names, you can use the `@JsName` annotation:

```
// Module 'kjs'
class Person(val name: String) {
    fun hello() {
        println("Hello $name!")
    }

    @JsName("helloWithGreeting")
    fun hello(greeting: String) {
        println("$greeting $name!")
    }
}
```

Now you can use this class from JavaScript in the following way:

```
// If necessary, import 'kjs' according to chosen module system
var person = new kjs.Person("Dmitry");   // refers to module 'kjs'
person.hello();                          // prints "Hello Dmitry!"
person.helloWithGreeting("Servus");      // prints "Servus Dmitry!"
```

If we didn't specify the `@JsName` annotation, the name of the corresponding function would contain a suffix calculated from the function signature, for example `hello_61zpoe$`.

Note that there are some cases in which the Kotlin compiler does not apply mangling:

- `external` declarations are not mangled.
- Any overridden functions in non-`external` classes inheriting from `external` classes are not mangled.

The parameter of `@JsName` is required to be a constant string literal which is a valid identifier. The compiler will report an error on any attempt to pass a non-identifier string to `@JsName`. The following example produces a compile-time error:

```
@JsName("new C()")   // error here
external fun newC()
```

Experimental

`@JsExport` annotation

By applying the `@JsExport` annotation to a top-level declaration (like a class, interface, or function), you can make Kotlin declarations available from JavaScript or TypeScript. The annotation exports all nested declarations with the name given in Kotlin.

For example, here's how you can export a Kotlin interface with a nested class and a named companion object:

```kotlin
@JsExport
interface Identity {
     class Metadata(val tag: String)

    companion object Registry {
        val defaultTag = "GUEST"
    }
}
```

Currently, the `@JsExport` annotation is the only way to make your functions visible from Kotlin.

The `@JsExport` annotation is also available:

- In common code in multiplatform projects. It only has an effect when compiling for the JavaScript target and allows you to also export Kotlin declarations that are not platform-specific.
- Together with the `@JsName` annotation to specify the names for the generated and exported functions. This helps to resolve ambiguities in exports (like overloads for functions with the same name).
- At the file level using `@file:JsExport`.

Export value classes

You can export Kotlin's inline value classes as regular TypeScript classes.

To export a value class, mark it with the `@JsExport` annotation on the Kotlin side:

```kotlin
// Kotlin
@JsExport
@JvmInline
value class Email(val address: String) {
    init { require(address.contains("@")) { "Invalid email" } }
}

@JsExport
class AuthService {
    suspend fun login(email: Email): String = ...
}
```

On the TypeScript side, it looks like a regular class:

```typescript
// TypeScript
import { AuthService, Email } from "..."
const auth = new AuthService();

console.log(await auth.login(new Email("jane@example.com")));
// "Welcome, jane@example.com!"
console.log(await auth.login(new Email("not-an-email")));
// "Invalid email"
```

Export suspending lambdas

You can export Kotlin's suspending lambda expressions as JavaScript async functions:

1. To enable this feature, add the following compiler option to your `build.gradle.kts` file:

```
kotlin {
    js {
        compilations.all {
            compileTaskProvider.configure {
                compilerOptions {
                    freeCompilerArgs.add("-Xsuspend-lambda-exporting")
                }
            }
        }
    }
}
```

2. Mark the relevant Kotlin declarations with the `@JsExport` annotation:

```
// Kotlin
@JsExport
class TaskRunner {
    suspend fun runTask(task: suspend () -> String): String {
        return task()
    }
}
```

3. On the TypeScript side, the `suspend` lambda will be mapped to a regular `async` function:

```
// TypeScript
import { TaskRunner } from "..."

const runner = new TaskRunner();
const result = await runner.runTask(async () => "done");
console.log(result); // "done"
```

`@JsNoRuntime` annotation

You can export Kotlin interfaces to JavaScript/TypeScript with the `@JsNoRuntime` annotation. It allows for direct mapping to regular TypeScript interfaces.

To export a Kotlin interface, for example, from a Kotlin Multiplatform project:

1. Annotate the Kotlin interface with `@JsNoRuntime` in common code:

```
// commonMain
import kotlin.js.JsNoRuntime

@JsNoRuntime
expect interface DataProcessor {
    fun process(data: String): Int
}
```

2. Provide the actual implementation with `@JsNoRuntime` in your JS-specific source code:

```
// jsMain
import kotlin.js.JsNoRuntime

@JsNoRuntime
actual interface DataProcessor {
    actual fun process(data: String): Int
}
```

3. On the TypeScript side, the interface will be mapped to a regular TypeScript interface:

```
// Generated .d.ts
export interface DataProcessor {
    process(data: string): number;
}
```

For Kotlin Multiplatform projects, the general rules are:

- Both `expect` and `actual` interface declarations must be annotated with `@JsNoRuntime`. The only exception is `external` implementations in platform-specific code on the `actual` side that require no annotation.
- Using `external` interface declarations in common code on the `expect` side is prohibited. Instead, use regular interfaces annotated with `@JsNoRuntime`.

Exporting Kotlin interfaces with `@JsNoRuntime` has some restrictions. The annotation isn't allowed with:

- `external` interfaces as they already behave as if they have `@JsNoRuntime` by default. Adding it results in a compiler warning.
- `is` and `as` type checks.
- Class references that use the `::class` syntax.
- Interfaces that are passed as reified type argument.

Experimental

`@JsStatic`

The `@JsStatic` annotation instructs the compiler to generate additional static methods for the target declaration. This helps you use static members from your Kotlin code directly in JavaScript.

You can apply the `@JsStatic` annotation to functions defined in named objects, as well as in companion objects declared inside classes and interfaces. If you use this annotation, the compiler will generate both a static method of the object and an instance method in the object itself. For example:

```
// Kotlin
class C {
    companion object {
        @JsStatic
        fun callStatic() {}
        fun callNonStatic() {}
    }
}
```

Now, the `callStatic()` function is static in JavaScript while the `callNonStatic()` function is not:

```
// JavaScript
C.callStatic();              // Works, accessing the static function
C.callNonStatic();           // Error, not a static function in the generated JavaScript
C.Companion.callStatic();    // Instance method remains
C.Companion.callNonStatic(); // The only way it works
```

It's also possible to apply the `@JsStatic` annotation to a property of an object or a companion object, making its getter and setter methods static members in that object or the class containing the companion object.

This feature is Experimental. Share your feedback in our issue tracker, YouTrack.

Experimental

Use `BigInt` type to represent Kotlin's `Long` type

Kotlin/JS uses JavaScript's built-in `BigInt` type to represent Kotlin `Long` values when compiling to modern JavaScript (ES2020).

To enable support for the `BigInt` type, you need to add the following compiler option to your `build.gradle(.kts)` file:

```
// build.gradle.kts
kotlin {
    js {
        ...
        compilerOptions {
            freeCompilerArgs.add("-Xes-long-as-bigint")
        }
    }
}
```

This feature is Experimental. Share your feedback in our issue tracker, YouTrack.

Use `Long` in exported declarations

Since Kotlin's `Long` type can compile to JavaScript's `BigInt` type, Kotlin/JS supports exporting `Long` values to JavaScript.

To enable this feature:

1. Allow exporting `Long` in Kotlin/JS. Add the following compiler option to the `freeCompilerArgs` attribute in your `build.gradle(.kts)` file:

   ```
   // build.gradle.kts
   kotlin {
      js {
          ...
          compilerOptions {
              freeCompilerArgs.add("-XXLanguage:+JsAllowLongInExportedDeclarations")
          }
      }
   }
   ```

2. Enable the `BigInt` type. See how to enable it in Use `BigInt` type to represent Kotlin's `Long` type.

Experimental

Use `BigInt64Array` type to represent Kotlin's `LongArray` type

Kotlin/JS can use JavaScript's built-in `BigInt64Array` type to represent Kotlin's `LongArray` values when compiling to JavaScript.

To enable support for the `BigInt64Array` type, add the following compiler option to your `build.gradle(.kts)` file:

```
// build.gradle.kts
kotlin {
    js {
        ...
        compilerOptions {
            freeCompilerArgs.add("-Xes-long-as-bigint")
        }
    }
}
```

This feature is Experimental. Share your feedback in our issue tracker, YouTrack.

Kotlin types in JavaScript

See how Kotlin types are mapped to JavaScript ones:

Kotlin	JavaScript	Comments
`Byte`, `Short`, `Int`, `Float`, `Double`	`Number`	
`Char`	`Number`	The number represents the character's code.
`Long`	`BigInt`	Needs the `-Xes-long-as-bigint` compiler option configured.
`Boolean`	`Boolean`	
`String`	`String`	
`Array`	`Array`	
`ByteArray`	`Int8Array`	
`ShortArray`	`Int16Array`	
`IntArray`	`Int32Array`	
`CharArray`	`UInt16Array`	Carries the property `$type$ == "CharArray"`.
`FloatArray`	`Float32Array`	
`DoubleArray`	`Float64Array`	
`LongArray`	`BigInt64Array`	

Kotlin	JavaScript	Comments
`BooleanArray`	`Int8Array`	Carries the property `$type$ == "BooleanArray"`.
`List`, `MutableList`	`KtList`, `KtMutableList`	Exposes an `Array` via `KtList.asJsReadonlyArrayView` or `KtMutableList.asJsArrayView`.
`Map`, `MutableMap`	`KtMap`, `KtMutableMap`	Exposes an ES2015 `Map` via `KtMap.asJsReadonlyMapView` or `KtMutableMap.asJsMapView`.
`Set`, `MutableSet`	`KtSet`, `KtMutableSet`	Exposes an ES2015 `Set` via `KtSet.asJsReadonlySetView` or `KtMutableSet.asJsSetView`.
`Unit`	Undefined	Exportable when used as return type, but not when used as parameter type.
`Any`	`Object`	
`Throwable`	`Error`	
`enum class Type`	`Type`	Enum entries are exposed as static class properties (`Type.ENTRY`).
Nullable `Type?`	`Type | null | undefined`	
All other Kotlin types, except for those marked with `@JsExport`	Not supported	Includes Kotlin's unsigned integer types.

Additionally, it is important to know that:

- Kotlin preserves overflow semantics for `kotlin.Int`, `kotlin.Byte`, `kotlin.Short`, `kotlin.Char` and `kotlin.Long`.
- Kotlin cannot distinguish between numeric types at runtime (except for `kotlin.Long`), so the following code works:

```
fun f() {
    val x: Int = 23
    val y: Any = x
    println(y as Float)
}
```

- Kotlin preserves lazy object initialization in JavaScript.

JavaScript modules

You can compile your Kotlin projects to JavaScript modules for various popular module systems. We currently support the following configurations for JavaScript modules:

- ES Modules, the standard way to declare a module in JavaScript (with the `import/export` JavaScript syntax). It's used by default if the `target` is set to `es2015`.
- Unified Module Definitions (UMD), which is compatible with both *AMD* and *CommonJS*. UMD modules are also able to be executed without being imported or when no module system is present. This is the default option for the `browser` and `nodejs` targets.
- Asynchronous Module Definitions (AMD), which is in particular used by the RequireJS library.
- CommonJS, widely used by Node.js/npm (`require` function and `module.exports` object).
- Plain. Don't compile for any module system. You can access a module by its name in the global scope.

Browser targets

If you intend to run your code in a web browser environment and want to use a module system other than UMD, you can specify the desired module type in the `webpackTask` configuration block. For example, to switch to CommonJS, use:

```
kotlin {
    js {
        browser {
            webpackTask {
                output.libraryTarget = "commonjs2"
            }
        }
        binaries.executable()
    }
}
```

Webpack provides two different flavors of CommonJS, `commonjs` and `commonjs2`, which affect the way your declarations are made available. In most cases, you probably want `commonjs2`, which adds the `module.exports` syntax to the generated library. Alternatively, you can also opt for the `commonjs` option, which adheres strictly to the CommonJS specification. To learn more about the difference between `commonjs` and `commonjs2`, see the Webpack repository.

JavaScript libraries and Node.js files

If you are creating a library for use in JavaScript or Node.js environments, and want to use a different module system, the instructions are slightly different.

Choose the target module system

To select the target module system, set the `moduleKind` compiler option in the Gradle build script:

Kotlin

```
tasks.withType<org.jetbrains.kotlin.gradle.targets.js.ir.KotlinJsIrLink> {
    compilerOptions.moduleKind.set(org.jetbrains.kotlin.gradle.dsl.JsModuleKind.MODULE_COMMONJS)
}
```

Groovy

```
compileKotlinJs.compilerOptions.moduleKind =
org.jetbrains.kotlin.gradle.dsl.JsModuleKind.MODULE_COMMONJS
```

The available values are: `umd` (default), `es`, `commonjs`, `amd`, `plain`.

This is different from adjusting `webpackTask.output.libraryTarget`. The library target changes the output *generated by webpack* (after your code has already been compiled). `compilerOptions.moduleKind` changes the output generated *by the Kotlin compiler*.

In the Kotlin Gradle DSL, there is also a shortcut for setting the CommonJS and ESM module kinds:

```
kotlin {
    js {
        useCommonJs()
        // OR
        useEsModules()
        // ...
    }
}
```

@JsModule annotation

To tell Kotlin that an `external` class, package, function or property is a JavaScript module, you can use `@JsModule` annotation. Consider you have the following CommonJS module called "hello":

```
module.exports.sayHello = function (name) { alert("Hello, " + name); }
```

You should declare it like this in Kotlin:

```
@JsModule("hello")
external fun sayHello(name: String)
```

Apply @JsModule to packages

Some JavaScript libraries export packages (namespaces) instead of functions and classes. In terms of JavaScript, it's an *object* that has *members* that are classes, functions, and properties. Importing these packages as Kotlin objects often looks unnatural. The compiler can map imported JavaScript packages to Kotlin packages, using the following notation:

```
@file:JsModule("extModule")

package ext.jspackage.name

external fun foo()

external class C
```

Where the corresponding JavaScript module is declared like this:

```
module.exports = {
  foo: { /* some code here */ },
  C: { /* some code here */ }
}
```

Files marked with `@file:JsModule` annotation can't declare non-external members. The example below produces a compile-time error:

```
@file:JsModule("extModule")

package ext.jspackage.name

external fun foo()

fun bar() = "!" + foo() + "!" // error here
```

Import deeper package hierarchies

In the previous example, the JavaScript module exports a single package. However, some JavaScript libraries export multiple packages from within a module. This case is also supported by Kotlin, though you have to declare a new `.kt` file for each package you import.

For example, let's make the example a bit more complicated:

```
module.exports = {
  mylib: {
    pkg1: {
      foo: function () { /* some code here */ },
      bar: function () { /* some code here */ }
    },
    pkg2: {
      baz: function () { /* some code here */ }
    }
  }
}
```

To import this module in Kotlin, you have to write two Kotlin source files:

```
@file:JsModule("extModule")
@file:JsQualifier("mylib.pkg1")

package extlib.pkg1

external fun foo()

external fun bar()
```

and

```
@file:JsModule("extModule")
@file:JsQualifier("mylib.pkg2")

package extlib.pkg2

external fun baz()
```

@JsNonModule annotation

When a declaration is marked as `@JsModule`, you can't use it from Kotlin code when you don't compile it to a JavaScript module. Usually, developers distribute their libraries both as JavaScript modules and downloadable `.js` files that you can copy to your project's static resources and include via a `<script>` tag. To tell Kotlin that it's okay to use a `@JsModule` declaration from a non-module environment, add the `@JsNonModule` annotation. For example, consider the following JavaScript code:

```
function topLevelSayHello (name) { alert("Hello, " + name); }

if (module && module.exports) {
  module.exports = topLevelSayHello;
}
```

You could describe it from Kotlin as follows:

```
@JsModule("hello")
@JsNonModule
@JsName("topLevelSayHello")
external fun sayHello(name: String)
```

Module system used by the Kotlin Standard Library

Kotlin is distributed with the Kotlin/JS standard library as a single file, which is itself compiled as an UMD module, so you can use it with any module system described above. For most use cases of Kotlin/JS, it is recommended to use a Gradle dependency on `kotlin-stdlib-js`, which is also available on NPM as the `kotlin` package.

Kotlin/JS reflection

Kotlin/JS provides a limited support for the Kotlin reflection API. The only supported parts of the API are:

- Class references (`::class`)
- `KType` and `typeof()`
- `KClass` and `createInstance()`

Class references

The `::class` syntax returns a reference to the class of an instance, or the class corresponding to the given type. In Kotlin/JS, the value of a `::class` expression is a stripped-down KClass implementation that supports only:

- simpleName and isInstance() members.
- cast() and safeCast() extension functions.

In addition to that, you can use KClass.js to access the JsClass instance corresponding to the class. The `JsClass` instance itself is a reference to the constructor function. This can be used to interoperate with JS functions that expect a reference to a constructor.

KType and typeOf()

The `typeof()` function constructs an instance of `KType` for a given type. The `KType` API is fully supported in Kotlin/JS except for Java-specific parts.

KClass and createInstance()

The `createInstance()` function from the KClass interface creates a new instance of the specified class, which is useful for getting the runtime reference to a Kotlin class.

Example

Here is an example of the reflection usage in Kotlin/JS.

```
open class Shape
class Rectangle : Shape()

inline fun <reified T> accessReifiedTypeArg() =
    println(typeOf<T>().toString())

fun main() {
    val s = Shape()
    val r = Rectangle()

    println(r::class.simpleName) // Prints "Rectangle"
    println(Shape::class.simpleName) // Prints "Shape"
    println(Shape::class.js.name) // Prints "Shape"

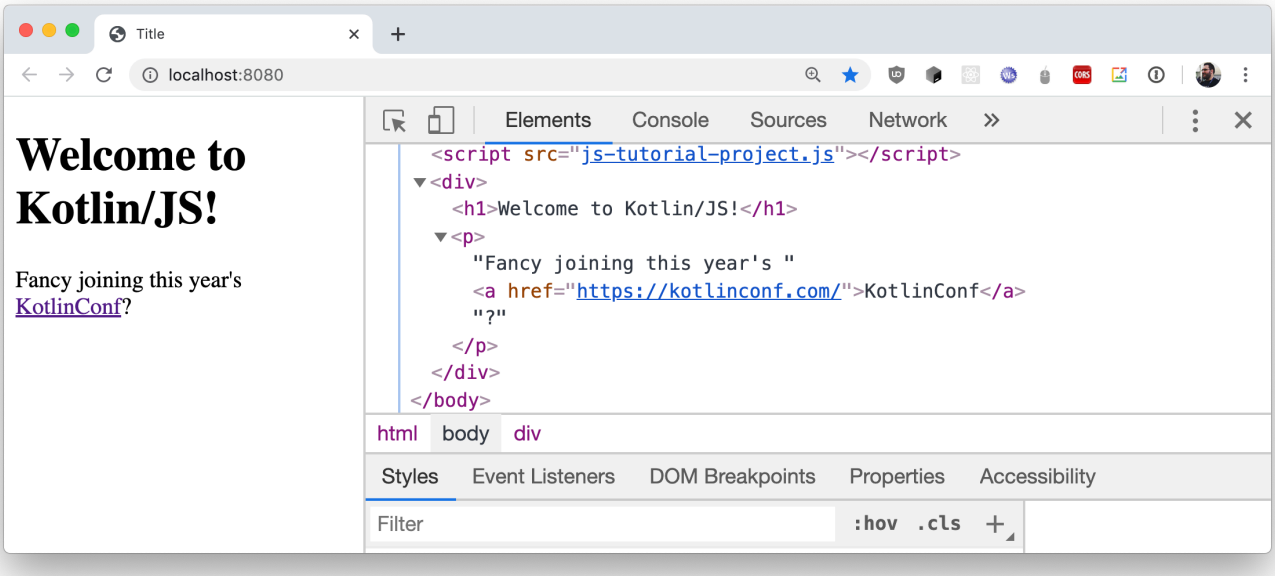
    println(Shape::class.isInstance(r)) // Prints "true"
    println(Rectangle::class.isInstance(s)) // Prints "false"
    val rShape = Shape::class.cast(r) // Casts a Rectangle "r" to Shape

    accessReifiedTypeArg<Rectangle>() // Accesses the type via typeOf(). Prints "Rectangle"
}
```

Typesafe HTML DSL

The kotlinx.html library provides the ability to generate DOM elements using statically typed HTML builders (and besides JavaScript, it is even available on the JVM target!) To use the library, include the corresponding repository and dependency to our `build.gradle.kts` file:

```
repositories {
    // ...
    mavenCentral()
}



dependencies {
    implementation(kotlin("stdlib-js"))
    implementation("org.jetbrains.kotlinx:kotlinx-html-js:0.8.0")
    // ...
}
```

Once the dependency is included, you can access the different interfaces provided to generate the DOM. To render a headline, some text, and a link, the following snippet would be sufficient, for example:

```
import kotlinx.browser.*
import kotlinx.html.*
import kotlinx.html.dom.*

fun main() {
    document.body!!.append.div {
        h1 {
            +"Welcome to Kotlin/JS!"
        }
        p {
            +"Fancy joining this year's "
            a("https://kotlinconf.com/") {
                +"KotlinConf"
            }
            +"?"
        }
    }
}
```

When running this example in the browser, the DOM will be assembled in a straightforward way. This is easily confirmed by checking the Elements of the website using the developer tools of our browser:

Rendering a website from kotlinx.html

To learn more about the `kotlinx.html` library, check out the GitHub Wiki, where you can find more information about how to create elements without adding them to the DOM, binding to events like `onClick`, and examples on how to apply CSS classes to your HTML elements, to name just a few.

Interoperability with Swift/Objective-C

> The Objective-C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from Objective-C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

Kotlin/Native provides indirect interoperability with Swift through Objective-C. This document covers how you can use Kotlin declarations in Swift/Objective-C code and Objective-C declarations in Kotlin code.

Some other resources you might find useful:

- The Kotlin-Swift interopedia, a collection of examples on how to use Kotlin declarations in Swift code.
- The Integration with Swift/Objective-C ARC section, covering the details of integration between Kotlin's tracing GC and Objective-C's ARC.

Importing Swift/Objective-C libraries to Kotlin

Objective-C frameworks and libraries can be used in Kotlin code if properly imported to the build (system frameworks are imported by default). For more details, see:

- Create and configure a library definition file
- Configure compilation for native libraries

A Swift library can be used in Kotlin code if its API is exported to Objective-C with `@objc`. Pure Swift modules are not yet supported.

Using Kotlin in Swift/Objective-C

Kotlin modules can be used in Swift/Objective-C code if compiled into a framework:

- See Build final native binaries to see how to declare binaries.
- Check out the Kotlin Multiplatform sample project for an example.

Experimental

Hide Kotlin declarations from Objective-C and Swift

To make your Kotlin code more Swift/Objective-C-friendly, use the `@HiddenFromObjC` annotation to hide a Kotlin declaration from Objective-C and Swift. It disables the function or property export to Objective-C.

Alternatively, you can mark Kotlin declarations with the `internal` modifier to restrict their visibility in the compilation module. Use `@HiddenFromObjC` if you want to hide the Kotlin declaration from Objective-C and Swift while keeping it visible to other Kotlin modules.

See an example in the Kotlin-Swift interopedia.

Experimental

Use refining in Swift

`@ShouldRefineInSwift` helps to replace a Kotlin declaration with a wrapper written in Swift. The annotation marks a function or property as `swift_private` in the generated Objective-C API. Such declarations get the `__` prefix, which makes them invisible from Swift.

You can still use these declarations in your Swift code to create a Swift-friendly API, but they won't be suggested in the Xcode autocomplete.

- For more information on refining Objective-C declarations in Swift, see the official Apple documentation.
- For an example on how to use the `@ShouldRefineInSwift` annotation, see the Kotlin-Swift interopedia.

Experimental

Change declaration names

To avoid renaming Kotlin declarations, use the `@ObjCName` annotation. It instructs the Kotlin compiler to use the custom Objective-C and Swift name for the annotated class, interface, or another Kotlin entity:

```
@ObjCName(swiftName = "MySwiftArray")
class MyKotlinArray {
    @ObjCName("index")
    fun indexOf(@ObjCName("of") element: String): Int = TODO()
}

// Usage with the ObjCName annotations
let array = MySwiftArray()
let index = array.index(of: "element")
```

See another example in the Kotlin-Swift interopedia.

Provide documentation with KDoc comments

Documentation is essential for understanding any API. Providing documentation for the shared Kotlin API allows you to communicate with its users on matters of usage, dos and don'ts, and so on.

When generating Objective-C headers, KDoc comments from Kotlin code are translated into corresponding Objective-C comments. For example, the following Kotlin code with KDoc:

```
/**
 * Prints the sum of the arguments.
 * Properly handles the case when the sum doesn't fit in 32-bit integer.
 */
fun printSum(a: Int, b: Int) = println(a.toLong() + b)
```

Will produce an Objective-C header with the corresponding comment:

```
/**
 * Prints the sum of the arguments.
 * Properly handles the case when the sum doesn't fit in 32-bit integer.
 */
+ (void)printSumA:(int32_t)a b:(int32_t)b __attribute__((swift_name("printSum(a:b:)")));
```

KDoc comments are embedded into klibs and extracted from klibs into the produced Apple frameworks. As a result, comments on classes and methods appear during autocompletion, for example in Xcode. If you go to the definition of functions in the `.h` file, you'll see comments on `@param`, `@return`, and similar tags.

Known limitations:

- Dependency documentation is not exported unless it is compiled with the `-Xexport-kdoc` option. Libraries compiled with this compiler option might be incompatible with other compiler versions.
- KDoc comments are mostly exported as is, but many KDoc block tags, such as `@property`, are not supported.

If necessary, you can disable the export of KDoc comments from klibs to the produced Apple frameworks in the `binaries {}` block of your Gradle build file:

```
// build.gradle.kts
import org.jetbrains.kotlin.gradle.ExperimentalKotlinGradlePluginApi

kotlin {
    iosArm64 {
        binaries {
            framework {
                baseName = "sdk"
                @OptIn(ExperimentalKotlinGradlePluginApi::class)
                exportKdoc.set(false)
            }
        }
    }
}
```

Mappings

The table below shows how Kotlin concepts are mapped to Swift/Objective-C and vice versa.

"->" and "<-" indicate that mapping only goes one way.

Kotlin	Swift	Objective-C	Notes
`class`	`class`	`@interface`	note
`interface`	`protocol`	`@protocol`	
`constructor` / `create`	Initializer	Initializer	note
Property	Property	Property	note 1, note 2
Method	Method	Method	note 1, note 2
`enum class`	`class`	`@interface`	note
`suspend` ->	`completionHandler:` / `async`	`completionHandler:`	note 1, note 2
`@Throws fun`	`throws`	`error:(NSError**)error`	note
Extension	Extension	Category member	note

Kotlin	Swift	Objective-C	Notes
`companion` member <-	Class method or property	Class method or property	
`null`	`nil`	`nil`	
`Singleton`	`shared` or `companion` property	`shared` or `companion` property	note
Primitive type	Primitive type / `NSNumber`		note
`Unit` return type	`Void`	`void`	
`String`	`String`	`NSString`	note
`String`	`NSMutableString`	`NSMutableString`	note
`List`	`Array`	`NSArray`	
`MutableList`	`NSMutableArray`	`NSMutableArray`	
`Set`	`Set`	`NSSet`	
`MutableSet`	`NSMutableSet`	`NSMutableSet`	note
`Map`	`Dictionary`	`NSDictionary`	
`MutableMap`	`NSMutableDictionary`	`NSMutableDictionary`	note
Function type	Function type	Block pointer type	note
Inline classes	Unsupported	Unsupported	note

Classes

Name translation

Objective-C classes are imported into Kotlin with their original names. Protocols are imported as interfaces with a `Protocol` name suffix, for example, `@protocol Foo` -> `interface FooProtocol`. These classes and interfaces are placed into a package specified in build configuration (`platform.*` packages for preconfigured system frameworks).

The names of Kotlin classes and interfaces are prefixed when imported to Objective-C. The prefix is derived from the framework name.

Objective-C does not support packages in a framework. If the Kotlin compiler finds Kotlin classes in the same framework which have the same name but different packages, it renames them. This algorithm is not stable yet and can change between Kotlin releases. To work around this, you can rename the conflicting Kotlin classes in the framework.

Strong linking

Whenever you use an Objective-C class in the Kotlin source, it's marked as a strongly linked symbol. The resulting build artifact mentions related symbols as strong external references.

This means that the app tries to link symbols during the launch dynamically, and if they are unavailable, the app crashes. The crash happens even if symbols were never used. Symbols might be unavailable on a particular device or OS version.

To work around this issue and avoid "Symbol not found" errors, use a Swift or Objective-C wrapper that checks if the class is actually available. See how this workaround was implemented in the Compose Multiplatform framework.

Initializers

A Swift/Objective-C initializer is imported to Kotlin as constructors or as factory methods named `create`. The latter happens with initializers declared in the Objective-C category or as a Swift extension, because Kotlin has no concept of extension constructors.

> Before importing Swift initializers to Kotlin, don't forget to annotate them with `@objc`.

Kotlin constructors are imported as initializers to Swift/Objective-C.

Setters

Writeable Objective-C properties overriding read-only properties of the superclass are represented as the `setFoo()` method for the property `foo`. The same goes for a protocol's read-only properties that are implemented as mutable.

Top-level functions and properties

Top-level Kotlin functions and properties are accessible as members of special classes. Each Kotlin file is translated into such a class, for example:

```
// MyLibraryUtils.kt
package my.library

fun foo() {}
```

You can then call the `foo()` function from Swift like this:

```
MyLibraryUtilsKt.foo()
```

See a collection of examples on accessing top-level Kotlin declarations in the Kotlin-Swift interopedia:

- Top-level functions
- Top-level read-only properties

- Top-level mutable properties

Method names translation

Generally, Swift argument labels and Objective-C selector pieces are mapped to Kotlin parameter names. These two concepts have different semantics, so sometimes Swift/Objective-C methods can be imported with a clashing Kotlin signature. In this case, the clashing methods can be called from Kotlin using named arguments, for example:

```
[player moveTo:LEFT byMeters:17]
[player moveTo:UP byInches:42]
```

In Kotlin, it's:

```
player.moveTo(LEFT, byMeters = 17)
player.moveTo(UP, byInches = 42)
```

Here's how the `kotlin.Any` functions are mapped to Swift/Objective-C:

Kotlin	Swift	Objective-C
`equals()`	`isEquals(_:)`	`isEquals:`
`hashCode()`	`hash`	`hash`
`toString()`	`description`	`description`

See an example with data classes in the Kotlin-Swift interopedia.

You can specify a more idiomatic name in Swift or Objective-C, instead of renaming the Kotlin declaration with the `@ObjCName` annotation.

Errors and exceptions

All Kotlin exceptions are unchecked, meaning that errors are caught at runtime. However, Swift has only checked errors that are handled at compile time. So, if Swift or Objective-C code calls a Kotlin method that throws an exception, the Kotlin method should be marked with the `@Throws` annotation, specifying a list of "expected" exception classes.

When compiling to the Swift/Objective-C framework, non-`suspend` functions that have or inherit the `@Throws` annotation are represented as `NSError*`-producing methods in Objective-C and as `throws` methods in Swift. Representations for `suspend` functions always have an `NSError*` / `Error` parameter in the completion handler.

When a Kotlin function called from Swift/Objective-C code throws an exception which is an instance of one of the classes specified with `@Throws` or their subclasses, the exception is propagated as an `NSError`. Other Kotlin exceptions reaching Swift/Objective-C are considered unhandled and cause program termination.

`suspend` functions without `@Throws` propagate only `CancellationException` (as `NSError`). Non-`suspend` functions without `@Throws` don't propagate Kotlin exceptions at all.

Note that the opposite reversed translation is not implemented yet: Swift/Objective-C error-throwing methods aren't imported to Kotlin as exception-throwing.

See an example in the Kotlin-Swift interopedia.

Enums

Kotlin enums are imported into Objective-C as `@interface` and into Swift as `class`. These data structures have properties corresponding to each enum value. Consider this Kotlin code:

```
// Kotlin
enum class Colors {
    RED, GREEN, BLUE
}
```

You can access the properties of this enum class from Swift as follows:

```
// Swift
Colors.red
Colors.green
Colors.blue
```

To use variables of a Kotlin enum in a Swift `switch` statement, provide a default statement to prevent a compilation error:

```
switch color {
    case .red: print("It's red")
    case .green: print("It's green")
    case .blue: print("It's blue")
    default: fatalError("No such color")
}
```

See another example in the Kotlin-Swift interopedia.

Experimental

Suspending functions

Kotlin's suspending functions (`suspend`) are presented in the generated Objective-C headers as functions with callbacks, or completion handlers in Swift/Objective-C terminology.

Starting from Swift 5.5, Kotlin's `suspend` functions are also available for calling from Swift as `async` functions without using the completion handlers. Currently, this functionality is highly experimental and has certain limitations. See this YouTrack issue for details.

- Learn more about the `async` / `await` mechanism in the Swift documentation.
- See an example and recommendations on third-party libraries that implement the same functionality in the Kotlin-Swift interopedia.

Extensions and category members

Members of Objective-C categories and Swift extensions are generally imported to Kotlin as extensions. That's why these declarations can't be overridden in Kotlin, and the extension initializers aren't available as Kotlin constructors.

Currently, there are two exceptions. Starting with Kotlin 1.8.20, category members that are declared in the same headers as the NSView class (from the AppKit framework) or UIView classes (from the UIKit framework) are imported as members of these classes. This means that you can override methods that subclass from NSView or UIView.

Kotlin extensions to "regular" Kotlin classes are imported to Swift and Objective-C as extensions and category members, respectively. Kotlin extensions to other types are treated as top-level declarations with an additional receiver parameter. These types include:

- Kotlin `String` type
- Kotlin collection types and subtypes
- Kotlin `interface` types
- Kotlin primitive types
- Kotlin `inline` classes
- Kotlin `Any` type
- Kotlin function types and subtypes
- Objective-C classes and protocols

See a collection of examples in the Kotlin-Swift interopedia.

Kotlin singletons

Kotlin singleton (made with an `object` declaration, including `companion object`) is imported to Swift/Objective-C as a class with a single instance.

The instance is available through the `shared` and `companion` properties.

For the following Kotlin code:

```
object MyObject {
    val x = "Some value"
}

class MyClass {
    companion object {
        val x = "Some value"
    }
}
```

Access these objects as follows:

```
MyObject.shared
MyObject.shared.x
MyClass.companion
MyClass.Companion.shared
```

Access objects through `[MySingleton mySingleton]` in Objective-C and `MySingleton()` in Swift has been deprecated.

See more examples in the Kotlin-Swift interopedia:

- How to access Kotlin objects using `shared`
- How to access members of Kotlin companion objects from Swift.

Primitive types

Kotlin primitive type boxes are mapped to special Swift/Objective-C classes. For example, the `kotlin.Int` box is represented as the `KotlinInt` class instance in Swift (or the `${prefix}Int` instance in Objective-C, where `prefix` is the framework's name prefix). These classes are derived from `NSNumber`, so the instances are proper `NSNumber` s supporting all corresponding operations.

The `NSNumber` type is not automatically translated to Kotlin primitive types when used as a Swift/Objective-C parameter type or return value. The reason is that the `NSNumber` type doesn't provide enough information about a wrapped primitive value type, for example, `NSNumber` is statically not known to be `Byte`, `Boolean`, or `Double`. So Kotlin primitive values should be cast to and from `NSNumber` manually.

Strings

When a Kotlin `String` is passed to Swift, it's first exported as an Objective-C object, and then the Swift compiler copies it one more time for a Swift conversion. This results in additional runtime overhead.

To avoid that, access Kotlin strings in Swift directly as an Objective-C `NSString` instead. See the conversion example.

NSMutableString

`NSMutableString` Objective-C class is not available from Kotlin. All instances of `NSMutableString` are copied when passed to Kotlin.

Collections

Kotlin -> Objective-C -> Swift

When a Kotlin collection is passed to Swift, it's first converted to an Objective-C equivalent, and then the Swift compiler copies the entire collection and converts it into a Swift-native collection as described in the mappings table.

This last conversion leads to performance costs. To prevent this, when using Kotlin collections in Swift, explicitly cast them to their Objective-C counterparts: `NSDictionary`, `NSArray`, or `NSSet`.

See the conversion example

For example, the following Kotlin declaration:

```
val map: Map<String, String>
```

In Swift, it looks like this:

```
map[key]?.count ?? 0
```

Here, the `map` is implicitly converted to Swift's `Dictionary`, and its string values are mapped to Swift's `String`. This results in a performance cost.

To avoid the conversion, explicitly cast `map` to Objective-C's `NSDictionary` and access values as `NSString` instead:

```
let nsMap: NSDictionary = map as NSDictionary
(nsMap[key] as? NSString)?.length ?? 0
```

This ensures that the Swift compiler doesn't perform an additional conversion step.

Swift -> Objective-C -> Kotlin

Swift/Objective-C collections are mapped to Kotlin as described in the mappings table, except for `NSMutableSet` and `NSMutableDictionary`.

`NSMutableSet` isn't converted to a Kotlin's `MutableSet`. To pass an object to Kotlin `MutableSet`, explicitly create this kind of Kotlin collection. To do this, use, for example, the `mutableSetOf()` function in Kotlin or the `KotlinMutableSet` class in Swift and `${prefix}MutableSet` in Objective-C (`prefix` is the framework names prefix). The same is true for `MutableMap`.

See an example in the Kotlin-Swift interopedia.

Function types

Kotlin function-typed objects (for example, lambdas) are converted to closures in Swift and blocks in Objective-C. See an example of a Kotlin function with a lambda in the Kotlin-Swift interopedia.

However, there is a difference in how types of parameters and return values are mapped when translating a function and a function type. In the latter case, primitive types are mapped to their boxed representation. Kotlin `Unit` return value is represented as a corresponding `Unit` singleton in Swift/Objective-C. The value of this singleton can be retrieved the same way as for any other Kotlin `object`. See singletons in the table above.

Consider the following Kotlin function:

```
fun foo(block: (Int) -> Unit) { ... }
```

It's represented in Swift as follows:

```
func foo(block: (KotlinInt) -> KotlinUnit)
```

And you can call it like this:

```
foo {
    bar($0 as! Int32)
    return KotlinUnit()
}
```

Experimental

Explicit parameter names in Objective-C block types

You can add explicit parameter names to Kotlin's function types for exported Objective-C headers. Xcode's autocompletion then suggests these names when calling Objective-C functions in the Objective-C block. This helps to avoid Clang warnings in generated blocks.

To enable explicit parameter names, add the following binary option to your `gradle.properties` file:

```
kotlin.native.binary.objcExportBlockExplicitParameterNames=true
```

For example, for the following Kotlin code:

```
// Kotlin:
fun greetUser(block: (name: String) -> Unit) = block("John")
```

Kotlin forwards the parameter names from Kotlin function types to Objective-C block types, allowing Xcode to use them in suggestions:

```
// Objective-C:
greetUserBlock:^(NSString *name) {
    // ...
};
```

This option affects Objective-C interop only. It applies when calling generated Objective-C code from Objective-C in Xcode, and generally doesn't affect calls from Swift.

Generics

Objective-C supports "lightweight generics" defined in classes, with a relatively limited feature set. Swift can import generics defined on classes to help provide additional type information to the compiler.

Generic feature support for Objective-C and Swift differ from Kotlin, so the translation will inevitably lose some information, but the features supported retain meaningful information.

For specific examples on how to use Kotlin generics in Swift, see the Kotlin-Swift interopedia.

Limitations

Objective-C generics do not support all features of either Kotlin or Swift, so there will be some information lost in the translation.

Generics can only be defined on classes, not on interfaces (protocols in Objective-C and Swift) or functions.

Nullability

Kotlin and Swift both define nullability as part of the type specification, while Objective-C defines nullability on methods and properties of a type. So, the following Kotlin code:

```
class Sample<T>() {
    fun myVal(): T
}
```

In Swift, it looks like this:

```
class Sample<T>() {
    fun myVal(): T?
}
```

To support a potentially nullable type, the Objective-C header needs to define `myVal` with a nullable return value.

To mitigate this, when defining your generic classes, provide a non-nullable type constraint if the generic type should *never* be null:

```
class Sample<T : Any>() {
    fun myVal(): T
}
```

That will force the Objective-C header to mark `myVal` as non-nullable.

Variance

Objective-C allows generics to be declared covariant or contravariant. Swift has no support for variance. Generic classes coming from Objective-C can be force-cast as needed.

```
data class SomeData(val num: Int = 42) : BaseData()
class GenVarOut<out T : Any>(val arg: T)
```

```
let variOut = GenVarOut<SomeData>(arg: sd)
let variOutAny : GenVarOut<BaseData> = variOut as! GenVarOut<BaseData>
```

Constraints

In Kotlin, you can provide upper bounds for a generic type. Objective-C also supports this, but that support is unavailable in more complex cases and is currently not supported in the Kotlin - Objective-C interop. The exception here being a non-nullable upper bound will make Objective-C methods/properties non-nullable.

To disable

To have the framework header written without generics, add the following compiler option in your build file:

```
binaries.framework {
    freeCompilerArgs += "-Xno-objc-generics"
}
```

Forward declarations

To import forward declarations, use the `objcnames.classes` and `objcnames.protocols` packages. For example, to import a `objcprotocolName` forward declaration declared in an Objective-C library with a `library.package`, use a special forward declaration package: `import objcnames.protocols.objcprotocolName`.

Consider two objcinterop libraries: one that uses `objcnames.protocols.ForwardDeclaredProtocolProtocol` and another with an actual implementation in another package:

```
// First objcinterop library
#import <Foundation/Foundation.h>

@protocol ForwardDeclaredProtocol;

NSString* consumeProtocol(id<ForwardDeclaredProtocol> s) {
    return [NSString stringWithUTF8String:"Protocol"];
}
```

```
// Second objcinterop library
// Header:
#import <Foundation/Foundation.h>
@protocol ForwardDeclaredProtocol
@end
// Implementation:
@interface ForwardDeclaredProtocolImpl : NSObject <ForwardDeclaredProtocol>
@end

id<ForwardDeclaredProtocol> produceProtocol() {
    return [ForwardDeclaredProtocolImpl new];
}
```

To transfer objects between the two libraries, use an explicit `as` cast in your Kotlin code:

```
// Kotlin code:
fun test() {
    consumeProtocol(produceProtocol() as objcnames.protocols.ForwardDeclaredProtocolProtocol)
}
```

> You can only cast to `objcnames.protocols.ForwardDeclaredProtocolProtocol` from the corresponding real class. Otherwise, you'll get an error.

Casting between mapped types

When writing Kotlin code, an object may need to be converted from a Kotlin type to the equivalent Swift/Objective-C type or vice versa. In this case, you can use the `as` cast, for example:

```
@file:Suppress("CAST_NEVER_SUCCEEDS")
import platform.Foundation.*

val nsNumber = 42 as NSNumber
val nsArray = listOf(1, 2, 3) as NSArray
val nsString = "Hello" as NSString
val string = nsString as String
```

IDEs might incorrectly emit "This cast can never succeed" warnings. In such cases, use the `@Suppress("CAST_NEVER_SUCCEEDS")` annotation.

Subclassing

Subclassing Kotlin classes and interfaces from Swift/Objective-C

Kotlin classes and interfaces can be subclassed by Swift/Objective-C classes and protocols.

Subclassing Swift/Objective-C classes and protocols from Kotlin

Swift/Objective-C classes and protocols can be subclassed with a Kotlin `final` class. Non-`final` Kotlin classes inheriting Swift/Objective-C types aren't supported yet, so it is not possible to declare a complex class hierarchy inheriting Swift/Objective-C types.

Normal methods can be overridden using the `override` Kotlin keyword. In this case, the overriding method must have the same parameter names as the overridden one.

Sometimes it is required to override initializers, for example, when subclassing `UIViewController`. Initializers imported as Kotlin constructors can be overridden by Kotlin constructors marked with the `@OverrideInit` annotation:

```
class ViewController : UIViewController {
    @OverrideInit constructor(coder: NSCoder) : super(coder)

    ...
}
```

The overriding constructor must have the same parameter names and types as the overridden one.

To override different methods with clashing Kotlin signatures, you can add the `@ObjCSignatureOverride` annotation to the class. The annotation instructs the Kotlin compiler to ignore conflicting overloads, in case several functions with the same argument types, but different argument names, are inherited from the Objective-C class.

By default, the Kotlin/Native compiler doesn't allow calling a non-designated Objective-C initializer as a `super()` constructor. This behavior can be inconvenient if the designated initializers aren't marked properly in the Objective-C library. To disable these compiler checks, add the `disableDesignatedInitializerChecks = true` to the library's `.def` file.

C features

See Interoperability with C for an example case where the library uses some plain C features, such as unsafe pointers, structs, and so on.

Unsupported

Some features of the Kotlin programming language are not yet mapped into the respective features of Objective-C or Swift. Currently, the following features are not properly exposed in generated framework headers:

- Inline classes (arguments are mapped as either underlying primitive type or `id`)
- Custom classes implementing standard Kotlin collection interfaces (`List`, `Map`, `Set`) and other special classes
- Kotlin subclasses of Objective-C classes

Kotlin/Native as an Apple framework – tutorial

> The Objective-C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from Objective-C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

Kotlin/Native provides bidirectional interoperability with Swift/Objective-C. You can both use Objective-C frameworks and libraries in Kotlin code, and Kotlin modules in Swift/Objective-C code.

Kotlin/Native comes with a set of pre-imported system frameworks; it's also possible to import an existing framework and use it from Kotlin. In this tutorial, you'll learn how to create your own framework and use Kotlin/Native code from Swift/Objective-C applications on macOS and iOS.

In this tutorial, you will:

- Create a Kotlin library and compile it to a framework
- Examine the generated Swift/Objective-C API code
- Use the framework from Objective-C
- Use the framework from Swift

You can use the command line to generate a Kotlin framework, either directly or with a script file (such as `.sh` or `.bat` file). However, this approach doesn't scale well for larger projects that have hundreds of files and libraries. Using a build system simplifies the process by downloading and caching the Kotlin/Native compiler binaries and libraries with transitive dependencies, as well as by running the compiler and tests. Kotlin/Native can use the Gradle build system through the Kotlin Multiplatform plugin.

If you use a Mac and want to create and run applications for iOS or other Apple targets, you also need to install the Xcode Command Line Tools, launch it, and accept the license terms first.

Create a Kotlin library

See the Get started with Kotlin/Native tutorial for detailed first steps and instructions on how to create a new Kotlin/Native project and open it in IntelliJ IDEA.

The Kotlin/Native compiler can produce a framework for macOS and iOS from the Kotlin code. The created framework contains all declarations and binaries needed to use it with Swift/Objective-C.

Let's first create a Kotlin library:

1. In the `src/nativeMain/kotlin` directory, create the `lib.kt` file with the library contents:

```kotlin
package example

object Object {
    val field = "A"
}

interface Interface {
    fun iMember() {}
}

class Clazz : Interface {
    fun member(p: Int): ULong? = 42UL
}

fun forIntegers(b: Byte, s: UShort, i: Int, l: ULong?) { }
fun forFloats(f: Float, d: Double?) { }

fun strings(str: String?) : String {
    return "That is '$str' from C"
}

fun acceptFun(f: (String) -> String?) = f("Kotlin/Native rocks!")
fun supplyFun() : (String) -> String? = { "$it is cool!" }
```

2. Update your `build.gradle(.kts)` Gradle build file with the following:

Kotlin

```kotlin
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    kotlin("multiplatform") version "2.4.20"
}

repositories {
    mavenCentral()
}

kotlin {
    iosArm64()
    // macosArm64()
    // iosSimulatorArm64()

    targets.withType<KotlinNativeTarget>().configureEach {
        binaries {
            framework {
                baseName = "Demo"
            }
        }
    }
}

tasks.wrapper {
    gradleVersion = "9.7.0"
    distributionType = Wrapper.DistributionType.ALL
}
```

Groovy

```
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}

repositories {
    mavenCentral()
}

kotlin {
    iosArm64()
    // macosArm64()
    // iosSimulatorArm64()

    targets.withType(KotlinNativeTarget).configureEach {
        binaries {
            framework {
                baseName = "Demo"
            }
        }
    }
}

wrapper {
    gradleVersion = "9.7.0"
    distributionType = "ALL"
}
```

The `binaries {}` block configures the project to generate a dynamic or shared library.

Kotlin/Native supports the `iosArm64` and `iosSimulatorArm64` targets for iOS, as well as the `macosArm64` target for macOS. So, you can replace `iosArm64()` with the respective Gradle function for your target platform:

Target/device	Gradle function
macOS ARM64	`macosArm64()`
iOS ARM64	`iosArm64()`
iOS Simulator (ARM64)	`iosSimulatorArm64()`

For information on other supported Apple targets, see Kotlin/Native target support.

3. To build the framework, run the `linkDebugFramework<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, for example:

```
./gradlew linkDebugFrameworkIosArm64
```

The build generates the framework into the `build/bin/<yourTargetName>/debugFramework` directory.

You can also use the general `link<YourTargetName>` Gradle task to generate both `debug` and `release` variants of the framework.

Generated framework headers

Each framework variant contains a header file. The headers don't depend on the target platform. Header files contain definitions for your Kotlin code and a few Kotlin-wide declarations. Let's see what's inside.

Kotlin/Native runtime declarations

In the `build/bin/<yourTargetName>/debugFramework/Demo.framework/Headers` directory, open the `Demo.h` header file. Take a look at Kotlin runtime declarations:

```
NS_ASSUME_NONNULL_BEGIN
#pragma clang diagnostic push
#pragma clang diagnostic ignored "-Wunknown-warning-option"
#pragma clang diagnostic ignored "-Wincompatible-property-type"
#pragma clang diagnostic ignored "-Wnullability"

#pragma push_macro("_Nullable_result")
#if !__has_feature(nullability_nullable_result)
#undef _Nullable_result
#define _Nullable_result _Nullable
#endif

__attribute__((swift_name("KotlinBase")))
@interface DemoBase : NSObject
- (instancetype)init __attribute__((unavailable));
+ (instancetype)new __attribute__((unavailable));
+ (void)initialize __attribute__((objc_requires_super));
@end

@interface DemoBase (DemoBaseCopying) <NSCopying>
@end

__attribute__((swift_name("KotlinMutableSet")))
@interface DemoMutableSet<ObjectType> : NSMutableSet<ObjectType>
@end

__attribute__((swift_name("KotlinMutableDictionary")))
@interface DemoMutableDictionary<KeyType, ObjectType> : NSMutableDictionary<KeyType, ObjectType>
@end

@interface NSError (NSErrorDemoKotlinException)
@property (readonly) id _Nullable kotlinException;
@end
```

Kotlin classes have a `KotlinBase` base class in Swift/Objective-C that extends the `NSObject` class there. There are also wrappers for collections and exceptions. Most of the collection types are mapped to similar collection types in Swift/Objective-C:

Kotlin	Swift	Objective-C
List	Array	NSArray

Kotlin	Swift	Objective-C
MutableList	NSMutableArray	NSMutableArray
Set	Set	NSSet
MutableSet	NSMutableSet	NSMutableSet
Map	Dictionary	NSDictionary
MutableMap	NSMutableDictionary	NSMutableDictionary

Kotlin numbers and NSNumber

The next part of the `Demo.h` file contains type mappings between Kotlin/Native number types and `NSNumber`. The base class is called `DemoNumber` in Objective-C and `KotlinNumber` in Swift. It extends `NSNumber`.

For each Kotlin number type, there is a corresponding predefined child class:

Kotlin	Swift	Objective-C	Simple type
`-`	`KotlinNumber`	`<Package>Number`	`-`
`Byte`	`KotlinByte`	`<Package>Byte`	`char`
`UByte`	`KotlinUByte`	`<Package>UByte`	`unsigned char`
`Short`	`KotlinShort`	`<Package>Short`	`short`
`UShort`	`KotlinUShort`	`<Package>UShort`	`unsigned short`
`Int`	`KotlinInt`	`<Package>Int`	`int`
`UInt`	`KotlinUInt`	`<Package>UInt`	`unsigned int`
`Long`	`KotlinLong`	`<Package>Long`	`long long`
`ULong`	`KotlinULong`	`<Package>ULong`	`unsigned long long`
`Float`	`KotlinFloat`	`<Package>Float`	`float`
`Double`	`KotlinDouble`	`<Package>Double`	`double`
`Boolean`	`KotlinBoolean`	`<Package>Boolean`	`BOOL/Bool`

Every number type has a class method to create a new instance from the corresponding simple type. Also, there is an instance method to extract a simple value back. Schematically, all such declarations look like that:

```
__attribute__((swift_name("Kotlin__TYPE__")))
@interface Demo__TYPE__ : DemoNumber
- (instancetype)initWith__TYPE__:(__CTYPE__)value;
+ (instancetype)numberWith__TYPE__:(__CTYPE__)value;
@end;
```

Here, `__TYPE__` is one of the simple type names, and `__CTYPE__` is the corresponding Objective-C type, for example, `initWithChar(char)`.

These types are used to map boxed Kotlin number types to Swift/Objective-C. In Swift, you can call the constructor to create an instance, for example, `KotlinLong(value: 42)`.

Classes and objects from Kotlin

Let's see how `class` and `object` are mapped to Swift/Objective-C. The generated `Demo.h` file contains the exact definitions for `Class`, `Interface`, and `Object`:

```
__attribute__((swift_name("Interface")))
@protocol DemoInterface
@required
- (void)iMember __attribute__((swift_name("iMember()")));
@end

__attribute__((objc_subclassing_restricted))
__attribute__((swift_name("Clazz")))
@interface DemoClazz : DemoBase <DemoInterface>
- (instancetype)init __attribute__((swift_name("init()")))
__attribute__((objc_designated_initializer));
+ (instancetype)new __attribute__((availability(swift, unavailable, message="use object initializers
instead")));
- (DemoULong * _Nullable)memberP:(int32_t)p __attribute__((swift_name("member(p:)")));
@end

__attribute__((objc_subclassing_restricted))
__attribute__((swift_name("Object")))
@interface DemoObject : DemoBase
+ (instancetype)alloc __attribute__((unavailable));
+ (instancetype)allocWithZone:(struct _NSZone *)zone __attribute__((unavailable));
+ (instancetype)object __attribute__((swift_name("init()")));
@property (class, readonly, getter=shared) DemoObject *shared __attribute__((swift_name("shared")));
@property (readonly) NSString *field __attribute__((swift_name("field")));
@end
```

Objective-C attributes in this code help use the framework from both Swift and Objective-C languages. `DemoInterface`, `DemoClazz`, and `DemoObject` are created for `Interface`, `Clazz`, and `Object`, respectively.

The `Interface` is turned into `@protocol`, while both a `class` and an `object` are represented as `@interface`. The `Demo` prefix comes from the framework name. The nullable return type `ULong?` is turned into `DemoULong` in Objective-C.

Global declarations from Kotlin

All global functions from Kotlin are turned into `DemoLibKt` in Objective-C and into `LibKt` in Swift, where `Demo` is the framework name set by the `-output` parameter of `kotlinc-native`:

```
__attribute__((objc_subclassing_restricted))
__attribute__((swift_name("LibKt")))
@interface DemoLibKt : DemoBase
+ (NSString * _Nullable)acceptFunF:(NSString * _Nullable (^)(NSString *))f
__attribute__((swift_name("acceptFun(f:)")));
+ (void)forFloatsF:(float)f d:(DemoDouble * _Nullable)d
__attribute__((swift_name("forFloats(f:d:)")));
+ (void)forIntegersB:(int8_t)b s:(uint16_t)s i:(int32_t)i l:(DemoULong * _Nullable)l
__attribute__((swift_name("forIntegers(b:s:i:l:)")));
+ (NSString *)stringsStr:(NSString * _Nullable)str __attribute__((swift_name("strings(str:)")));
+ (NSString * _Nullable (^)(NSString *))supplyFun __attribute__((swift_name("supplyFun()")));
@end
```

Kotlin `String` and Objective-C `NSString*` are mapped transparently. Similarly, `Unit` type from Kotlin is mapped to `void`. The primitive types are mapped directly. Non-nullable primitive types are mapped transparently. Nullable primitive types are mapped to `Kotlin<TYPE>*` types, as shown in the table. Both higher-order functions `acceptFunF` and `supplyFun` are included and accept Objective-C blocks.

You can find more information about type mapping in Interoperability with Swift/Objective-C.

Garbage collection and reference counting

Swift and Objective-C use automatic reference counting (ARC). Kotlin/Native has its own garbage collector, which is also integrated with Swift/Objective-C ARC.

Unused Kotlin objects are automatically removed. You don't need to take additional steps to control the lifetime of Kotlin/Native instances from Swift or Objective-C.

Use code from Objective-C

Let's call the framework from Objective-C. In the framework directory, create the `main.m` file with the following code:

```
#import <Foundation/Foundation.h>
#import <Demo/Demo.h>

int main(int argc, const char * argv[]) {
    @autoreleasepool {
        [DemoObject.shared field];

        DemoClazz* clazz = [[ DemoClazz alloc] init];
        [clazz memberP:42];

        [DemoLibKt forIntegersB:1 s:1 i:3 l:[DemoULong numberWithUnsignedLongLong:4]];
        [DemoLibKt forIntegersB:1 s:1 i:3 l:nil];

        [DemoLibKt forFloatsF:2.71 d:[DemoDouble numberWithDouble:2.71]];
        [DemoLibKt forFloatsF:2.71 d:nil];

        NSString* ret = [DemoLibKt acceptFunF:^NSString * _Nullable(NSString * it) {
            return [it stringByAppendingString:@" Kotlin is fun"];
        }];

        NSLog(@"%@", ret);
        return 0;
    }
}
```

Here, you call Kotlin classes directly from Objective-C code. A Kotlin object uses the `<object name>.shared` class property, which allows you to get the object's only instance and call object methods on it.

The widespread pattern is used to create an instance of the `Clazz` class. You call the `[[ DemoClazz alloc] init]` on Objective-C. You can also use `[DemoClazz new]` for constructors without parameters.

Global declarations from the Kotlin sources are scoped under the `DemoLibKt` class in Objective-C. All Kotlin functions are turned into class methods of that class.

The `strings` function is turned into `DemoLibKt.stringsStr` function in Objective-C, so you can pass `NSString` directly to it. The return value is visible as `NSString` too.

Use code from Swift

The framework you generated has helper attributes to make it easier to use with Swift. Let's convert the previous Objective-C example into Swift.

In the framework directory, create the `main.swift` file with the following code:

```
import Foundation
import Demo

let kotlinObject = Object.shared

let field = Object.shared.field

let clazz = Clazz()
clazz.member(p: 42)

LibKt.forIntegers(b: 1, s: 2, i: 3, l: 4)
LibKt.forFloats(f: 2.71, d: nil)

let ret = LibKt.acceptFun { "\($0) Kotlin is fun" }
if (ret ≠ nil) {
    print(ret!)
}
```

There are some small differences between the original Kotlin code and its Swift version. In Kotlin, any object declaration has only one instance. The `Object.shared` syntax is used to access this single instance.

Kotlin function and property names are translated as is. Kotlin's `String` is turned into Swift's `String`. Swift hides `NSNumber*` boxing too. You can also pass a Swift closure to Kotlin and call a Kotlin lambda function from Swift.

You can find more information about type mapping in Interoperability with Swift/Objective-C.

Connect the framework to your iOS project

Now you can connect the generated framework to your iOS project as a dependency. There are multiple ways to set it up and automate the process, choose the method that suits you best:

Choose iOS integration method

- See how interoperability with C is implemented in Kotlin
- Check out the Kotlin/Native as a dynamic library tutorial

Interoperability with Swift using Swift export

Kotlin's interoperability with Swift through Swift export is currently in Alpha. Swift export allows you to export Kotlin sources directly and call Kotlin code from Swift idiomatically, eliminating the need for Objective-C headers.

Swift export makes multiplatform development for Apple targets more streamlined. For example, if you have a Kotlin module with top-level functions, Swift export enables clean, module-specific imports, removing the confusing Objective-C underscores and mangled names.

Current Swift export features are:

- **Multi-module support**. Each Kotlin module is exported as a separate Swift module, simplifying function calls.
- **Package support**. Kotlin packages are explicitly preserved during export, avoiding naming conflicts in the generated Swift code.
- **Type aliases**. Kotlin type aliases are exported and preserved in Swift, improving readability.
- **Enhanced nullability for primitives**. Unlike Objective-C interop, which required boxing types like `Int?` into wrapper classes like `KotlinInt` to preserve nullability, Swift export converts nullability information directly.
- **Overloads**. You can call Kotlin's overloaded functions in Swift without ambiguity.
- **Flattened package structure**. You can translate Kotlin packages into Swift enums, removing the package prefix from generated Swift code.
- **Module name customization**. You can customize the resulting Swift module names in the Gradle configuration of your Kotlin project.
- **Concurrency support**. You can seamlessly call suspending Kotlin code from Swift and export `kotlinx.coroutines` flows as Swift's `AsyncSequence` out of the box.

Enable Swift export

Swift export is currently in Alpha and still incomplete, so breaking changes are expected. To try it out, configure the build file in your Kotlin project and set up Xcode to integrate Swift export.

Configure Kotlin project

You can use the following build file in your project as a starting point for setting up Swift export:

```kotlin
// build.gradle.kts
kotlin {

    iosArm64()
    iosSimulatorArm64()

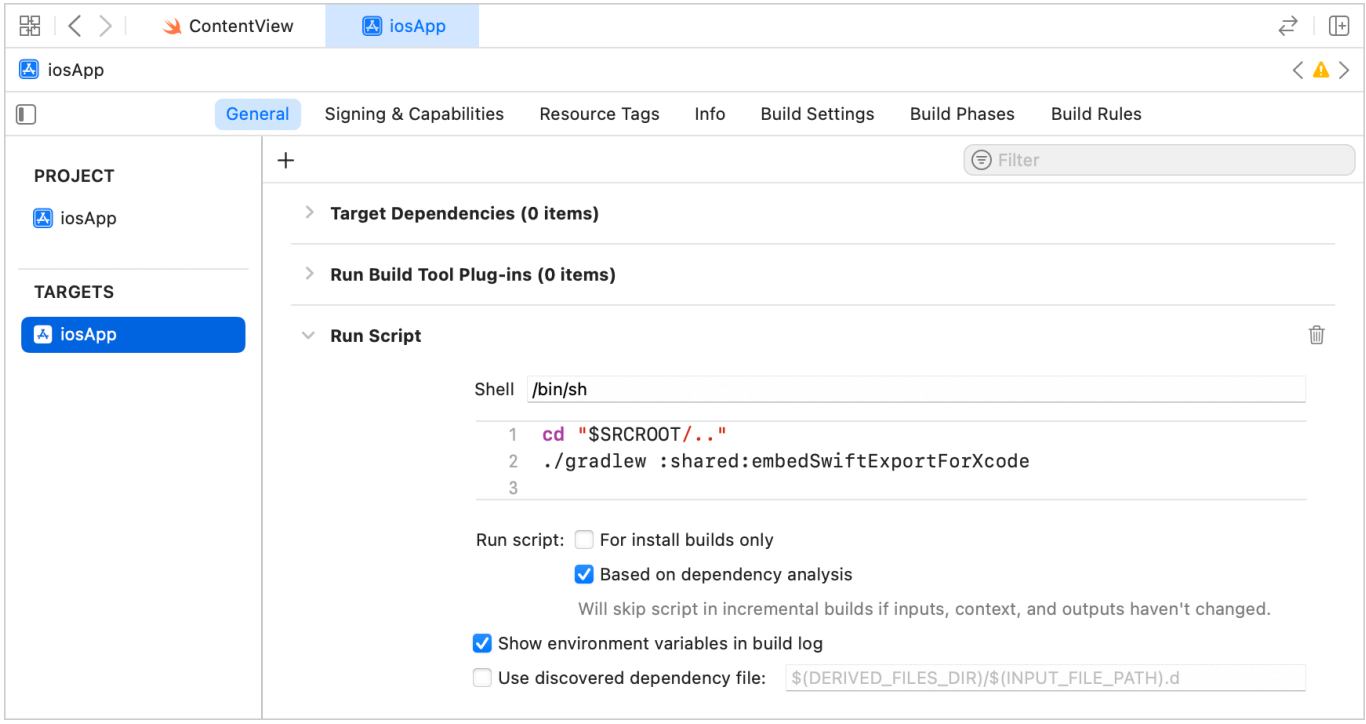
    swiftExport {
        // Set the root module name
        moduleName = "Shared"

        // Set the collapse rule
        // Removes package prefix from generated Swift code
        flattenPackage = "com.example.sandbox"

        // Configure external modules export
        export(project(":subproject")) {
            // Set the name for the exported module
            moduleName = "Subproject"
            // Set the collapse rule for the exported dependency
            flattenPackage = "com.subproject.library"
        }

        // Provide compiler arguments to link tasks
        configure {
            freeCompilerArgs.add("-Xexpect-actual-classes")
        }
    }
}
```

The Kotlin compiler automatically generates all the necessary files (including `swiftmodule` files, static `.a` library, a header file, and a `modulemap` file) and copies them into the app's build directory, which you can access from Xcode.



> You can also clone our public sample with Swift export already set up.

Configure Xcode project

To configure Xcode to integrate Swift export into your project:

1. In Xcode, open the project settings.
2. On the **Build Phases** tab, locate the **Run Script** phase with the `embedAndSignAppleFrameworkForXcode` task.
3. Replace the script with the `embedSwiftExportForXcode` task in the run script phase:

```
./gradlew :<Shared module name>:embedSwiftExportForXcode
```

Add the Swift export script

4. Build the project. The build generates Swift modules in the output directory.

Current limitations

Swift export currently works only in projects that use direct integration to connect the iOS framework to the Xcode project. This is a standard configuration for Kotlin Multiplatform projects created with the Kotlin Multiplatform plugin in IntelliJ IDEA or through the web wizard.

Other known issues:

- Types that inherit from `List`, `Set`, or `Map` are ignored during the export (KT-80416).
- Inheritors of `List`, `Set`, or `Map` cannot be instantiated on the Swift side (KT-80417).
- When exported to Swift, Kotlin generic type parameters are type-erased to their upper bounds.
- No IDE migration tips or automation are available.
- When using declarations that require opt-in, you must add an explicit `optIn` compiler option at the *module level* to your Gradle build file. For example, for the `kotlinx.datetime` library:

```
swiftExport {
    moduleName = "Shared"

    export("org.jetbrains.kotlinx:kotlinx-datetime:0.8.0") {
        moduleName = "KotlinDateTime"
        flattenPackage = "kotlinx.datetime"
    }
}

// Add a separate opt-in block at the module level
compilerOptions {
    optIn.add("kotlin.time.ExperimentalTime")
}
```

Mappings

The table below shows how Kotlin concepts are mapped to Swift.

Kotlin	Swift
`class`	`class`
`object`	`class` with `shared` property
`enum class`	`enum`
`sealed` classes and interfaces	`enum`
`typealias`	`typealias`
Function	Function
`suspend fun`	`async`
`kotlinx.coroutines` flows	`AsyncSequence`
Property	Property
Constructor	Initializer
Package	Nested enum
`Boolean`	`Bool`
`Char`	`Unicode.UTF16.CodeUnit`
`Byte`	`Int8`
`Short`	`Int16`
`Int`	`Int32`
`Long`	`Int64`
`UByte`	`UInt8`
`UShort`	`UInt16`

Kotlin	Swift
`UInt`	`UInt32`
`ULong`	`UInt64`
`Float`	`Float`
`Double`	`Double`
`Any`	`KotlinBase` class
`Unit`	`Void`
`Nothing`	`Never`

Declarations

Classes

Swift export supports only final classes that directly inherit from `Any`, like `class Foo()`. They are translated to Swift classes that inherit from a special `KotlinBase` class:

```
// Kotlin
class MyClass {
    val property: Int = 0

    fun method() {}
}
```

```
// Swift
public class MyClass : KotlinRuntime.KotlinBase {
    public var property: Swift.Int32 {
        get {
            // ...
        }
    }
    public override init() {
        // ...
    }
    public func method() -> Swift.Void {
        // ...
    }
}
```

Objects

Objects are translated to Swift classes with a private `init` and static `shared` accessor:

```
// Kotlin
object O
```

```
// Swift
public class O : KotlinRuntime.KotlinBase {
    public static var shared: O {
        get {
            // ...
        }
    }
    private override init() {
        // ...
    }
}
```

Type aliases

Kotlin type aliases are exported as is:

```
// Kotlin
typealias MyInt = Int
```

```
// Swift
public typealias MyInt = Swift.Int32
```

Enums

Kotlin `enum class` declarations are exported as regular native Swift `enum` types:

```
// Kotlin
enum class Color(val rgb: Int) {
    RED(0xFF0000),
    GREEN(0x00FF00),
    BLUE(0x0000FF)
}

val color = Color.RED
```

```
// Swift
public enum Color: Swift.CaseIterable, Swift.LosslessStringConvertible, Swift.RawRepresentable {
    case RED, GREEN, BLUE

    public var rgb: Swift.Int32 { get }
}
```

Sealed classes and interfaces

Sealed hierarchies defined in Kotlin are mapped to Swift enums, enabling exhaustive `switch` statements.

Swift export generates a `.sealedType()` method on each sealed type. This method returns a Swift enum whose cases match the direct subclasses of the sealed hierarchy. You can nest these calls to match deeper levels of the hierarchy.

For example, declare a sealed interface with a class hierarchy in Kotlin:

```kotlin
// Kotlin
sealed interface Shape

class Circle : Shape {
    override fun toString(): String = "Circle"
}

class Rectangle : Shape {
    override fun toString(): String = "Rectangle"
}

fun createCircle(): Shape = Circle()
```

On the Swift side, you can use an exhaustive `switch` without a `default` case:

```swift
// Swift
let shape = createCircle()

let name = switch shape.sealedType() {
    case let .circle(type): "It's a \(type.value)"
    case let .rectangle(type): "It's a \(type.value)"
}
// name == "It's a Circle"
```

Because the `switch` is exhaustive, the compiler warns you if a new subclass is added to the sealed hierarchy, so you can handle it immediately instead of relying on a `default` case for `switch`.

Functions

Swift export supports simple top-level functions and methods:

```kotlin
// Kotlin
fun foo(a: Short, b: Bar) {}

fun baz(): Long = 0
```

```swift
// Swift
public func foo(a: Swift.Int16, b: Bar) -> Swift.Void {
    // ...
}

public func baz() -> Swift.Int64 {
    // ...
}
```

For Kotlin's extension functions, the receiver parameter becomes an ordinary Swift parameter in the first position:

```kotlin
// Kotlin
fun Int.foo(): Unit = TODO()
```

```swift
// Swift
func foo(_ receiver: Int32) {}
```

Kotlin's functions with `vararg` are mapped to Swift's variadic function parameters:

```kotlin
// Kotlin
fun log(vararg messages: String)
```

```kotlin
// Swift
public func log(messages: Swift.String...)
```

- Support for functions with the `operator` modifier is currently limited.
- Generic types are generally not supported.

Properties

Kotlin properties are translated to Swift properties:

```kotlin
// Kotlin
val a: Int = 0

var b: Short = 15

const val c: Int = 0
```

```kotlin
// Swift
public var a: Swift.Int32 {
    get {
        // ...
    }
}
public var b: Swift.Int16 {
    get {
        // ...
    }
    set {
        // ...
    }
}
public var c: Swift.Int32 {
    get {
        // ...
    }
}
```

Constructors

Constructors are translated to Swift initializers:

```kotlin
// Kotlin
class Foo(val prop: Int)
```

```
// Swift
public class Foo : KotlinRuntime.KotlinBase {
    public init(
        prop: Swift.Int32
    ) {
        // ...
    }
}
```

Types

kotlin.Nothing

The Kotlin `Nothing` type is translated to the `Never` type:

```
// Kotlin
fun foo(): Nothing = TODO()

fun baz(input: Nothing) {}
```

```
// Swift
public func foo() -> Swift.Never {
    // ...
}

public func baz(input: Swift.Never) -> Void {
    // ...
}
```

Classifier types

Swift export currently supports only final classes that directly inherit from `Any`.

Packages

Kotlin packages are translated to nested Swift enums to avoid name collisions:

```
// Kotlin
// bar.kt file in foo.bar package
fun callMeMaybe() {}
```

```
// Kotlin
// baz.kt file in foo.baz package
fun callMeMaybe() {}
```

```swift
// Swift
public extension foo.bar {
    public func callMeMaybe() {}
}

public extension foo.baz {
    public func callMeMaybe() {}
}

public enum foo {
    public enum bar {}

    public enum baz {}
}
```

Concurrency

Suspending functions

You can call suspending Kotlin code from Swift. Kotlin suspending functions and suspending functional types are exported as Swift's `async` counterparts:

```kotlin
// Kotlin
suspend fun hello(): String {
    delay(1000)
    return "Hello Swift! This is Kotlin."
}
```

```swift
// Swift
let msg = try await hello()
```

Flows

You can also export `kotlinx.coroutines` flows as Swift's `AsyncSequence` :

```kotlin
// Kotlin
// Preserves the String type when exporting Flow
fun flowOfStrings(): Flow<String> = flowOf("hello", "any", "world")
```

```swift
// Swift
var actual: [String] = []

// Infers the String type from Kotlin
for try await element in flowOfStrings().asAsyncSequence() {
    actual.append(element)
}
```

Coroutine dispatchers

By default, when you call a Kotlin suspending function from Swift or use the `asAsyncSequence` function, Kotlin creates a coroutine context that uses the `Dispatchers.Default` dispatcher and executes the exported code there.

To run the exported code on a different dispatcher, use the `withContext()` function to switch the coroutine context in Kotlin. For example:

```
suspend fun runOnMain(): Int = withContext(Dispatchers.Main) {
    delay(10L)
    42
}
```

Cross-language inheritance

Swift export supports cross-language inheritance. A common use case for this feature is the reverse import pattern, where you define a contract in Kotlin and provide platform-specific implementations on the Swift side. This is especially useful when you need to use pure Swift libraries that can't be directly imported into Kotlin.

To implement the pattern, you need to declare a Kotlin interface and a Kotlin superclass that the Swift implementation can inherit from. You then implement the interface in Swift and pass the Swift object to Kotlin functions that accept that interface. For example, for the CryptoKit library:

1. On the Kotlin side, declare an interface, a function that accepts it, and an `open` base class:

   ```
   // Kotlin
   interface CryptoProvider {
       fun hashMD5(input: String): String
   }

   fun processHash(provider: CryptoProvider, input: String): String = provider.hashMD5(input)

   open class SwiftBase
   ```

2. On the Swift side, inherit from the exported `SwiftBase` class, implement the interface using a pure Swift library, and pass the object back to Kotlin:

   ```
   // Swift
   import CryptoKit

   final class IosCryptoProvider: SwiftBase, CryptoProvider {
       func hashMD5(input: String) -> String {
           guard let data = input.data(using: .utf8) else { return "failed" }
           return Insecure.MD5.hash(data: data).description
       }
   }

   let provider = IosCryptoProvider()

   // Calls the Kotlin function, which calls hashMD5() back in Swift
   print(processHash(provider: provider, input: "Hello, world!"))
   ```

When Kotlin receives the Swift object, it treats it like an implementation of a regular Kotlin interface, calling the Swift code directly.

Evolution of Swift export

We're planning to expand and gradually stabilize Swift export in future Kotlin releases, improving interoperability between Kotlin and Swift. You can leave your feedback:

- In Kotlin Slack – get an invite and join the #swift-export channel.

- Report issues in YouTrack.

Interoperability with C

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

This document covers general aspects of Kotlin's interoperability with C. Kotlin/Native comes with a cinterop tool, which you can use to quickly generate everything you need to interact with an external C library.

The tool analyzes C headers and produces a straightforward mapping of C types, functions, and strings into Kotlin. The generated stubs then can be imported into an IDE to enable code completion and navigation.

> Kotlin also provides interoperability with Objective-C. Objective-C libraries are imported through the cinterop tool as well. For more details, see Swift/Objective-C interop.

Setting up your project

Here's a general workflow when working with a project that needs to consume a C library:

1. Create and configure a definition file. It describes what the cinterop tool should include into Kotlin bindings.
2. Configure your Gradle build file to include cinterop in the build process.
3. Compile and run the project to produce the final executable.

> For a hands-on experience, complete the Create an app using C interop tutorial.

In many cases, there's no need to configure custom interoperability with a C library. Instead, you can use APIs available on the platform standardized bindings called platform libraries. For example, POSIX on Linux/macOS platforms, Win32 on the Windows platform, or Apple frameworks on macOS/iOS are available this way.

Bindings

Basic interop types

All the supported C types have corresponding representations in Kotlin:

- Signed, unsigned integral, and floating point types are mapped to their Kotlin counterpart with the same width.
- Pointers and arrays are mapped to `CPointer<T>?`.
- Enums can be mapped to either Kotlin enum or integral values, depending on heuristics and the definition file settings.
- Structs and unions are mapped to types having fields available via the dot notation, i.e. `someStructInstance.field1`.

- `typedef` are represented as `typealias`.

Also, any C type has the Kotlin type representing the lvalue of this type, i.e., the value located in memory rather than a simple immutable self-contained value. Think C++ references as a similar concept. For structs (and `typedef`s to structs), this representation is the main one and has the same name as the struct itself. For Kotlin enums, it's named `${type}.Var`; for `CPointer<T>`, it's `CPointerVar<T>`; and for most other types, it's `${type}Var`.

For types that have both representations, the one with the lvalue has a mutable `.value` property for accessing the value.

Pointer types

The type argument `T` of `CPointer<T>` must be one of the lvalue types described above. For example, the C type `struct S*` is mapped to `CPointer<S>`, `int8_t*` is mapped to `CPointer<int_8tVar>`, and `char**` is mapped to `CPointer<CPointerVar<ByteVar>>`.

C null pointer is represented as Kotlin's `null`, and the pointer type `CPointer<T>` is not nullable, but the `CPointer<T>?` is. The values of this type support all the Kotlin operations related to handling `null`, for example, `?:`, `?.`, `!!`, and so on:

```
val path = getenv("PATH")?.toKString() ?: ""
```

Since the arrays are also mapped to `CPointer<T>`, it supports the `[]` operator for accessing values by index:

```
import kotlinx.cinterop.*

@OptIn(ExperimentalForeignApi::class)
fun shift(ptr: CPointer<ByteVar>, length: Int) {
    for (index in 0 .. length - 2) {
        ptr[index] = ptr[index + 1]
    }
}
```

The `.pointed` property for `CPointer<T>` returns the lvalue of type `T`, pointed by this pointer. The reverse operation is `.ptr`, it takes the lvalue and returns the pointer to it.

`void*` is mapped to `COpaquePointer` – the special pointer type which is the supertype for any other pointer type. So if the C function takes `void*`, the Kotlin binding accepts any `CPointer`.

Casting a pointer (including `COpaquePointer`) can be done with `.reinterpret<T>`, for example:

```
import kotlinx.cinterop.*

@OptIn(ExperimentalForeignApi::class)
val intPtr = bytePtr.reinterpret<IntVar>()
```

Or:

```
import kotlinx.cinterop.*

@OptIn(ExperimentalForeignApi::class)
val intPtr: CPointer<IntVar> = bytePtr.reinterpret()
```

As is with C, these `.reinterpret` casts are unsafe and can potentially lead to subtle memory problems in the application.

Also, there are unsafe casts between `CPointer<T>?` and `Long` available, provided by the `.toLong()` and `.toCPointer<T>()` extension methods:

```
val longValue = ptr.toLong()
val originalPtr = longValue.toCPointer<T>()
```

> If the type of the result is known from the context, you can omit the type argument thanks to the type inference.

Memory allocation

The native memory can be allocated using the `NativePlacement` interface, for example:

```
@file:OptIn(ExperimentalForeignApi::class)
import kotlinx.cinterop.*

val placement: NativePlacement = // See below for placement examples
val byteVar = placement.alloc<ByteVar>()
val bytePtr = placement.allocArray<ByteVar>(5)
```

The most logical placement is in the object `nativeHeap`. It corresponds to allocating native memory with `malloc` and provides an additional `.free()` operation to free allocated memory:

```
@file:OptIn(ExperimentalForeignApi::class)
import kotlinx.cinterop.*

fun main() {
    val size: Long = 0
    val buffer = nativeHeap.allocArray<ByteVar>(size)
    nativeHeap.free(buffer)
}
```

`nativeHeap` requires memory to be freed manually. However, it's often useful to allocate memory with a lifetime bound to the lexical scope. It's helpful if such memory is freed automatically.

To address this, you can use `memScoped { }`. Inside the braces, the temporary placement is available as an implicit receiver, so it's possible to allocate native memory with alloc and allocArray, and the allocated memory will be automatically freed after leaving the scope.

For example, a C function returning values through pointer parameters can be used like:

```
@file:OptIn(ExperimentalForeignApi::class)
import kotlinx.cinterop.*
import platform.posix.*

val fileSize = memScoped {
    val statBuf = alloc<stat>()
    val error = stat("/", statBuf.ptr)
    statBuf.st_size
}
```

Pass pointers to bindings

Although C pointers are mapped to the `CPointer<T> type`, C function pointer-typed parameters are mapped to `CValuesRef<T>.` When passing a `CPointer<T>` as a value of such a parameter, it's passed to the C function as

is. However, a sequence of values can be passed instead of a pointer. In this case, the sequence is passed "by value", i.e., the C function receives the pointer to the temporary copy of that sequence, which is valid only until the function returns.

The `CValuesRef<T>` representation of pointer parameters is designed to support C array literals without explicit native memory allocation. To construct the immutable self-contained sequence of C values, the following methods are provided:

- `${type}Array.toCValues()`, where `type` is the Kotlin primitive type
- `Array<CPointer<T>?>.toCValues()`, `List<CPointer<T>?>.toCValues()`
- `cValuesOf(vararg elements: ${type})`, where `type` is a primitive or pointer

For example:

```
// C:
void foo(int* elements, int count);
...
int elements[] = {1, 2, 3};
foo(elements, 3);
```

```
// Kotlin:

foo(cValuesOf(1, 2, 3), 3)
```

Strings

Unlike other pointers, the parameters of type `const char*` are represented as a Kotlin `String`. So it's possible to pass any Kotlin string to a binding expecting a C string.

There are also some tools available to convert between Kotlin and C strings manually:

- `fun CPointer<ByteVar>.toKString(): String`
- `val String.cstr: CValuesRef<ByteVar>`.

To get the pointer, `.cstr` should be allocated in native memory, for example:

```
val cString = kotlinString.cstr.getPointer(nativeHeap)
```

In all cases, the C string is supposed to be encoded as UTF-8.

To skip automatic conversion and ensure raw pointers are used in the bindings, add the `noStringConversion` property to the `.def` file:

```
noStringConversion = LoadCursorA LoadCursorW
```

This way, any value of type `CPointer<ByteVar>` can be passed as an argument of `const char*` type. If a Kotlin string should be passed, code like this could be used:

```
import kotlinx.cinterop.*

@OptIn(kotlinx.cinterop.ExperimentalForeignApi::class)
memScoped {
    LoadCursorA(null, "cursor.bmp".cstr.ptr)  // for ASCII or UTF-8 version
    LoadCursorW(null, "cursor.bmp".wcstr.ptr) // for UTF-16 version
}
```

Scope-local pointers

It's possible to create a scope-stable pointer of C representation for the `CValues<T>` instance using the `CValues<T>.ptr` extension property, available under `memScoped {}`. It allows using APIs that require C pointers with a lifetime bound to a certain `MemScope`. For example:

```
import kotlinx.cinterop.*

@OptIn(kotlinx.cinterop.ExperimentalForeignApi::class)
memScoped {
    items = arrayOfNulls<CPointer<ITEM>?>(6)
    arrayOf("one", "two").forEachIndexed { index, value -> items[index] = value.cstr.ptr }
    menu = new_menu("Menu".cstr.ptr, items.toCValues().ptr)
    // ...
}
```

In this example, all values passed to the C API `new_menu()` have a lifetime of the innermost `memScope` it belongs to. Once the control flow leaves the `memScoped` scope, C pointers become invalid.

Pass and receive structs by value

When a C function takes or returns a struct/union `T` by value, the corresponding argument type or return type is represented as `CValue<T>`.

`CValue<T>` is an opaque type, so the structure fields cannot be accessed with the appropriate Kotlin properties. This can be fine if an API uses structures as opaque handles. However, if field access is required, the following conversion methods are available:

- `fun T.readValue(): CValue<T>` converts (the lvalue) `T` to a `CValue<T>`. So to construct the `CValue<T>`, `T` can be allocated, filled, and then converted to `CValue<T>`.
- `CValue<T>.useContents(block: T.() -> R): R` temporarily stores the `CValue<T>` in memory, and then runs the passed lambda with this placed value `T` as receiver. So to read a single field, you can use the following code:

  ```
  val fieldValue = structValue.useContents { field }
  ```

- `fun cValue(initialize: T.() -> Unit): CValue<T>` applies the provided `initialize` function to allocate `T` in memory and converts the result into a `CValue<T>`.
- `fun CValue<T>.copy(modify: T.() -> Unit): CValue<T>` creates a modified copy of an existing `CValue<T>`. The original value is placed in memory, altered using the `modify()` function, and then converted back into a new `CValue<T>`.
- `fun CValues<T>.placeTo(scope: AutofreeScope): CPointer<T>` places the `CValues<T>` into an `AutofreeScope`, returning a pointer to the allocated memory. The allocated memory is automatically freed when the `AutofreeScope` is disposed.

Callbacks

To convert a Kotlin function to a pointer to a C function, you can use `staticCFunction(::kotlinFunction)`. It's also possible to provide a lambda instead of a function reference. The function or lambda must not capture any values.

Pass user data to callbacks

Often C APIs allow passing some user data to callbacks. Such data is usually provided by the user when configuring the callback. It's passed to some C function (or written to the struct) as `void*`, for example. However, references to Kotlin objects can't be directly passed to C. So they require wrapping before configuring the callback and then unwrapping in the callback itself, to safely swim from Kotlin to Kotlin through the C world. Such wrapping is possible with the `StableRef` class.

To wrap the reference:

```
import kotlinx.cinterop.*

@OptIn(ExperimentalForeignApi::class)
val stableRef = StableRef.create(kotlinReference)
val voidPtr = stableRef.asCPointer()
```

Here, the `voidPtr` is a `COpaquePointer` and can be passed to the C function.

To unwrap the reference:

```
@OptIn(ExperimentalForeignApi::class)
val stableRef = voidPtr.asStableRef<KotlinClass>()
val kotlinReference = stableRef.get()
```

Here, `kotlinReference` is the original wrapped reference.

The created `StableRef` eventually be manually disposed using the `.dispose()` method to prevent memory leaks:

```
stableRef.dispose()
```

After that it becomes invalid, so `voidPtr` can't be unwrapped anymore.

Macros

Every C macro that expands to a constant is represented as a Kotlin property.

Macros without parameters are supported in cases when the compiler can infer the type:

```
int foo(int);
#define FOO foo(42)
```

In this case, `FOO` is available in Kotlin.

To support other macros, you can expose them manually by wrapping them with supported declarations. For example, function-like macro `FOO` can be exposed as a function `foo()` by adding custom declaration to the library:

```
headers = library/base.h

---

static inline int foo(int arg) {
    return FOO(arg);
}
```

Portability

Sometimes the C libraries have function parameters or struct fields of a platform-dependent type, for example, `long` or `size_t`. Kotlin itself doesn't provide either implicit integer casts or C-style integer casts (for example, `(size_t) intValue`), so to make writing portable code in such cases easier, the `convert` method is provided:

```
fun ${type1}.convert<${type2}>(): ${type2}
```

Here, each of `type1` and `type2` must be an integral type, either signed or unsigned.

`.convert<${type}>` has the same semantics as one of the `.toByte`, `.toShort`, `.toInt`, `.toLong`, `.toUByte`, `.toUShort`, `.toUInt` or `.toULong` methods, depending on `type`.

An example of using `convert`:

```
import kotlinx.cinterop.*
import platform.posix.*

@OptIn(ExperimentalForeignApi::class)
fun zeroMemory(buffer: COpaquePointer, size: Int) {
    memset(buffer, 0, size.convert<size_t>())
}
```

Also, the type parameter can be inferred automatically and so may be omitted in some cases.

Object pinning

Kotlin objects could be pinned, i.e. their position in memory is guaranteed to be stable until they are unpinned, and pointers to such objects' inner data could be passed to C functions.

There's a couple of approaches you can take:

- Use the `.usePinned()` extension function that pins an object, executes a block, and unpins it on normal and exception paths:

```
import kotlinx.cinterop.*
import platform.posix.*

@OptIn(ExperimentalForeignApi::class)
fun readData(fd: Int) {
    val buffer = ByteArray(1024)
    buffer.usePinned { pinned ->
        while (true) {
            val length = recv(fd, pinned.addressOf(0), buffer.size.convert(), 0).toInt()
            if (length <= 0) {
                break
            }
            // Now `buffer` has raw data obtained from the `recv()` call.
        }
    }
}
```

Here, `pinned` is an object of a special type `Pinned<T>`. It provides useful extensions like `.addressOf()`, which allows getting the address of a pinned array body.

- Use the `.refTo()` extension function that has similar functionality under the hood but, in certain cases, may help you reduce boilerplate code:

```
import kotlinx.cinterop.*
import platform.posix.*

@OptIn(ExperimentalForeignApi::class)
fun readData(fd: Int) {
    val buffer = ByteArray(1024)
    while (true) {
        val length = recv(fd, buffer.refTo(0), buffer.size.convert(), 0).toInt()

        if (length <= 0) {
            break
        }
        // Now `buffer` has raw data obtained from the `recv()` call.
    }
}
```

Here, `buffer.refTo(0)` has the `CValuesRef` type that pins the array before entering the `recv()` function, passes the address of its zeroth element to the function, and unpins the array after exiting.

Forward declarations

To import forward declarations, use the `cnames` package. For example, to import a `cstructName` forward declaration declared in a C library with a `library.package`, use a special forward declaration package: `import cnames.structs.cstructName`.

Consider two cinterop libraries: one that has a forward declaration of a struct and another with an actual implementation in another package:

```c
// First C library
#include <stdio.h>

struct ForwardDeclaredStruct;

void consumeStruct(struct ForwardDeclaredStruct* s) {
    printf("Struct consumed\n");
}
```

```c
// Second C library
// Header:
#include <stdlib.h>

struct ForwardDeclaredStruct {
    int data;
};

// Implementation:
struct ForwardDeclaredStruct* produceStruct() {
    struct ForwardDeclaredStruct* s = malloc(sizeof(struct ForwardDeclaredStruct));
    s->data = 42;
    return s;
}
```

To transfer objects between the two libraries, use an explicit `as` cast in your Kotlin code:

```
// Kotlin code:
fun test() {
    consumeStruct(produceStruct() as CPointer<cnames.structs.ForwardDeclaredStruct>)
}
```

What's next

Learn how types, functions, and strings are mapped between Kotlin and C by completing the following tutorials:

1. Mapping primitive data types from C
2. Mapping struct and union types from C
3. Mapping function pointers from C
4. Mapping strings from C

Start

Mapping primitive data types from C – tutorial

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

Let's explore which C data types are visible in Kotlin/Native and vice versa and examine advanced C interop-related use cases of Kotlin/Native and multiplatform Gradle builds.

In this tutorial, you'll:

- Learn about data types in the C language
- Create a C Library that uses those types in exports
- Inspect generated Kotlin APIs from a C library

You can use the command line to generate a Kotlin library, either directly or with a script file (such as `.sh` or `.bat` file). However, this approach doesn't scale well for larger projects that have hundreds of files and libraries. Using a build system simplifies the process by downloading and caching the Kotlin/Native compiler binaries and libraries with transitive dependencies, as well as by running the compiler and tests. Kotlin/Native can use the Gradle build system through the Kotlin Multiplatform plugin.

Types in C language

The C programming language has the following data types:

- Basic types: `char, int, float, double` with modifiers `signed, unsigned, short, long`
- Structures, unions, arrays
- Pointers
- Function pointers

There are also more specific types:

- Boolean type (from C99)
- `size_t` and `ptrdiff_t` (also `ssize_t`)
- Fixed width integer types, such as `int32_t` or `uint64_t` (from C99)

There are also the following type qualifiers in the C language: `const` , `volatile` , `restrict` , `atomic` .

Let's see which C data types are visible in Kotlin.

Create a C library

In this tutorial, you won't create a `lib.c` source file, which is only necessary if you want to compile and run your C library. For this setup, you'll only need a `.h` header file that is required for running the cinterop tool.

The cinterop tool generates a Kotlin/Native library (a `.klib` file) for each set of `.h` files. The generated library helps bridge calls from Kotlin/Native to C. It includes Kotlin declarations that correspond to the definitions from the `.h` files.

To create a C library:

1. Create an empty folder for your future project.
2. Inside, create a `lib.h` file with the following content to see how C functions are mapped into Kotlin:

```
#ifndef LIB2_H_INCLUDED
#define LIB2_H_INCLUDED

void ints(char c, short d, int e, long f);
void uints(unsigned char c, unsigned short d, unsigned int e, unsigned long f);
void doubles(float a, double b);

#endif
```

The file doesn't have the `extern "C"` block, which is not needed for this example but may be necessary if you use C++ and overloaded functions. See this Stackoverflow thread for more details.

3. Create the `lib.def` definition file with the following content:

```
headers = lib.h
```

4. It can be helpful to include macros or other C definitions in the code generated by the cinterop tool. This way, method bodies are also compiled and fully included in the binary. With this feature, you can create a runnable example without needing a C compiler.

   To do that, add implementations to the C functions from the `lib.h` file to a new `interop.def` file after the `---` separator:

```
---

void ints(char c, short d, int e, long f) { }
void uints(unsigned char c, unsigned short d, unsigned int e, unsigned long f) { }
void doubles(float a, double b) { }
```

The `interop.def` file provides everything necessary to compile, run, or open the application in an IDE.

Create a Kotlin/Native project

> See the Get started with Kotlin/Native tutorial for detailed first steps and instructions on how to create a new Kotlin/Native project and open it in IntelliJ IDEA.

To create project files:

1. In your project folder, create a `build.gradle(.kts)` Gradle build file with the following content:

Kotlin

```kotlin
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    kotlin("multiplatform") version "2.4.20"
}

repositories {
    mavenCentral()
}

kotlin {
    macosArm64()    // macOS on Apple Silicon
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // Windows on x86_64 platforms

    targets.withType<KotlinNativeTarget>().configureEach {
        val main by compilations.getting
        val interop by main.cinterops.creating

        binaries {
            executable()
        }
    }
}

tasks.wrapper {
    gradleVersion = "9.7.0"
    distributionType = Wrapper.DistributionType.BIN
}
```

Groovy

```
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}

repositories {
    mavenCentral()
}

kotlin {
    macosArm64()    // Apple Silicon macOS
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // Windows

    targets.withType(KotlinNativeTarget).configureEach {
        compilations.main.cinterops {
            interop
        }

        binaries {
            executable()
        }
    }
}

wrapper {
    gradleVersion = '9.7.0'
    distributionType = 'BIN'
}
```

The project file configures the C interop as an additional build step. Check out the Multiplatform Gradle DSL reference to learn about different ways you can configure it.

2. Move your `interop.def`, `lib.h`, and `lib.def` files to the `src/nativeInterop/cinterop` directory.
3. Create a `src/nativeMain/kotlin` directory. This is where you should place all the source files, following Gradle's recommendations on using conventions instead of configurations.

   By default, all the symbols from C are imported to the `interop` package.
4. In `src/nativeMain/kotlin`, create a `hello.kt` stub file with the following content:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    ints(/* fix me*/)
    uints(/* fix me*/)
    doubles(/* fix me*/)
}
```

You'll complete the code later as you learn how C primitive type declarations look from the Kotlin side.

Inspect generated Kotlin APIs for a C library

Let's see how C primitive types are mapped into Kotlin/Native and update the example project accordingly.

Use IntelliJ IDEA's Go to declaration command (Cmd + B/Ctrl + B) to navigate to the following generated API for C functions:

```
fun ints(c: kotlin.Byte, d: kotlin.Short, e: kotlin.Int, f: kotlin.Long)
fun uints(c: kotlin.UByte, d: kotlin.UShort, e: kotlin.UInt, f: kotlin.ULong)
fun doubles(a: kotlin.Float, b: kotlin.Double)
```

C types are mapped directly, except for the `char` type, which is mapped to `kotlin.Byte` as it's usually an 8-bit signed value:

C	Kotlin
char	kotlin.Byte
unsigned char	kotlin.UByte
short	kotlin.Short
unsigned short	kotlin.UShort
int	kotlin.Int
unsigned int	kotlin.UInt
long long	kotlin.Long
unsigned long long	kotlin.ULong
float	kotlin.Float
double	kotlin.Double

Update Kotlin code

Now that you've seen the C definitions, you can update your Kotlin code. The final code in the `hello.kt` file may look like this:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    ints(1, 2, 3, 4)
    uints(5u, 6u, 7u, 8u)
    doubles(9.0f, 10.0)
}
```

To verify that everything works as expected, run the `runDebugExecutable<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, in this example:

```
./gradlew runDebugExecutableMacosArm64
```

Next step

In the next part of the series, you'll learn how struct and union types are mapped between Kotlin and C:

- Next step

Mapping struct and union types from C – tutorial

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

Let's explore which C struct and union declarations are visible from Kotlin and examine advanced C interop-related use cases of Kotlin/Native and multiplatform Gradle builds.

In the tutorial, you'll learn:

- How struct and union types are mapped
- How to use struct and union types from Kotlin

Mapping struct and union C types

To understand how Kotlin maps struct and union types, let's declare them in C and examine how they are represented in Kotlin.

In the previous tutorial, you've already created a C library with the necessary files. For this step, update the declarations in the `interop.def` file after the `---` separator:

```
---

typedef struct {
  int a;
  double b;
} MyStruct;

void struct_by_value(MyStruct s) {}
void struct_by_pointer(MyStruct* s) {}

typedef union {
  int a;
  MyStruct b;
  float c;
} MyUnion;

void union_by_value(MyUnion u) {}
void union_by_pointer(MyUnion* u) {}
```

The `interop.def` file provides everything necessary to compile, run, or open the application in an IDE.

Inspect generated Kotlin APIs for a C library

Let's see how C struct and union types are mapped into Kotlin/Native and update your project:

1. In `src/nativeMain/kotlin`, update your `hello.kt` file from the previous tutorial with the following content:

   ```
   import interop.*
   import kotlinx.cinterop.ExperimentalForeignApi

   @OptIn(ExperimentalForeignApi::class)
   fun main() {
       println("Hello Kotlin/Native!")

       struct_by_value(/* fix me*/)
       struct_by_pointer(/* fix me*/)
       union_by_value(/* fix me*/)
       union_by_pointer(/* fix me*/)
   }
   ```

2. To avoid compiler errors, add interoperability to the build process. For that, update your `build.gradle(.kts)` build file with the following content:

Kotlin

```
kotlin {
    macosArm64()    // macOS on Apple Silicon
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // on Windows

    targets.withType<KotlinNativeTarget>().configureEach {
        val main by compilations.getting
        val interop by main.cinterops.creating {
            definitionFile.set(project.file("src/nativeInterop/cinterop/interop.def"))
        }

        binaries {
            executable()
        }
    }
}
```

Groovy

```
kotlin {
    macosArm64()    // Apple Silicon macOS
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // Windows

    targets.withType(KotlinNativeTarget).configureEach {
        compilations.main.cinterops {
            interop {
                definitionFile = project.file('src/nativeInterop/cinterop/interop.def')
            }
        }

        binaries {
            executable()
        }
    }
}
```

3. Use IntelliJ IDEA's Go to declaration command (Cmd + B/Ctrl + B) to navigate to the following generated API for C functions, struct, and union:

```
fun struct_by_value(s: kotlinx.cinterop.CValue<interop.MyStruct>)
fun struct_by_pointer(s: kotlinx.cinterop.CValuesRef<interop.MyStruct>?)

fun union_by_value(u: kotlinx.cinterop.CValue<interop.MyUnion>)
fun union_by_pointer(u: kotlinx.cinterop.CValuesRef<interop.MyUnion>?)
```

Technically, there is no difference between struct and union types on the Kotlin side. The cinterop tool generates Kotlin types for both struct and union C declarations.

The generated API includes fully qualified package names for `CValue<T>` and `CValuesRef<T>`, reflecting their location in `kotlinx.cinterop`. `CValue<T>` represents a by-value structure parameter, while `CValuesRef<T>?` is used to pass a pointer to a structure or a union.

Use struct and union types from Kotlin

Using C struct and union types from Kotlin is straightforward thanks to the generated API. The only question is how to create new instances of these types.

Let's take a look at the generated functions that take `MyStruct` and `MyUnion` as parameters. By-value parameters are represented as `kotlinx.cinterop.CValue<T>`, while pointer-typed parameters use `kotlinx.cinterop.CValuesRef<T>?`.

Kotlin provides a convenient API for creating and working with these types. Let's explore how to use it in practice.

Create a CValue<T>

`CValue<T>` type is used to pass by-value parameters to a C function call. Use the `cValue` function to create a `CValue<T>` instance. The function requires a lambda function with a receiver to initialize the underlying C type in-place. The function is declared as follows:

```
fun <reified T : CStructVar> cValue(initialize: T.() → Unit): CValue<T>
```

Here's how to use `cValue` and pass by-value parameters:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.cValue

@OptIn(ExperimentalForeignApi::class)
fun callValue() {

    val cStruct = cValue<MyStruct> {
        a = 42
        b = 3.14
    }
    struct_by_value(cStruct)

    val cUnion = cValue<MyUnion> {
        b.a = 5
        b.b = 2.7182
    }

    union_by_value(cUnion)
}
```

Create struct and union as CValuesRef<T>

The `CValuesRef<T>` type is used in Kotlin to pass a pointer-typed parameter of a C function. To allocate `MyStruct` and `MyUnion` in the native memory, use the following extension function on `kotlinx.cinterop.NativePlacement` type:

```
fun <reified T : kotlinx.cinterop.CVariable> alloc(): T
```

`NativePlacement` represents native memory with functions similar to `malloc` and `free`. There are several implementations of `NativePlacement`:

- The global implementation is `kotlinx.cinterop.nativeHeap`, but you must call `nativeHeap.free()` to release the memory after use.

- A safer alternative is `memScoped()`, which creates a short-lived memory scope where all allocations are automatically freed at the end of the block:

```
fun <R> memScoped(block: kotlinx.cinterop.MemScope.() → R): R
```

With `memScoped()`, your code for calling functions with pointers can look like this:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.memScoped
import kotlinx.cinterop.alloc
import kotlinx.cinterop.ptr

@OptIn(ExperimentalForeignApi::class)
fun callRef() {
    memScoped {
        val cStruct = alloc<MyStruct>()
        cStruct.a = 42
        cStruct.b = 3.14

        struct_by_pointer(cStruct.ptr)

        val cUnion = alloc<MyUnion>()
        cUnion.b.a = 5
        cUnion.b.b = 2.7182

        union_by_pointer(cUnion.ptr)
    }
}
```

Here, the `ptr` extension property, which is available within the `memScoped {}` block, converts `MyStruct` and `MyUnion` instances into native pointers.

Since memory is managed inside the `memScoped {}` block, it's automatically freed at the end of the block. Avoid using pointers outside of this scope to prevent accessing deallocated memory. If you need longer-lived allocations (for example, for caching in a C library), consider using `Arena()` or `nativeHeap`.

Conversion between CValue<T> and CValuesRef<T>

Sometimes you need to pass a struct as a value in one function call and then pass the same struct as a reference in another.

To do this, you'll need a `NativePlacement`, but first, let's see how `CValue<T>` is turned into a pointer:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.cValue
import kotlinx.cinterop.memScoped

@OptIn(ExperimentalForeignApi::class)
fun callMix_ref() {
    val cStruct = cValue<MyStruct> {
        a = 42
        b = 3.14
    }

    memScoped {
        struct_by_pointer(cStruct.ptr)
    }
}
```

Here again, the `ptr` extension property from `memScoped {}` turns `MyStruct` instances into native pointers. These pointers are only valid inside the `memScoped {}` block.

To turn a pointer back into a by-value variable, call the `.readValue()` extension function:

```
import interop.*
import kotlinx.cinterop.alloc
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.memScoped
import kotlinx.cinterop.readValue

@OptIn(ExperimentalForeignApi::class)
fun callMix_value() {
    memScoped {
        val cStruct = alloc<MyStruct>()
        cStruct.a = 42
        cStruct.b = 3.14

        struct_by_value(cStruct.readValue())
    }
}
```

Update Kotlin code

Now that you've learned how to use C declarations in Kotlin code, try to use them in your project. The final code in the `hello.kt` file may look like this:

```
import interop.*
import kotlinx.cinterop.alloc
import kotlinx.cinterop.cValue
import kotlinx.cinterop.memScoped
import kotlinx.cinterop.ptr
import kotlinx.cinterop.readValue
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    val cUnion = cValue<MyUnion> {
        b.a = 5
        b.b = 2.7182
    }

    memScoped {
        union_by_value(cUnion)
        union_by_pointer(cUnion.ptr)
    }

    memScoped {
        val cStruct = alloc<MyStruct> {
            a = 42
            b = 3.14
        }

        struct_by_value(cStruct.readValue())
        struct_by_pointer(cStruct.ptr)
    }
}
```

To verify that everything works as expected, run the `runDebugExecutable<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, in this example:

```
./gradlew runDebugExecutableMacosArm64
```

Next step

In the next part of the series, you'll learn how function pointers are mapped between Kotlin and C:

Mapping function pointers from C – tutorial

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

Let's explore which C function pointers are visible from Kotlin and examine advanced C interop-related use cases of Kotlin/Native and multiplatform Gradle builds.

In this tutorial, you'll:

- Learn how to pass Kotlin function as a C function pointer
- Use C function pointers from Kotlin

Mapping function pointer types from C

To understand the mapping between Kotlin and C, let's declare two functions: one that accepts a function pointer as a parameter and another that returns a function pointer.

In the first part of the series, you've already created a C library with the necessary files. For this step, update the declarations in the `interop.def` file after the `---` separator:

```
---

int myFun(int i) {
  return i+1;
}

typedef int  (*MyFun)(int);

void accept_fun(MyFun f) {
  f(42);
}

MyFun supply_fun() {
  return myFun;
}
```

The `interop.def` file provides everything necessary to compile, run, or open the application in an IDE.

Inspect generated Kotlin APIs for a C library

Let's see how C function pointers are mapped into Kotlin/Native and update your project:

1. In `src/nativeMain/kotlin`, update your `hello.kt` file from the previous tutorial with the following content:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    accept_fun(/* fix me*/)
    val useMe = supply_fun()
}
```

2. Use IntelliJ IDEA's Go to declaration command (Cmd + B/Ctrl + B) to navigate to the following generated API for C functions:

```
fun myFun(i: kotlin.Int): kotlin.Int
fun accept_fun(f: kotlinx.cinterop.CPointer<kotlinx.cinterop.CFunction<(kotlin.Int) →
kotlin.Int>>? /* from: interop.MyFun? */)
fun supply_fun(): kotlinx.cinterop.CPointer<kotlinx.cinterop.CFunction<(kotlin.Int) →
kotlin.Int>>? /* from: interop.MyFun? */
```

As you can see, C function pointers are represented in Kotlin using `CPointer<CFunction<...>>`. The `accept_fun()` function takes an optional function pointer as a parameter, while `supply_fun()` returns a function pointer.

`CFunction<(Int) -> Int>` represents the function signature, and `CPointer<CFunction<...>>?` represents a nullable function pointer. There is an `.invoke()` operator extension function available for all `CPointer<CFunction<...>>` types, allowing you to call function pointers as if they were regular Kotlin functions.

Pass Kotlin function as a C function pointer

It's time to try using C functions from Kotlin code. Call the `accept_fun()` function and pass the C function pointer to a Kotlin lambda:

```
import interop.*
import kotlinx.cinterop.staticCFunction
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun myFun() {
    accept_fun(staticCFunction<Int, Int> { it + 1 })
}
```

This call uses the `staticCFunction {}` helper function from Kotlin/Native to wrap a Kotlin lambda function into a C function pointer. It allows only unbound and non-capturing lambda functions. For example, it cannot capture a local variable from the function, only globally visible declarations.

Ensure that the function doesn't throw any exceptions. Throwing exceptions from a `staticCFunction {}` causes non-deterministic side effects.

Use the C function pointer from Kotlin

The next step is to invoke a C function pointer returned from the `supply_fun()` call:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.invoke

@OptIn(ExperimentalForeignApi::class)
fun myFun2() {
    val functionFromC = supply_fun() ?: error("No function is returned")

    functionFromC(42)
}
```

Kotlin turns the function pointer return type into a nullable `CPointer<CFunction<>>` object. You need to first explicitly check for `null`, which is why the Elvis operator is used in the code above. The cinterop tool allows you to call a C function pointer as a regular Kotlin function call: `functionFromC(42)`.

Update Kotlin code

Now that you've seen all the definitions, try to use them in your project. The code in the `hello.kt` file may look like this:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.invoke
import kotlinx.cinterop.staticCFunction

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    val cFunctionPointer = staticCFunction<Int, Int> { it + 1 }
    accept_fun(cFunctionPointer)

    val funFromC = supply_fun() ?: error("No function is returned")
    funFromC(42)
}
```

To verify that everything works as expected, run the `runDebugExecutable<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, in this example:

```
./gradlew runDebugExecutableMacosArm64
```

Next step

In the next part of the series, you'll learn how strings are mapped between Kotlin and C:

Previous step

Next step

See also

Learn more in the Interoperability with C documentation that covers more advanced scenarios.

Mapping strings from C – tutorial

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

In the final part of the series, let's see how to deal with C strings in Kotlin/Native.

In this tutorial, you'll learn how to:

- Pass a Kotlin string to C
- Read a C string in Kotlin
- Receive C string bytes into a Kotlin string

Working with C strings

C doesn't have a dedicated string type. Method signatures or documentation can help you identify whether a given `char *` represents a C string in a particular context.

Strings in the C language are null-terminated, so a trailing zero character `\0` is added to the end of a byte sequence to mark the end of a string. Usually, UTF-8 encoded strings are used. The UTF-8 encoding uses variable-width characters and is backward-compatible with ASCII. Kotlin/Native uses UTF-8 character encoding by default.

To understand how strings are mapped between Kotlin and C, first create the library headers. In the first part of the series, you've already created a C library with the necessary files. For this step:

1. Update your `lib.h` file with the following function declarations that work with C strings:

   ```
   #ifndef LIB2_H_INCLUDED
   #define LIB2_H_INCLUDED

   void pass_string(char* str);
   char* return_string();
   int copy_string(char* str, int size);

   #endif
   ```

   This example shows common ways to pass or receive a string in the C language. Handle the return value of the `return_string()` function carefully. Ensure you use the correct `free()` function to release the returned `char*`.

2. Update the declarations in the `interop.def` file after the `---` separator:

```
---

void pass_string(char* str) {
}

char* return_string() {
  return "C string";
}

int copy_string(char* str, int size) {
    *str++ = 'C';
    *str++ = ' ';
    *str++ = 'K';
    *str++ = '/';
    *str++ = 'N';
    *str++ = 0;
    return 0;
}
```

The `interop.def` file provides everything necessary to compile, run, or open the application in an IDE.

Inspect generated Kotlin APIs for a C library

Let's see how C string declarations are mapped into Kotlin/Native:

1. In `src/nativeMain/kotlin`, update your `hello.kt` file from the previous tutorial with the following content:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    pass_string(/*fix me*/)
    val useMe = return_string()
    val useMe2 = copy_string(/*fix me*/)
}
```

2. Use IntelliJ IDEA's Go to declaration command (Cmd + B/Ctrl + B) to navigate to the following generated API for C functions:

```
fun pass_string(str: kotlinx.cinterop.CValuesRef<kotlinx.cinterop.ByteVarOf<kotlin.Byte> /* from:
kotlinx.cinterop.ByteVar */>?)
fun return_string(): kotlinx.cinterop.CPointer<kotlinx.cinterop.ByteVarOf<kotlin.Byte> /* from:
kotlinx.cinterop.ByteVar */>?
fun copy_string(str: kotlinx.cinterop.CValuesRef<kotlinx.cinterop.ByteVarOf<kotlin.Byte> /* from:
kotlinx.cinterop.ByteVar */>?, size: kotlin.Int): kotlin.Int
```

These declarations are straightforward. In Kotlin, C `char *` pointers are mapped into `str: CValuesRef<ByteVarOf>?` for parameters and into `CPointer<ByteVarOf>?` for return types. Kotlin represents the `char` type as `kotlin.Byte`, as it's usually an 8-bit signed value.

In the generated Kotlin declarations, `str` is defined as `CValuesRef<ByteVarOf<Byte>>?`. Since this type is nullable, you can pass `null` as the argument value.

Pass Kotlin strings to C

Let's try to use the API from Kotlin. Call the `pass_string()` function first:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.cstr

@OptIn(ExperimentalForeignApi::class)
fun passStringToC() {
    val str = "This is a Kotlin string"
    pass_string(str.cstr)
}
```

Passing a Kotlin string to C is straightforward, thanks to the `String.cstr` extension property. There is also the `String.wcstr` property for cases that involve UTF-16 characters.

Read C strings in Kotlin

Now take a returned `char *` from the `return_string()` function and turn it into a Kotlin string:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.toKString

@OptIn(ExperimentalForeignApi::class)
fun passStringToC() {
    val stringFromC = return_string()?.toKString()

    println("Returned from C: $stringFromC")
}
```

Here, the `.toKString()` extension function converts a C string returned from the `return_string()` function into a Kotlin string.

Kotlin provides several extension functions for converting C `char *` strings into Kotlin strings, depending on the encoding:

```
fun CPointer<ByteVarOf<Byte>>.toKString(): String // Standard function for UTF-8 strings
fun CPointer<ByteVarOf<Byte>>.toKStringFromUtf8(): String // Explicitly converts UTF-8 strings
fun CPointer<ShortVarOf<Short>>.toKStringFromUtf16(): String // Converts UTF-16 encoded strings
fun CPointer<IntVarOf<Int>>.toKStringFromUtf32(): String // Converts UTF-32 encoded strings
```

Receive C string bytes from Kotlin

This time, use the `copy_string()` C function to write a C string to a given buffer. It takes two arguments: a pointer to the memory location where the string should be written and the allowed buffer size.

The function should also return something to indicate if it has succeeded or failed. Let's assume `0` means it succeeded, and the supplied buffer was big enough:

```
import interop.*
import kotlinx.cinterop.ExperimentalForeignApi
import kotlinx.cinterop.addressOf
import kotlinx.cinterop.usePinned

@OptIn(ExperimentalForeignApi::class)
fun sendString() {
    val buf = ByteArray(255)
    buf.usePinned { pinned ->
        if (copy_string(pinned.addressOf(0), buf.size - 1) != 0) {
            throw Error("Failed to read string from C")
        }
    }

    val copiedStringFromC = buf.decodeToString()
    println("Message from C: $copiedStringFromC")
}
```

Here, a native pointer is passed to the C function first. The `.usePinned()` extension function temporarily pins the native memory address of the byte array. The C function fills in the byte array with data. Another extension function, `ByteArray.decodeToString()`, turns the byte array into a Kotlin string, assuming UTF-8 encoding.

Update Kotlin code

Now that you've learned how to use C declarations in Kotlin code, try to use them in your project. The code in the final `hello.kt` file may look like this:

```
import interop.*
import kotlinx.cinterop.*

@OptIn(ExperimentalForeignApi::class)
fun main() {
    println("Hello Kotlin/Native!")

    val str = "This is a Kotlin string"
    pass_string(str.cstr)

    val useMe = return_string()?.toKString() ?: error("null pointer returned")
    println(useMe)

    val copyFromC = ByteArray(255).usePinned { pinned ->
        val useMe2 = copy_string(pinned.addressOf(0), pinned.get().size - 1)
        if (useMe2 != 0) throw Error("Failed to read a string from C")
        pinned.get().decodeToString()
    }

    println(copyFromC)
}
```

To verify that everything works as expected, run the `runDebugExecutable<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, in this example:

```
./gradlew runDebugExecutableMacosArm64
```

What's next

Learn more in the Interoperability with C documentation that covers more advanced scenarios.

Kotlin/Native as a dynamic library – tutorial

You can create dynamic libraries to use Kotlin code from existing programs. This enables code sharing across many platforms or languages, including JVM, Python, Android, and others.

> For iOS and other Apple targets, we recommend generating a framework. See the Kotlin/Native as an Apple framework tutorial.

You can use the Kotlin/Native code from existing native applications or libraries. For this, you need to compile the Kotlin code into a dynamic library in the `.so`, `.dylib`, or `.dll` format.

In this tutorial, you will:

- Compile Kotlin code to a dynamic library
- Examine generated C headers
- Use the Kotlin dynamic library from C
- Compile and run the project

You can use the command line to generate a Kotlin library, either directly or with a script file (such as `.sh` or `.bat` file). However, this approach doesn't scale well for larger projects that have hundreds of files and libraries. Using a build system simplifies the process by downloading and caching the Kotlin/Native compiler binaries and libraries with transitive dependencies, as well as by running the compiler and tests. Kotlin/Native can use the Gradle build system through the Kotlin Multiplatform plugin.

Let's examine the advanced C interop-related usages of Kotlin/Native and Kotlin Multiplatform builds with Gradle.

> If you use a Mac and want to create and run applications for macOS or other Apple targets, you also need to install the Xcode Command Line Tools, launch it, and accept the license terms first.

Create a Kotlin library

The Kotlin/Native compiler can produce a dynamic library from the Kotlin code. A dynamic library often comes with a `.h` header file, which you use to call the compiled code from C.

Let's create a Kotlin library and use it from a C program.

> See the Get started with Kotlin/Native tutorial for detailed first steps and instructions on how to create a new Kotlin/Native project and open it in IntelliJ IDEA.

1. Navigate to the `src/nativeMain/kotlin` directory and create the `lib.kt` file with the following library contents:

```
package example

object Object {
    val field = "A"
}

class Clazz {
    fun memberFunction(p: Int): ULong = 42UL
}

fun forIntegers(b: Byte, s: Short, i: UInt, l: Long) { }
fun forFloats(f: Float, d: Double) { }

fun strings(str: String) : String? {
    return "That is '$str' from C"
}

val globalString = "A global String"
```

2. Update your `build.gradle(.kts)` Gradle build file with the following:

Kotlin

```
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    kotlin("multiplatform") version "2.4.20"
}

repositories {
    mavenCentral()
}

kotlin {
    macosArm64()    // macOS on Apple Silicon
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // on Windows

    targets.withType<KotlinNativeTarget>().configureEach {
        binaries {
            sharedLib {
                baseName = "native"       // macOS
                // baseName = "native"    // Linux
                // baseName = "libnative" // Windows
            }
        }
    }
}

tasks.wrapper {
    gradleVersion = "9.7.0"
    distributionType = Wrapper.DistributionType.ALL
}
```

Groovy

```
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

plugins {
    id 'org.jetbrains.kotlin.multiplatform' version '2.4.20'
}

repositories {
    mavenCentral()
}

kotlin {
    macosArm64()    // Apple Silicon macOS
    // linuxArm64() // Linux on ARM64 platforms
    // linuxX64()   // Linux on x86_64 platforms
    // mingwX64()   // Windows

    targets.withType(KotlinNativeTarget).configureEach {
        binaries {
            sharedLib {
                baseName = "native"       // macOS
                // baseName = "native"    // Linux
                // baseName = "libnative" // Windows
            }
        }
    }
}

wrapper {
    gradleVersion = "9.7.0"
    distributionType = "ALL"
}
```

- The `binaries {}` block configures the project to generate a dynamic or shared library.
- `libnative` is used as the library name, the prefix for the generated header file name. It also prefixes all declarations in the header file.

3. To build the library, run the `linkDebugShared<YourTargetName>` Gradle task in your IDE or use the console command in your terminal, in this example:

```
./gradlew linkDebugSharedMacosArm64
```

The build generates the library into the `build/bin/<yourTargetName>/debugShared` directory with the following files:

- macOS: `libnative_api.h` and `libnative.dylib`
- Linux: `libnative_api.h` and `libnative.so`
- Windows: `libnative_api.h`, `libnative.def`, and `libnative.dll`

> You can also use the `linkNative` Gradle task to generate both `debug` and `release` variants of the library.

The Kotlin/Native compiler uses the same rules to generate the `.h` file for all platforms. Let's check out the C API of the Kotlin library.

Generated header file

Let's examine how Kotlin/Native declarations are mapped to C functions.

In the `build/bin/<yourTargetName>/debugShared` directory, open the `libnative_api.h` header file. The very first part contains the standard C/C++ header and footer:

```
#ifndef KONAN_LIBNATIVE_H
#define KONAN_LIBNATIVE_H
#ifdef __cplusplus
extern "C" {
#endif

/// The rest of the generated code

#ifdef __cplusplus
}  /* extern "C" */
#endif
#endif  /* KONAN_LIBNATIVE_H */
```

Following this, the `libnative_api.h` includes a block with the common type definitions:

```
#ifdef __cplusplus
typedef bool            libnative_KBoolean;
#else
typedef _Bool           libnative_KBoolean;
#endif
typedef unsigned short     libnative_KChar;
typedef signed char        libnative_KByte;
typedef short              libnative_KShort;
typedef int                libnative_KInt;
typedef long long          libnative_KLong;
typedef unsigned char      libnative_KUByte;
typedef unsigned short     libnative_KUShort;
typedef unsigned int       libnative_KUInt;
typedef unsigned long long libnative_KULong;
typedef float              libnative_KFloat;
typedef double             libnative_KDouble;
typedef float __attribute__ ((__vector_size__ (16))) libnative_KVector128;
typedef void*              libnative_KNativePtr;
```

Kotlin uses the `libnative_` prefix for all declarations in the created `libnative_api.h` file. Here's the complete list of type mappings:

Kotlin definition	C type
`libnative_KBoolean`	`bool` or `_Bool`
`libnative_KChar`	`unsigned short`
`libnative_KByte`	`signed char`

Kotlin definition	C type
`libnative_KShort`	`short`
`libnative_KInt`	`int`
`libnative_KLong`	`long long`
`libnative_KUByte`	`unsigned char`
`libnative_KUShort`	`unsigned short`
`libnative_KUInt`	`unsigned int`
`libnative_KULong`	`unsigned long long`
`libnative_KFloat`	`float`
`libnative_KDouble`	`double`
`libnative_KVector128`	`float __attribute__ ((__vector_size__ (16))`
`libnative_KNativePtr`	`void*`

The definition section of the `libnative_api.h` file shows how Kotlin primitive types are mapped to C primitive types. The Kotlin/Native compiler generates these entries automatically for every library. The reverse mapping is described in the Mapping primitive data types from C tutorial.

After the automatically generated type definitions, you'll find the separate type definitions used in your library:

```
struct libnative_KType;
typedef struct libnative_KType libnative_KType;

/// Automatically generated type definitions

typedef struct {
  libnative_KNativePtr pinned;
} libnative_kref_example_Object;
typedef struct {
  libnative_KNativePtr pinned;
} libnative_kref_example_Clazz;
```

In C, the `typedef struct { ... } TYPE_NAME` syntax declares the structure.

> See this StackOverflow thread for more explanations of this pattern.

As you can see from these definitions, Kotlin types are mapped using the same pattern: `Object` is mapped to `libnative_kref_example_Object`, and `Clazz` is mapped to `libnative_kref_example_Clazz`. All structs

contain nothing but the `pinned` field with a pointer. The field type `libnative_KNativePtr` is defined as `void*` earlier in the file.

Since C doesn't support namespaces, the Kotlin/Native compiler generates long names to avoid any possible clashes with other symbols in the existing native project.

Service runtime functions

The `libnative_ExportedSymbols` structure defines all the functions provided by Kotlin/Native and your library. It uses nested anonymous structures heavily to mimic packages. The `libnative_` prefix comes from the library name.

`libnative_ExportedSymbols` includes several helper functions in the header file:

```
typedef struct {
  /* Service functions. */
  void (*DisposeStablePointer)(libnative_KNativePtr ptr);
  void (*DisposeString)(const char* string);
```

These functions deal with Kotlin/Native objects. `DisposeStablePointer` is called to release a reference to a Kotlin object, and `DisposeString` is called to release a Kotlin string, which has the `char*` type in C.

The next part of the `libnative_api.h` file consists of structure declarations of runtime functions:

```
libnative_KBoolean (*IsInstance)(libnative_KNativePtr ref, const libnative_KType* type);
libnative_KBoolean (*IsInstance)(libnative_KNativePtr ref, const libnative_KType* type);
libnative_kref_kotlin_Byte (*createNullableByte)(libnative_KByte);
libnative_KByte (*getNonNullValueOfByte)(libnative_kref_kotlin_Byte);
libnative_kref_kotlin_Short (*createNullableShort)(libnative_KShort);
libnative_KShort (*getNonNullValueOfShort)(libnative_kref_kotlin_Short);
libnative_kref_kotlin_Int (*createNullableInt)(libnative_KInt);
libnative_KInt (*getNonNullValueOfInt)(libnative_kref_kotlin_Int);
libnative_kref_kotlin_Long (*createNullableLong)(libnative_KLong);
libnative_KLong (*getNonNullValueOfLong)(libnative_kref_kotlin_Long);
libnative_kref_kotlin_Float (*createNullableFloat)(libnative_KFloat);
libnative_KFloat (*getNonNullValueOfFloat)(libnative_kref_kotlin_Float);
libnative_kref_kotlin_Double (*createNullableDouble)(libnative_KDouble);
libnative_KDouble (*getNonNullValueOfDouble)(libnative_kref_kotlin_Double);
libnative_kref_kotlin_Char (*createNullableChar)(libnative_KChar);
libnative_KChar (*getNonNullValueOfChar)(libnative_kref_kotlin_Char);
libnative_kref_kotlin_Boolean (*createNullableBoolean)(libnative_KBoolean);
libnative_KBoolean (*getNonNullValueOfBoolean)(libnative_kref_kotlin_Boolean);
libnative_kref_kotlin_Unit (*createNullableUnit)(void);
libnative_kref_kotlin_UByte (*createNullableUByte)(libnative_KUByte);
libnative_KUByte (*getNonNullValueOfUByte)(libnative_kref_kotlin_UByte);
libnative_kref_kotlin_UShort (*createNullableUShort)(libnative_KUShort);
libnative_KUShort (*getNonNullValueOfUShort)(libnative_kref_kotlin_UShort);
libnative_kref_kotlin_UInt (*createNullableUInt)(libnative_KUInt);
libnative_KUInt (*getNonNullValueOfUInt)(libnative_kref_kotlin_UInt);
libnative_kref_kotlin_ULong (*createNullableULong)(libnative_KULong);
libnative_KULong (*getNonNullValueOfULong)(libnative_kref_kotlin_ULong);
```

You can use the `IsInstance` function to check if a Kotlin object (referenced with its `.pinned` pointer) is an instance of a type. The actual set of operations generated depends on actual usages.

> Kotlin/Native has its own garbage collector, but it doesn't manage Kotlin objects accessed from C. However, Kotlin/Native provides interoperability with Swift/Objective-C, and the garbage collector is integrated with Swift/Objective-C ARC.

Your library functions

Let's take a look at the separate structure declarations used in your library. The `libnative_kref_example` field mimics the package structure of your Kotlin code with a `libnative_kref.` prefix:

```
typedef struct {
  /* User functions. */
  struct {
    struct {
      struct {
        struct {
          libnative_KType* (*_type)(void);
          libnative_kref_example_Object (*_instance)();
          const char* (*get_field)(libnative_kref_example_Object thiz);
        } Object;
        struct {
          libnative_KType* (*_type)(void);
          libnative_kref_example_Clazz (*Clazz)();
          libnative_KULong (*memberFunction)(libnative_kref_example_Clazz thiz, libnative_KInt p);
        } Clazz;
        const char* (*get_globalString)();
        void (*forFloats)(libnative_KFloat f, libnative_KDouble d);
        void (*forIntegers)(libnative_KByte b, libnative_KShort s, libnative_KUInt i, libnative_KLong
l);
        const char* (*strings)(const char* str);
      } example;
    } root;
  } kotlin;
} libnative_ExportedSymbols;
```

The code uses anonymous structure declarations. Here, `struct { ... } foo` declares a field in the outer struct of the anonymous structure type, which has no name.

Since C doesn't support objects either, function pointers are used to mimic object semantics. A function pointer is declared as `RETURN_TYPE (* FIELD_NAME)(PARAMETERS)`.

The `libnative_kref_example_Clazz` field represents the `Clazz` from Kotlin. The `libnative_KULong` is accessible with the `memberFunction` field. The only difference is that the `memberFunction` accepts a `thiz` reference as the first parameter. Since C doesn't support objects, the `thiz` pointer is passed explicitly.

There is a constructor in the `Clazz` field (aka `libnative_kref_example_Clazz_Clazz`), which acts as the constructor function to create an instance of the `Clazz`.

The Kotlin `object Object` is accessible as `libnative_kref_example_Object`. The `_instance` function retrieves the only instance of the object.

Properties are translated into functions. The `get_` and `set_` prefixes name the getter and the setter functions, respectively. For example, the read-only property `globalString` from Kotlin is turned into a `get_globalString` function in C.

Global functions `forFloats`, `forIntegers`, and `strings` are turned into functions pointers in the `libnative_kref_example` anonymous struct.

Entry point

Now you know how the API is created, the initialization of the `libnative_ExportedSymbols` structure is the starting point. Let's then take a look at the final part of the `libnative_api.h`:

```
extern libnative_ExportedSymbols* libnative_symbols(void);
```

The `libnative_symbols` function allows you to open the gateway from the native code to the Kotlin/Native library. This is the entry point for accessing the library. The library name is used as a prefix for the function name.

> It might be necessary to host the returned `libnative_ExportedSymbols*` pointer per thread.

Use generated headers from C

Using the generated headers from C is straightforward. In the library directory, create the `main.c` file with the following code:

```
#include "libnative_api.h"
#include "stdio.h"

int main(int argc, char** argv) {
  // Obtain reference for calling Kotlin/Native functions
  libnative_ExportedSymbols* lib = libnative_symbols();

  lib->kotlin.root.example.forIntegers(1, 2, 3, 4);
  lib->kotlin.root.example.forFloats(1.0f, 2.0);

  // Use C and Kotlin/Native strings
  const char* str = "Hello from Native!";
  const char* response = lib->kotlin.root.example.strings(str);
  printf("in: %s\nout:%s\n", str, response);
  lib->DisposeString(response);

  // Create Kotlin object instance
  libnative_kref_example_Clazz newInstance = lib->kotlin.root.example.Clazz.Clazz();
  long x = lib->kotlin.root.example.Clazz.memberFunction(newInstance, 42);
  lib->DisposeStablePointer(newInstance.pinned);

  printf("DemoClazz returned %ld\n", x);

  return 0;
}
```

Compile and run the project

On macOS

To compile the C code and link it with the dynamic library, navigate to the library directory and run the following command:

```
clang main.c libnative.dylib
```

The compiler generates an executable called `a.out`. Run it to execute the Kotlin code from the C library.

On Linux

To compile the C code and link it with the dynamic library, navigate to the library directory and run the following command:

```
gcc main.c libnative.so
```

The compiler generates an executable called `a.out`. Run it to execute the Kotlin code from the C library. On Linux, you need to include `.` into the `LD_LIBRARY_PATH` to let the application know to load the `libnative.so` library from the current folder.

On Windows

First, you'll need to install a Microsoft Visual C++ compiler that supports the x64_64 target.

The easiest way to do this is to install Microsoft Visual Studio on a Windows machine. During installation, select the necessary components to work with C++, for example, **Desktop development with C++**.

On Windows, you can include dynamic libraries either by generating a static library wrapper or manually with the LoadLibrary or similar Win32API functions.

Let's use the first option and generate the static wrapper library for the `libnative.dll`:

1. Call `lib.exe` from the toolchain to generate the static library wrapper `libnative.lib` that automates the DLL usage from the code:

   ```
   lib /def:libnative.def /out:libnative.lib
   ```

2. Compile your `main.c` into an executable. Include the generated `libnative.lib` into the build command and start:

   ```
   cl.exe main.c libnative.lib
   ```

   The command produces the `main.exe` file, which you can run.

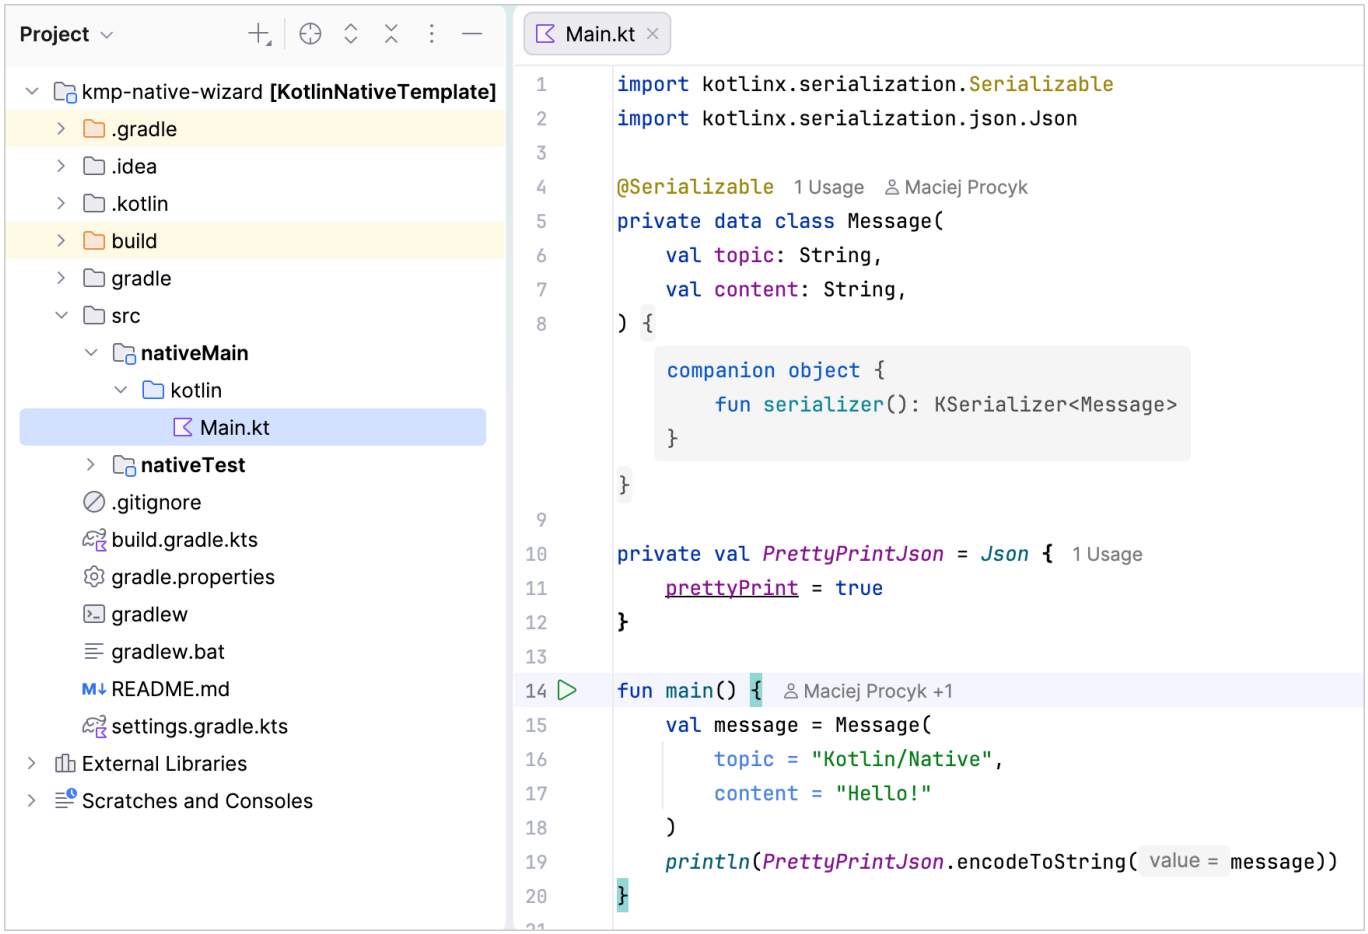
- Check out the Kotlin/Native as an Apple framework tutorial

Create an app using C interop and libcurl – tutorial

> The C libraries import is in Beta. All Kotlin declarations generated by the cinterop tool from C libraries should have the `@ExperimentalForeignApi` annotation.
>
> Native platform libraries shipped with Kotlin/Native (like Foundation, UIKit, and POSIX) require opt-in only for some APIs.

This tutorial demonstrates how to use IntelliJ IDEA to create a command-line application. You'll learn how to create a simple HTTP client that can run natively on specified platforms using Kotlin/Native and the libcurl library.

The output will be an executable command-line app that you can run on macOS and Linux and make simple HTTP GET requests.



You can use the command line to generate a Kotlin library, either directly or with a script file (such as `.sh` or `.bat` file). However, this approach doesn't scale well for larger projects that have hundreds of files and libraries. Using a build system simplifies the process by downloading and caching the Kotlin/Native compiler binaries and libraries with transitive dependencies, as well as by running the compiler and tests. Kotlin/Native can use the Gradle build system through the Kotlin Multiplatform plugin.

Before you start

1. Download and install the latest version of IntelliJ IDEA.
2. Clone the project template by selecting **File** | **New** | **Project from Version Control** in IntelliJ IDEA and using this URL:

   ```
   https://github.com/Kotlin/kmp-native-wizard
   ```

3. Explore the project structure:

Native application project structure

The template includes a project with the files and folders you need to get started. It's important to understand that an application written in Kotlin/Native can target different platforms if the code does not have platform-specific requirements. Your code is placed in the `nativeMain` directory with a corresponding `nativeTest`. For this tutorial, keep the folder structure as is.

4. Open the `build.gradle.kts` file, the build script that contains the project settings. Pay special attention to the following in the build file:

```
import org.jetbrains.kotlin.gradle.plugin.mpp.KotlinNativeTarget

kotlin {
    macosArm64()
    linuxArm64()
    linuxX64()
    mingwX64()

    targets.withType<KotlinNativeTarget>().configureEach {
        binaries {
            executable {
                entryPoint = "main"
            }
        }
    }
}
```

- Targets are defined using `macosArm64`, `linuxArm64`, `linuxX64`, and `mingwX64` for macOS, Linux, and Windows. See the complete list of supported platforms.
- The `binaries {}` block defines how the binary is generated and the entry point of the application. These can be left as default values.
- C interoperability is configured as an additional step in the build. By default, all the symbols from C are imported to the `interop` package. You may want to import the whole package in `.kt` files. Learn more about how to configure it.

Create a definition file

When writing native applications, you often need access to certain functionalities that are not included in the Kotlin standard library, such as making HTTP requests, reading and writing from disk, and so on.

Kotlin/Native helps consume standard C libraries, opening up an entire ecosystem of functionality that exists for pretty much anything you may need. Kotlin/Native is already shipped with a set of prebuilt platform libraries, which provide some additional common functionality to the standard library.

An ideal scenario for interop is to call C functions as if you are calling Kotlin functions, following the same signature and conventions. This is when the cinterop tool comes in handy. It takes a C library and generates the corresponding Kotlin bindings, so that the library can be used as if it were Kotlin code.

To generate these bindings, each library needs a definition file, usually with the same name as the library. This is a property file that describes exactly how the library should be consumed.

In this app, you'll need the libcurl library to make some HTTP calls. To create its definition file:

1. Select the `src` folder and create a new directory with **File | New | Directory**.
2. Name the new directory **nativeInterop/cinterop**. This is the default convention for header file locations, though it can be overridden in the `build.gradle.kts` file if you use a different location.
3. Select this new subfolder and create a new `libcurl.def` file with **File | New | File**.
4. Update your file with the following code:

```
headers = curl/curl.h
headerFilter = curl/*

compilerOpts.linux = -I/usr/include -I/usr/include/x86_64-linux-gnu
linkerOpts.osx = -L/opt/local/lib -L/usr/local/opt/curl/lib -lcurl
linkerOpts.linux = -L/usr/lib/x86_64-linux-gnu -lcurl
```

- `headers` is the list of header files to generate Kotlin stubs for. You can add multiple files here, separating each with a space. In this case, it's only `curl.h`. The referenced files need to be available on the specified path (in this case, it's `/usr/include/curl`).
- `headerFilter` shows what exactly is included. In C, all the headers are also included when one file references another one with the `#include` directive. Sometimes it's not necessary, and you can add this parameter using glob patterns to make adjustments.

  You can use `headerFilter` if you don't want to fetch external dependencies (such as system `stdint.h` header) into the interop library. Also, it may be useful for library size optimization and fixing potential conflicts between the system and the provided Kotlin/Native compilation environment.
- If the behavior for a certain platform needs to be modified, you can use a format like `compilerOpts.osx` or `compilerOpts.linux` to provide platform-specific values to the options. In this case, they are macOS (the `.osx` suffix) and Linux (the `.linux` suffix). Parameters without a suffix are also possible (for example, `linkerOpts=`) and applied to all platforms.

For the full list of available options, see Definition file.

> You need to have the `curl` library binaries on your system to make the sample work. On macOS and Linux, they are usually included. On Windows, you can build it from sources (you'll need Microsoft Visual Studio or Windows SDK command-line tools). For more details, see the related blog post. Alternatively, you may want to consider a MinGW/MSYS2 `curl` binary.

Add interoperability to the build process

To use header files, make sure they are generated as a part of the build process. For this, add the following `compilations {}` block to the `build.gradle.kts` file:

```
targets.withType<KotlinNativeTarget>().configureEach {
    compilations.getByName("main") {
        cinterops {
            val libcurl by creating
        }
    }
    binaries {
        executable {
            entryPoint = "main"
        }
    }
}
```

First, `cinterops` is added, and then an entry for a definition file. By default, the name of the file is used. You can override this with additional parameters:

```
cinterops {
    val libcurl by creating {
        definitionFile.set(project.file("src/nativeInterop/cinterop/libcurl.def"))
        packageName("com.jetbrains.handson.http")
        compilerOpts("-I/path")
        includeDirs.allHeaders("path")
    }
}
```

Write the application code

Now that you have the library and the corresponding Kotlin stubs, you can use them from your application. For this tutorial, convert the simple.c example to Kotlin.

In the `src/nativeMain/kotlin/` folder, update your `Main.kt` file with the following code:

```
import kotlinx.cinterop.*
import libcurl.*

@OptIn(ExperimentalForeignApi::class)
fun main(args: Array<String>) {
    val curl = curl_easy_init()
    if (curl != null) {
        curl_easy_setopt(curl, CURLOPT_URL, "https://example.com")
        curl_easy_setopt(curl, CURLOPT_FOLLOWLOCATION, 1L)
        val res = curl_easy_perform(curl)
        if (res != CURLE_OK) {
            println("curl_easy_perform() failed ${curl_easy_strerror(res)?.toKString()}")
        }
        curl_easy_cleanup(curl)
    }
}
```

As you can see, explicit variable declarations are eliminated in the Kotlin version, but everything else is pretty much the same as the C version. All the calls you'd expect in the libcurl library are available in the Kotlin equivalent.

> This is a line-by-line literal translation. You could also write this in a more Kotlin idiomatic way.

Compile and run the application

1. To compile the application, run the `runDebugExecutable<YourTargetName>` Gradle task from the task list or use the console command in your terminal, for example:

   ```
   ./gradlew runDebugExecutableMacosArm64
   ```

   In this case, the part generated by the cinterop tool is implicitly included in the build.

2. If there are no errors during compilation, click the green **Run** icon in the gutter next to the `main()` function or use the Shift + Cmd + R/Shift + F10 shortcut.

   IntelliJ IDEA opens the **Run** tab and shows the output — the contents of example.com:

```
    div {
        width: 600px;
        margin: 5em auto;
        padding: 2em;
        background-color: #fdfdff;
        border-radius: 0.5em;
        box-shadow: 2px 3px 7px 2px rgba(0,0,0,0.02);
    }
    a:link, a:visited {
        color: #38488f;
        text-decoration: none;
    }
    @media (max-width: 700px) {
        div {
            margin: 0 auto;
            width: auto;
        }
    }
    </style>
</head>

<body>
<div>
    <h1>Example Domain</h1>
    <p>This domain is for use in illustrative examples in documents. You may use this
    domain in literature without prior coordination or asking for permission.</p>
    <p><a href="https://www.iana.org/domains/example">More information...</a></p>
</div>
</body>
</html>
```

Application output with HTML-code

You can see the actual output because the call `curl_easy_perform` prints the result to the standard output. You could hide this using `curl_easy_setopt`.

You can get the full project code in our GitHub repository.

What's next

Learn more about Kotlin's interoperability with C.

Definition file

Kotlin/Native enables you to consume C and Objective-C libraries, allowing you to use their functionality in Kotlin. A special tool called cinterop takes a C or an Objective-C library and generates the corresponding Kotlin bindings, so that the library's methods can be used in your Kotlin code as usual.

To generate these bindings, each library needs a definition file, usually with the same name as the library. This is a property file that describes exactly how the library should be consumed. See the full list of available properties.

Here's a general workflow when working with a project:

1. Create a `.def` file describing what to include in the bindings.
2. Use the generated bindings in your Kotlin code.
3. Run the Kotlin/Native compiler to produce the final executable.

Create and configure a definition file

Let's create a definition file and generate bindings for a C library:

1. In your IDE, select the `src` folder and create a new directory with **File | New | Directory**.
2. Name the new directory `nativeInterop/cinterop`.

   This is the default convention for `.def` file locations, but it can be overridden in the `build.gradle.kts` file if you use a different location.
3. Select the new subfolder and create a `png.def` file with **File | New | File**.
4. Add the necessary properties:

   ```
   headers = png.h
   headerFilter = png.h
   package = png

   compilerOpts.linux = -I/usr/include -I/usr/include/x86_64-linux-gnu
   linkerOpts.osx = -L/opt/local/lib -L/usr/local/opt/png/lib -lpng
   linkerOpts.linux = -L/usr/lib/x86_64-linux-gnu -lpng
   ```

   - `headers` is the list of header files to generate Kotlin stubs for. You can add multiple files to this entry, separating each with a space. In this case, it's only `png.h`. The referenced files need to be available on the specified path (in this case, it's `/usr/include/png`).
   - `headerFilter` shows what exactly is included. In C, all the headers are also included when one file references another one with the `#include` directive. Sometimes it's not necessary, and you can add this parameter using glob patterns to make adjustments.

     You can use `headerFilter` if you don't want to fetch external dependencies (such as system `stdint.h` header) into the interop library. Also, it may be useful for library size optimization and fixing potential conflicts between the system and the provided Kotlin/Native compilation environment.
   - If the behavior for a certain platform needs to be modified, you can use a format like `compilerOpts.osx` or `compilerOpts.linux` to provide platform-specific values to the options. In this case, they are macOS (the `.osx` suffix) and Linux (the `.linux` suffix). Parameters without a suffix are also possible (for example, `linkerOpts=`) and applied to all platforms.
5. To generate bindings, synchronize the Gradle files by clicking **Sync Now** in the notification.

Synchronize the Gradle files

After the bindings generation, the IDE can use them as a proxy view of the native library.

> You can also configure bindings generation by using the cinterop tool in the command line.

Properties

Here's the full list of properties you can use in your definition file to adjust the content of the generated binaries. For more information, see the corresponding sections below.

Property	Description
`headers`	The list of headers from a library to be included in the bindings.
`modules`	The list of Clang modules from an Objective-C library to be included in the bindings.
`language`	Specifies the language. C is used by default; change to `Objective-C` if necessary.
`compilerOpts`	Compiler options that the cinterop tool passes to the C compiler.
`linkerOpts`	Linker options that the cinterop tool passes to the linker.
`excludedFunctions`	A space-separated list of function names that should be ignored.
`staticLibraries`	Experimental. Includes a static library into `.klib`.
`libraryPaths`	Experimental. A space-separated list of directories where the cinterop tool searches for the library to be included in `.klib`.
`package`	Package prefix for the generated Kotlin API.
`headerFilter`	Filters headers by globs and includes only them when importing a library.
`excludeFilter`	Excludes specific headers when importing a library and takes priority over `headerFilter`.
`strictEnums`	A space-separated list of enums that should be generated as Kotlin enums.
`nonStrictEnums`	A space-separated list of enums that should be generated as integral values.
`noStringConversion`	A space-separated list of functions whose `const char*` parameters should not be auto-converted to Kotlin `String`s.

Property	Description
`allowedOverloadsForCFunctions`	By default, it's assumed that C functions have unique names. If several functions have the same name, only one is picked. However, you can change this by specifying these functions in `allowedOverloadsForCFunctions`.
`disableDesignatedInitializerChecks`	Disables the compiler check that doesn't allow calling a non-designated Objective-C initializer as a `super()` constructor.
`foreignExceptionMode`	Wraps exceptions from Objective-C code into Kotlin exceptions with the `ForeignException` type.
`userSetupHint`	Adds a custom message, for example, to help users resolve linker errors.

In addition to the list of properties, you can include custom declarations in your definition file.

Import headers

If a C library does not have a Clang module and instead consists of a set of headers, use the `headers` property to specify headers that should be imported:

```
headers = curl/curl.h
```

Filter headers by globs

You can filter headers by globs using filter properties from the `.def` file. To include declarations from headers, use the `headerFilter` property. If a header matches any of the globs, its declarations are included in the bindings.

The globs are applied to the header paths relative to the appropriate include path elements, for example, `time.h` or `curl/curl.h`. So if the library is usually included with `#include <SomeLibrary/Header.h>`, you can probably filter headers with the following filter:

```
headerFilter = SomeLibrary/**
```

If `headerFilter` is not provided, all the headers are included. However, we encourage you to use `headerFilter` and specify the glob as precisely as possible. In this case, the generated library contains only the necessary declarations. It can help avoid various issues when upgrading Kotlin or tools in your development environment.

Exclude headers

To exclude specific headers, use the `excludeFilter` property. It can be helpful to remove redundant or problematic headers and optimize compilation, as declarations from the specified headers are not included in the bindings:

```
excludeFilter = SomeLibrary/time.h
```

If the same header is both included with `headerFilter`, and excluded with `excludeFilter`, the specified header will not be included in the bindings.

Import modules

If an Objective-C library has a Clang module, use the `modules` property to specify the module to be imported:

```
modules = UIKit
```

Set the package name

Use the `package` property to specify a package prefix for the generated Kotlin API:

```
package = png
```

If you don't specify this property, the compiler generates declarations in the root package.

The `kotlin` and `kotlinx.cinterop` names are reserved and can't be used as package prefixes.

Pass compiler and linker options

Use the `compilerOpts` property to pass options to the C compiler, which is used to analyze headers under the hood. To pass options to the linker, which is used to link final executables, use `linkerOpts`. For example:

```
compilerOpts = -DFOO=bar
linkerOpts = -lpng
```

You can also specify target-specific options that apply only to a certain target:

```
compilerOpts = -DBAR=bar
compilerOpts.linux_x64 = -DFOO=foo1
compilerOpts.macos_x64 = -DFOO=foo2
```

With this configuration, headers are analyzed using `-DBAR=bar -DFOO=foo1` on Linux and `-DBAR=bar -DFOO=foo2` on macOS. Note that any definition file option can have both common and platform-specific parts.

Ignore specific functions

Use the `excludedFunctions` property to specify a list of the function names that should be ignored. This can be useful if a function declared in the header isn't guaranteed to be callable, and it's difficult or impossible to determine this automatically. You can also use this property to work around a bug in the interop itself.

Experimental

Include a static library

Sometimes it's more convenient to ship a static library with your product, rather than assume it is available within the user's environment. To include a static library into `.klib`, use `staticLibrary` and `libraryPaths` properties:

```
headers = foo.h
staticLibraries = libfoo.a
libraryPaths = /opt/local/lib /usr/local/opt/curl/lib
```

When given the above snippet, the cinterop tool searches `libfoo.a` in `/opt/local/lib` and `/usr/local/opt/curl/lib`, and if found, includes the library binary in the `klib`.

When using a `klib` like this in your program, the library is linked automatically.

Configure enums generation

Use the `strictEnums` property to generate enums as Kotlin enums or `nonStrictEnums` to generate them as integral values. If an enum is not included in either of these lists, it is generated based on heuristics.

Set up string conversion

Use the `noStringConversion` property to disable automatic conversion of the `const char*` function parameters as Kotlin `String`s.

Allow calling a non-designated initializer

By default, the Kotlin/Native compiler doesn't allow calling a non-designated Objective-C initializer as a `super()` constructor. This behavior can be inconvenient if the designated Objective-C initializers aren't marked properly in the library. To disable these compiler checks, use the `disableDesignatedInitializerChecks` property.

Handle Objective-C exceptions

By default, the program crashes if Objective-C exceptions reach the Objective-C to Kotlin interop boundary and get to the Kotlin code.

To propagate Objective-C exceptions to Kotlin, enable wrapping with the `foreignExceptionMode = objc-wrap` property. In this case, Objective-C exceptions are translated into Kotlin exceptions that get the `ForeignException` type.

Help resolve linker errors

Linker errors might occur when a Kotlin library depends on C or Objective-C libraries, for example, using the CocoaPods integration. If dependent libraries aren't installed locally on the machine or configured explicitly in the project build script, the "Framework not found" error occurs.

If you're a library author, you can help your users resolve linker errors with custom messages. To do that, add a `userSetupHint=message` property to your `.def` file or pass the `-Xuser-setup-hint` compiler option to `cinterop`.

Add custom declarations

Sometimes it is required to add custom C declarations to the library before generating bindings (for example, for macros). Instead of creating an additional header file with these declarations, you can include them directly to the end of the `.def` file, after a separating line, containing only the separator sequence `---`:

```
headers = errno.h
---

static inline int getErrno() {
    return errno;
}
```

Note that this part of the `.def` file is treated as part of the header file, so functions with the body should be declared as `static`. The declarations are parsed after including the files from the `headers` list.

Generate bindings using command line

In addition to the definition file, you can specify what to include in bindings by passing the corresponding properties as options in the `cinterop` call.

Here's an example of the command that produces a `png.klib` compiled library:

```
cinterop -def png.def -compiler-option -I/usr/local/include -o png
```

Note that the generated bindings are generally platform-specific, so if you are developing for multiple targets, the bindings need to be regenerated.

- For host libraries that are not included in the sysroot search paths, headers may be needed.
- For a typical UNIX library with a configuration script, the `compilerOpts` will likely contain the output of a configuration script with the `--cflags` option (maybe without exact paths).
- The output of a configuration script with `--libs` can be passed to the `linkerOpts` property.

What's next

- Bindings for C-interoperability
- Interoperability with Swift/Objective-C

C, Objective-C, and Swift library import

Kotlin/Native provides the ability to import C and Objective-C libraries. You can also work around importing pure Swift libraries into your Kotlin/Native projects.

Beta

Stability of C and Objective-C library import

Support for importing C and Objective-C libraries is currently in Beta.

One of the main reasons for the Beta status is that using C and Objective-C libraries might affect the compatibility of your code with different versions of Kotlin, dependencies, and Xcode. This guide lists compatibility problems that happen often in practice, problems that occur only in some cases, and hypothetical potential issues as well.

For simplicity, we divide C and Objective-C libraries, or *native libraries* here into:

- Platform libraries, which Kotlin provides by default to access the "system" native libraries on each platform.

- Third-party libraries, all other native libraries that require additional configuration for Kotlin use.

These two kinds of native libraries have different compatibility specifics.

Platform libraries

Platform libraries are shipped with the Kotlin/Native compiler. So, using different versions of Kotlin in the project results in getting different versions of platform libraries. For Apple targets (like iOS), platform libraries are generated based on the Xcode version supported by the particular compiler version.

Native library APIs shipped with Xcode SDKs change with every Xcode version. Even when such changes are source- and binary-compatible within the native language, they might become breaking for Kotlin due to the interoperability implementation.

As a result, updating the Kotlin version in a project might bring a breaking change in platform libraries. This might matter in two cases:

- There is a source breaking change in platform libraries that affects the compilation of the source code in your project. Usually, it's easy to fix.
- There is a binary breaking change in platform libraries that affects some of your dependencies. There is typically no easy workaround, and you'll need to wait until the library developer fixes this on their side, for example, by updating the Kotlin version.

> Such binary incompatibilities manifest as linkage warnings and runtime exceptions. If you prefer to detect them at compilation time, raise warnings to errors with the `-Xpartial-linkage-loglevel=ERROR` compiler option.

When the JetBrains team updates the Xcode version used to generate the platform libraries, it makes a reasonable effort to avoid breaking changes in platform libraries. Whenever a breaking change might occur, the team conducts impact analysis, and either decides to ignore a particular change (because the affected API is not commonly used) or applies an ad hoc fix.

Another potential reason for breaking changes in platform libraries is changes in the algorithm that translates native APIs to Kotlin. The JetBrains team makes reasonable efforts to avoid breaking changes in such cases as well.

Using new Objective-C classes from platform libraries

The Kotlin compiler doesn't prevent you from using Objective-C classes that are not available with your deployment target.

For example, if your deployment target is iOS 17.0, and you use a class that appeared only in iOS 18.0, the compiler doesn't warn you, and your application might crash during launch on a device with iOS 17.0. Moreover, such a crash happens even when the execution never reaches those usages, so guarding them with version checks is not enough.

For more details, see Strong linking.

Third-party libraries

Apart from system platform libraries, Kotlin/Native allows importing third-party native libraries. For example, you can use CocoaPods integration or set up a cinterops configuration.

Importing libraries with mismatched Xcode version

Importing third-party native libraries can lead to compatibility issues with different Xcode versions.

When processing a native library, the compiler typically uses header files from the locally installed Xcode because almost all native library headers import "standard" headers (for example, `stdint.h`) that come from Xcode.

That's why the Xcode version affects the import of native libraries to Kotlin. This is also one of the reasons why cross-compilation of Apple targets from a non-Mac host is still impossible when using third-party native libraries.

Every Kotlin version is compatible the most with a single Xcode version. This is the recommended version, which is tested the most against the corresponding Kotlin version. Check the compatibility with a particular Xcode version in the compatibility table.

Using newer or older Xcode versions is often possible but might lead to problems, usually affecting the import of third-party native libraries.

Xcode version is newer than recommended

Using an Xcode version newer than recommended might break some Kotlin features. Importing third-party native libraries is most affected by this . It often doesn't work at all with an unsupported version of Xcode.

Xcode version is older than recommended

Typically, Kotlin works well with older Xcode versions. There might be occasional issues that most often result in:

- The Kotlin API referring to a non-existent type as in KT-71694.
- A type from a system library is included in the Kotlin API of the native library. In this case, the project compiles successfully, but a system native type is added to your native library package. For example, you can then see this type unexpectedly in IDE autocompletion.

If your Kotlin library successfully compiles with an older Xcode version, it's safe to publish unless you use types from a third-party library in your Kotlin library API.

Using a transitive third-party native dependency

When a Kotlin library in your project imports a third-party native library as part of its implementation, your project also gets access to that native library. This happens because Kotlin/Native doesn't distinguish between `api` and `implementation` dependency types, so native libraries always end up being `api` dependencies.

Using such a transitive native dependency is prone to more compatibility issues. For example, a change made by the Kotlin library developer might make the Kotlin representation of the native library incompatible, leading to compatibility issues when you update the Kotlin library.

So, instead of relying on a transitive dependency, configure interoperability with the same native library directly. To do that, use another package name for the native library, similar to using custom package name to prevent compatibility issues.

Using native types in library API

If you publish a Kotlin library, be careful with native types in your library API. Such usages are expected to be broken in the future to fix compatibility and other issues, which will affect your library users.

There are cases when using native types in a library API is necessary because it's required for the library's purpose, for example, when a Kotlin library basically provides extensions to the native library. If that's not your case, avoid or limit using native types in the library API.

This recommendation only applies to usages of native types in library APIs and is not related to the application code. It also doesn't apply to library implementations, for example:

```
// Be extra careful! Native types are used in the library API:
public fun createUIView(): UIView
public fun handleThirdPartyNativeType(c: ThirdPartyNativeType)

// Be careful as usual; native types are not used in the library API:
internal fun createUIViewController(): UIViewController
public fun getDate(): String = NSDate().toString()
```

Publishing a library that uses third-party library

If you publish a Kotlin library that uses third-party native libraries, there are a few things you can do to avoid compatibility issues.

Use custom package name

Using custom package names for third-party native libraries might help prevent compatibility issues.

When a native library is imported to Kotlin, it gets a Kotlin package name. If it's not unique, library users might get a clash. For example, if a native library is imported with the same package name elsewhere in the user's project or other dependencies, those two usages will clash.

In such a case, the compilation might fail with the `Linking globals named '...': symbol multiply defined!` error. However, there might be other errors or even a successful compilation.

To use a custom name for third-party native libraries:

- When importing a native library through the CocoaPods integration, use the `packageName` property in the `pod {}` block of your Gradle build script.
- When importing a native library with a `cinterops` configuration, use the `packageName` property in the configuration block.

Check compatibility with older Kotlin versions

When publishing a Kotlin library, the usage of a third-party native library might affect library compatibility with other Kotlin versions, specifically:

- Kotlin Multiplatform libraries don't guarantee forward compatibility (when an older compiler can use a library compiled with a newer compiler).

  In practice, it works in some cases; however, using native libraries might further limit forward compatibility.

- Kotlin Multiplatform libraries provide backward compatibility (when a newer compiler can use libraries produced with an older version).

  Using a native library in the Kotlin library normally shouldn't affect its backward compatibility. But it opens the possibility of more compiler bugs affecting compatibility.

Avoid embedding static libraries

When importing a native library, it's possible to include the associated static library (`.a` file) using the `-staticLibrary` compiler option or the `staticLibraries` property in a `.def` file. In that case, your library users don't need to deal with native dependencies and linker options.

However, it's impossible to configure the usage of the included static library in any way: neither exclude nor replace (substitute) it. So, users won't be able to resolve potential clashes with other Kotlin libraries that include the same static library or adjust its version.

Evolution of native library support

Currently, using C and Objective-C in Kotlin projects can lead to compatibility issues; some of which are listed in this guide. To fix them, some breaking changes might be necessary in the future, which itself contributes to the compatibility problem.

Swift library import

Kotlin/Native does not support direct import of pure Swift libraries. However, there are a couple of options to work around that.

One way is to use manual Objective-C bridging. With this approach, you need to write custom Objective-C wrappers and `.def` files and consume those wrappers through cinterop.

In most cases, however, we recommend using the *reverse import* approach: you define the expected behavior on the Kotlin side, implement the actual functionality on the Swift side, and pass it back to Kotlin.

You can define the expected part in one of the following ways:

- Create an interface. The interface-based approach scales better for multiple functions and testability.
- Use Swift closures. They are great for quick prototypes, but this approach has its limitations — for example, it doesn't hold state.
- Use Swift export. You can implement a Kotlin interface directly in Swift and pass the Swift object back to Kotlin, without Objective-C bridging.

Consider this example of reverse importing the CryptoKit Swift library into a Kotlin project:

1. On the Kotlin side, create an interface to describe what Kotlin expects from Swift:

   Interface

   ```
   // CryptoProvider.kt
   interface CryptoProvider {
       fun hashMD5(input: String): String
   }
   ```

2. On the Kotlin side, pass the platform-specific implementation from `MainViewController` to the `App` composable as a parameter and use it where needed:

   ```
   // App.kt
   @Composable
   fun App(cryptoProvider: CryptoProvider) {
       // Example usage inside your UI
       val hashed = cryptoProvider.hashMD5("Hello, world!")
       androidx.compose.material3.Text("Compose: $hashed")
   }
   ```

```
// MainViewController.kt
fun MainViewController(cryptoProvider: CryptoProvider) = ComposeUIViewController {
    App(cryptoProvider)
}
```

3. On the Swift side, implement the MD5-hashing functionality using a pure Swift library, CryptoKit:

```
// iosApp/ContentView.swift
import CryptoKit

class IosCryptoProvider: CryptoProvider {
    func hashMD5(input: String) -> String {
        guard let data = input.data(using: .utf8) else { return "failed" }
        return Insecure.MD5.hash(data: data).description
    }
}
```

4. Pass the Swift implementation to the Kotlin component:

```
// iosApp/ContentView.swift
struct ComposeView: UIViewControllerRepresentable {
    func makeUIViewController(context: Context) -> UIViewController {
        // Inject the Swift implementation into the Kotlin UI entry point
        MainViewControllerKt.MainViewController(cryptoProvider: IosCryptoProvider())
    }

    func updateUIViewController(_ uiViewController: UIViewController, context: Context) {}
}
```

1. On the Kotlin side, declare a function parameter and use it where needed:

Swift closures

```
// App.kt
@Composable
fun App(md5Hasher: (String) -> String) {
    // Example usage inside your UI
    val hashed = md5Hasher("Hello, world!")
    androidx.compose.material3.Text("Compose: $hashed")
}
```

```
// MainViewController.kt
fun MainViewController(md5Hasher: (String) -> String) = ComposeUIViewController {
    App(md5Hasher)
}
```

2. On the Swift side, build the MD5 hasher with the CryptoKit library and pass it as a closure:

```swift
// iosApp/ContentView.swift
import CryptoKit
import SwiftUI

struct ComposeView: UIViewControllerRepresentable {
    func makeUIViewController(context: Context) -> UIViewController {
        MainViewControllerKt.MainViewController(md5Hasher: { input in
            guard let data = input.data(using: .utf8) else { return "failed" }
            return Insecure.MD5.hash(data: data).description
        })
    }

    func updateUIViewController(_ uiViewController: UIViewController, context: Context) {}
}
```

1. On the Kotlin side, declare an interface, a function that accepts it, and an `open` base class that the Swift implementation can inherit from:

Swift export

```kotlin
// CryptoProvider.kt
interface CryptoProvider {
    fun hashMD5(input: String): String
}

fun processHash(provider: CryptoProvider, input: String): String = provider.hashMD5(input)

open class SwiftBase
```

2. On the Swift side, inherit from the exported `SwiftBase` class, implement the interface using the pure Swift CryptoKit library, and pass the object back to Kotlin:

```swift
// iosApp/ContentView.swift
import CryptoKit

final class IosCryptoProvider: SwiftBase, CryptoProvider {
    func hashMD5(input: String) -> String {
        guard let data = input.data(using: .utf8) else { return "failed" }
        return Insecure.MD5.hash(data: data).description
    }
}

let provider = IosCryptoProvider()

// Calls the Kotlin function, which calls hashMD5() back in Swift
print(processHash(provider: provider, input: "Hello, world!"))
```

When Kotlin receives the Swift object, it treats it like an implementation of a regular Kotlin interface, calling the Swift code directly.

In a more complex project, it's more convenient to use dependency injection to pass the Swift implementation back to Kotlin. For more information, see Dependency injection framework or check out the Koin framework documentation.

Kotlin AI skills

Kotlin AI skills are reusable instructions that help AI agents perform Kotlin-specific tasks more reliably.

A skill gives an AI agent the context it needs before it starts executing a task. For example, a skill can point to a relevant API, define prerequisites, or provide step-by-step workflow guidance.

Kotlin AI skills help agents produce more accurate results and reduce the time you spend explaining the task yourself. For teams, skills also provide a shared framework for common tasks, so everyone gets consistent results.

Explore Kotlin AI skills

Kotlin AI skills follow the Agent Skills standard, so you can use them with compatible AI agents, for example, Junie, Claude Code, OpenAI Codex, Google Gemini, and GitHub Copilot.

Supported workflows

You can use Kotlin AI skills for different Kotlin-specific scenarios. The following examples show some of the tasks that AI skills can help you with.

Convert Java source files to Kotlin

Use the kotlin-tooling-java-to-kotlin skill when you want to convert your Java source files to idiomatic Kotlin while preserving behavior and applying Kotlin-specific conventions.

Learn more about this scenario in Convert Java files to Kotlin.

Migrate multiplatform projects with Android apps to use AGP 9

Use the kotlin-tooling-agp9-migration skill when your Kotlin Multiplatform project needs to migrate to AGP 9, and you want an AI agent to apply the required project and Gradle configuration changes.

Learn more about this scenario in Update multiplatform projects with Android apps to use AGP 9.

Migrate multiplatform projects from CocoaPods to SwiftPM dependencies

Use the kotlin-tooling-cocoapods-spm-migration when your Kotlin Multiplatform project uses CocoaPods for iOS integration, and you want an AI agent to move the setup to SwiftPM.

Learn more about this scenario in Migrate multiplatform projects from CocoaPods to SwiftPM dependencies.

Get support

If you have questions or encounter problems, ask for help in Slack: get an invite and share your experience in the `#ai` channel.

Kotlin for AI-powered app development

Kotlin provides a modern and pragmatic foundation for building AI-powered applications.
It can be used across platforms, integrates well with established AI frameworks, and supports common AI development patterns.

Koog

Koog is an open-source framework from JetBrains for building AI agents, from simple to complex. It provides multiplatform support, Spring Boot and Ktor integrations, an idiomatic DSL, and production-ready features out of the box.

Create a simple agent in a few lines

```
fun main() {
    runBlocking {
        val agent = AIAgent(
            // Use Anthropic, Google, OpenRouter, or any other provider
            executor = simpleOpenAIExecutor(System.getenv("OPENAI_API_KEY")),
            systemPrompt = "You are a helpful assistant. Answer user questions concisely.",
            llmModel = OpenAIModels.Chat.GPT4o
        )

        val result = agent.run("Hello! How can you help me?")
        println(result)
    }
}
```

Get started with Koog

Key features

- **Support for multiplatform development**. Multiplatform support enables agentic application development for the JVM, JavaScript, WebAssembly, Android, and iOS.
- **Reliability and fault-tolerance**. With built-in retries, Koog lets developers handle failures such as timeouts or tool errors. Agent persistence makes it possible to restore full agent state machines instead of just chat messages.
- **Built-in history compression techniques for long contexts**. Koog comes with advanced strategies to compress and manage long-running conversations without extra setup.
- **Enterprise-ready integrations**. Koog integrates with popular JVM frameworks like Spring Boot and Ktor.
- **Observability with OpenTelemetry exporters**. Koog offers ready-to-use integration with popular observability providers such as W&B Weave and Langfuse for monitoring and debugging AI applications.
- **LLM switching and seamless history adaptation**. Koog allows switching to a different LLM with a new set of tools at any point, without losing the existing conversation history. It also enables rerouting between multiple LLM providers, including OpenAI, Anthropic, Google, and others. You can run agents locally with local models through Koog's integration with Ollama.
- **Integration with JVM and Kotlin applications**. Koog provides an idiomatic, type-safe DSL specifically for the JVM and Kotlin developers.
- **Model Context Protocol (MCP) integration**. Koog enables the use of MCP tools in agents.
- **Knowledge retrieval and memory**. With embeddings, ranked document storage, and shared agent memory, Koog itself actively retains knowledge across conversations.
- **Streaming capabilities**. Koog lets developers process responses in real-time with streaming support and parallel tool calls.

Where to start

- Explore Koog capabilities in the Overview.
- Build your first Koog agent with the Quickstart guide.
- See the latest updates in the Koog release notes.
- Learn from the examples.

Model Context Protocol (MCP) Kotlin SDK

The MCP Kotlin SDK is a Kotlin Multiplatform implementation of the Model Context Protocol. The SDK lets developers build AI-powered applications in Kotlin and integrate with LLM surfaces across the JVM, WebAssembly, and iOS.

With the MCP Kotlin SDK, you can:

- Provide context to LLMs in a structured and standardized way by separating context handling from LLM interaction.
- Build MCP clients that consume resources from existing servers.
- Create MCP servers that expose prompts, tools, and resources to LLMs.
- Use standard communication transports such as stdio, SSE, and WebSocket.
- Handle all MCP protocol messages and lifecycle events.

Explore other AI-powered application scenarios

Thanks to seamless Java interoperability and Kotlin Multiplatform, you can combine Kotlin with established AI SDKs and frameworks, build backend and desktop/mobile UIs, and adopt patterns like RAG and agent-based workflows.

> You can explore and run examples from the Kotlin-AI-Examples repository. Each project is self-contained. You can use each project as a reference or template for building Kotlin-based AI applications.

Connect to major model providers

Use Kotlin to connect to major model providers such as OpenAI, Anthropic, Google, and others:

- OpenAI — official Java SDK for the OpenAI API. It covers responses and chats, images, and audio.
- Anthropic (Claude) — official Java SDK for the Claude Messages API. It includes modules for Vertex AI and Bedrock integrations.
- Google AI (Gemini / Vertex AI) — official Java SDK with a single client that switches between Gemini API and Vertex AI.
- Azure OpenAI — official Java client for the Azure OpenAI Service. It supports chat completions and embeddings.
- AWS Bedrock — official SDKs to invoke foundation models. It includes the Kotlin SDK and Java SDK for Bedrock and Bedrock Runtime.

Create RAG pipelines and agent-based apps

- Spring AI — multi-provider abstraction for prompts, chats, embeddings, tools and function calling, and vector stores.
- LangChain4j — JVM toolkit with Kotlin extensions for prompts, tools, retrieval-augmented generation (RAG) pipelines, and agents.

What's next

- Complete the Create a Kotlin app that answers questions with Spring AI tutorial to learn more about using Spring AI with Kotlin in IntelliJ IDEA
- Join the Kotlin community to connect with other developers building AI applications with Kotlin
- Learn about Kotlin AI skills

Create a Kotlin app that answers questions with Spring AI — tutorial

In this tutorial, you'll learn how to build a Kotlin app that connects to an LLM via Spring AI, stores documents in a vector database, and answers questions using context from those documents.

You will use the following tools during this tutorial:

- Spring Boot as the base to configure and run the web application.
- Spring AI to interact with the LLM and perform context-based retrieval.
- IntelliJ IDEA to generate the project and implement the application logic.
- Qdrant as the vector database for similarity search.
- Docker to run Qdrant locally.
- OpenAI as the LLM provider.

Before you start

1. Download and install the latest version of IntelliJ IDEA and use an Ultimate subscription.

   > If you use IntelliJ IDEA without an Ultimate subscription or you use another IDE, you can generate a Spring Boot project using a web-based project generator.

2. Create an OpenAI API key on the OpenAI platform to access the API.
3. Install Docker to run the Qdrant vector database locally.
4. After installing Docker, open your terminal and run the following command to start the container:

```
docker run -p 6333:6333 -p 6334:6334 qdrant/qdrant
```

Create the project

> You can use the Spring Boot web-based project generator as an alternative to generate your project.

Create a new Spring Boot project in IntelliJ IDEA with an Ultimate subscription:

1. In IntelliJ IDEA, select **File** | **New** | **Project**.
2. In the panel on the left, select **New Project** | **Spring Boot**.
3. Specify the following fields and options in the **New Project** window:
   - **Name**: springAIDemo
   - **Language**: Kotlin
   - **Type**: Gradle - Kotlin

     > This option specifies the build system and the DSL.

   - **Package name**: org.example.springaidemo
   - **JDK**: Java JDK

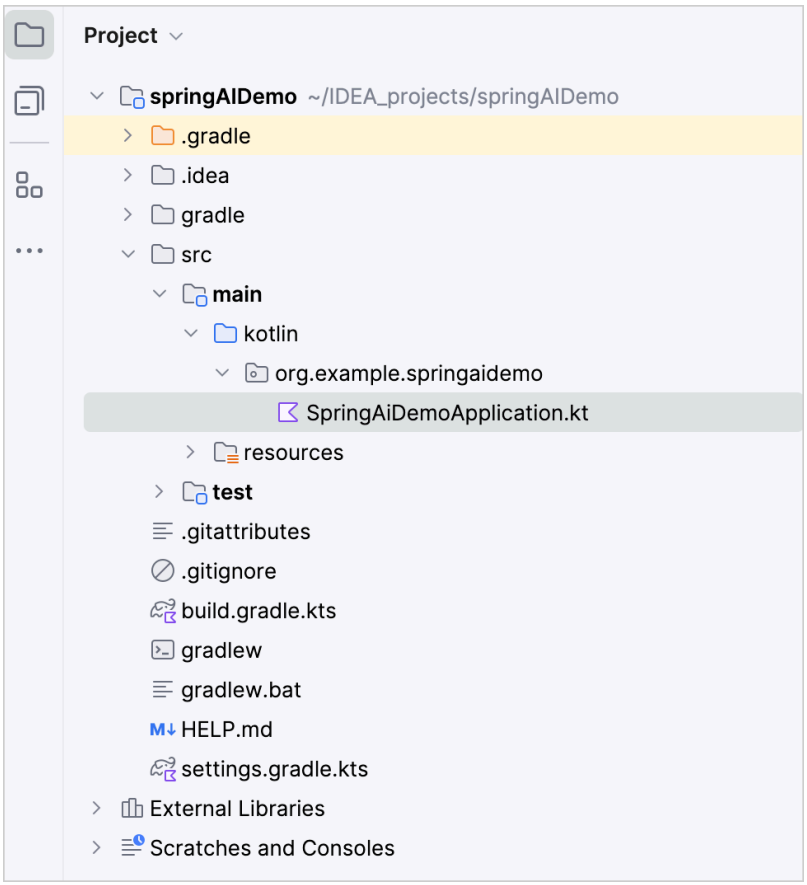
     > This tutorial uses **Oracle OpenJDK version 21.0.1**. If you don't have a JDK installed, you can download it from the dropdown list.

   - **Java**: 17

     > If you don't have Java 17 installed, you can download it from the JDK dropdown list.

Create Spring Boot project

4. Make sure that you have specified all the fields and click **Next**.
5. Select the latest stable Spring Boot version in the **Spring Boot** field.
6. Select the following dependencies required for this tutorial:
   - **Web | Spring Web**
   - **AI | OpenAI**
   - **SQL | Qdrant Vector Database**



Set up Spring Boot project

7. Click **Create** to generate and set up the project.

> The IDE will generate and open a new project. It may take some time to download and import the project dependencies.

After this, you can see the following structure in the **Project view**:

Spring Boot project view

The generated Gradle project corresponds to the Maven's standard directory layout:

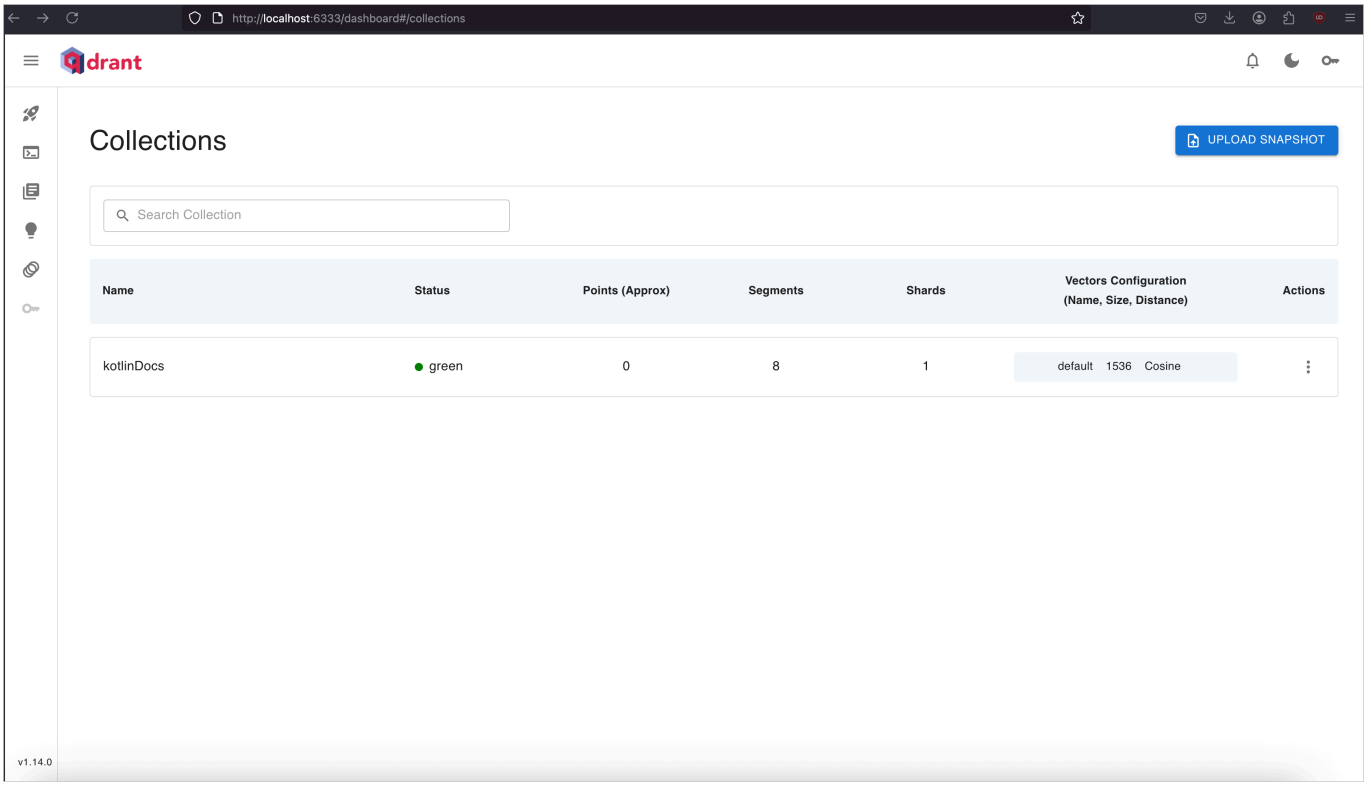
- There are packages and classes under the `main/kotlin` folder that belong to the application.
- The entry point to the application is the `main()` method of the `SpringAiDemoApplication.kt` file.

Update the project configuration

1. Update your `build.gradle.kts` Gradle build file with the following:

```
plugins {
    kotlin("jvm") version "2.4.20"
    kotlin("plugin.spring") version "2.4.20"
    // Rest of the plugins
}
```

2. Set `springAiVersion` to `2.0.0`:



```
extra["springAiVersion"] = "2.0.0"
```

3. Click the **Sync Gradle Changes** button to synchronize the Gradle files.
4. Update your `src/main/resources/application.properties` file with the following:

```
# OpenAI
spring.ai.openai.api-key=YOUR_OPENAI_API_KEY
spring.ai.openai.chat.model=gpt-4o-mini
spring.ai.openai.embedding.model=text-embedding-ada-002
# Qdrant
spring.ai.vectorstore.qdrant.host=localhost
spring.ai.vectorstore.qdrant.port=6334
spring.ai.vectorstore.qdrant.collection-name=kotlinDocs
spring.ai.vectorstore.qdrant.initialize-schema=true
```

Set your OpenAI API key to the `spring.ai.openai.api-key` property.

5. Run the `SpringAiDemoApplication.kt` file to start the Spring Boot application. Once it's running, open the Qdrant collections page in your browser to see the result:

Qdrant collections

Create a controller to load and search documents

Create a Spring `@RestController` to search documents and store them in the Qdrant collection:

1. In the `src/main/kotlin/org/example/springaidemo` directory, create a new file named `KotlinSTDController.kt`, and add the following code:

```kotlin
package org.example.springaidemo

// Imports the required Spring and utility classes
import org.slf4j.LoggerFactory
import org.springframework.ai.document.Document
import org.springframework.ai.vectorstore.SearchRequest
import org.springframework.ai.vectorstore.VectorStore
import org.springframework.web.bind.annotation.GetMapping
import org.springframework.web.bind.annotation.PostMapping
import org.springframework.web.bind.annotation.RequestMapping
import org.springframework.web.bind.annotation.RequestParam
import org.springframework.web.bind.annotation.RestController
import org.springframework.web.client.RestTemplate
import kotlin.uuid.ExperimentalUuidApi
import kotlin.uuid.Uuid

@RestController
@RequestMapping("/kotlin")
class KotlinSTDController(
    private val restTemplate: RestTemplate,
    private val vectorStore: VectorStore,
) {
    private val logger = LoggerFactory.getLogger(this::class.java)

    @OptIn(ExperimentalUuidApi::class)
    @PostMapping("/load-docs")
    fun load() {
        // Loads a list of documents from the Kotlin documentation
        val kotlinStdTopics = listOf(
            "collections-overview", "constructing-collections", "iterators", "ranges", "sequences",
            "collection-operations", "collection-transformations", "collection-filtering",
"collection-plus-minus",
            "collection-grouping", "collection-parts", "collection-elements", "collection-
ordering",
            "collection-aggregate", "collection-write", "list-operations", "set-operations",
            "map-operations", "read-standard-input", "opt-in-requirements", "scope-functions",
"time-measurement",
        )
        // Base URL for the documents
        val url = "https://raw.githubusercontent.com/JetBrains/kotlin-web-
site/refs/heads/master/docs/topics/"
        // Retrieves each document from the URL and adds it to the vector store
        kotlinStdTopics.forEach { topic ->
            val data = restTemplate.getForObject("$url$topic.md", String::class.java)
            data?.let { it ->
                val doc = Document.builder()
                    // Builds a document with a random UUID
                    .id(Uuid.random().toString())
                    .text(it)
                    .metadata("topic", topic)
                    .build()
                vectorStore.add(listOf(doc))
                logger.info("Document $topic loaded.")
            } ?: logger.warn("Failed to load document for topic: $topic")
        }
    }

    @GetMapping("docs")
    fun query(
        @RequestParam query: String = "operations, filtering, and transformations",
        @RequestParam topK: Int = 2
    ): List<Document>? {
        val searchRequest = SearchRequest.builder()
```

```
            .query(query)
            .topK(topK)
            .build()
        val results = vectorStore.similaritySearch(searchRequest)
        logger.info("Found ${results?.size ?: 0} documents for query: '$query'")
        return results
    }
}
```

2. Update the `SpringAiDemoApplication.kt` file to declare a `RestTemplate` bean:

```
package org.example.springaidemo

import org.springframework.boot.autoconfigure.SpringBootApplication
import org.springframework.boot.runApplication
import org.springframework.context.annotation.Bean
import org.springframework.web.client.RestTemplate

@SpringBootApplication
class SpringAiDemoApplication {
    @Bean
    fun restTemplate(): RestTemplate = RestTemplate()
}

fun main(args: Array<String>) {
    runApplication<SpringAiDemoApplication>(*args)
}
```

3. Run the application.

4. In the terminal, send a POST request to the `/kotlin/load-docs` endpoint to load the documents:

```
curl -X POST http://localhost:8080/kotlin/load-docs
```

5. Once the documents are loaded, you can search for them with a GET request:

```
curl -X GET http://localhost:8080/kotlin/docs
```

GET request results

> You can also view the results on the Qdrant collections page.

Implement an AI chat endpoint

Once the documents are loaded, the final step is to add an endpoint that answers questions using the documents in Qdrant through Spring AI's Retrieval-Augmented Generation (RAG) support:

1. Open the `KotlinSTDController.kt` file, and import the following classes:

```
import org.springframework.ai.chat.client.ChatClient
import org.springframework.ai.chat.client.advisor.SimpleLoggerAdvisor
import org.springframework.ai.chat.client.advisor.vectorstore.QuestionAnswerAdvisor
import org.springframework.ai.chat.prompt.Prompt
import org.springframework.ai.chat.prompt.PromptTemplate
import org.springframework.web.bind.annotation.RequestBody
```

2. Define a `ChatRequest` data class:

```
// Represents the request payload for chat queries
data class ChatRequest(val query: String, val topK: Int = 3)
```

3. Add `ChatClient.Builder` to the controller's constructor parameters:

```
class KotlinSTDController(
    // Provides the builder for creating the ChatClient
    private val chatClientBuilder: ChatClient.Builder,

    private val restTemplate: RestTemplate,
    private val vectorStore: VectorStore,
)
```

4. Inside the controller class, create a `ChatClient` instance:

```
// Builds the chat client with a simple logging advisor
private val chatClient = chatClientBuilder.defaultAdvisors(SimpleLoggerAdvisor()).build()
```

5. At the bottom of your `KotlinSTDController.kt` file, add a new `chatAsk()` endpoint, with the following logic:

```
@PostMapping("/chat/ask")
fun chatAsk(@RequestBody request: ChatRequest): String? {
    // Defines the prompt template with placeholders
    val promptTemplate = PromptTemplate(
        """
        {query}.
        Please provide a concise answer based on the "Kotlin standard library" documentation.
    """.trimIndent()
    )

    // Creates the prompt by substituting placeholders with actual values
    val prompt: Prompt =
        promptTemplate.create(mapOf("query" to request.query))

    // Configures the retrieval advisor to augment the query with relevant documents
    val retrievalAdvisor = QuestionAnswerAdvisor.builder(vectorStore)
        .searchRequest(
            SearchRequest.builder()
                .similarityThreshold(0.7)
                .topK(request.topK)
                .build()
        )
        .promptTemplate(promptTemplate)
        .build()

    // Sends the prompt to the LLM with the retrieval advisor and retrieves the generated content
    val response = chatClient.prompt(prompt)
        .advisors(retrievalAdvisor)
        .call()
        .content()
    logger.info("Chat response generated for query: '${request.query}'")
    return response
}
```

6. Run the application.
7. In the terminal, send a POST request to the new endpoint to see the results:

```
curl -X POST "http://localhost:8080/kotlin/chat/ask" \
     -H "Content-Type: application/json" \
     -d '{"query": "What are the performance implications of using lazy sequences in Kotlin for large datasets?", "topK": 3}'
```

OpenAI answer to chat request

Congratulations! You now have a Kotlin app that connects to OpenAI and answers questions using context retrieved from documentation stored in Qdrant. Try experimenting with different queries or importing other documents to explore more possibilities.

You can view the completed project in the Spring AI demo GitHub repository.

Kotlin for data analysis

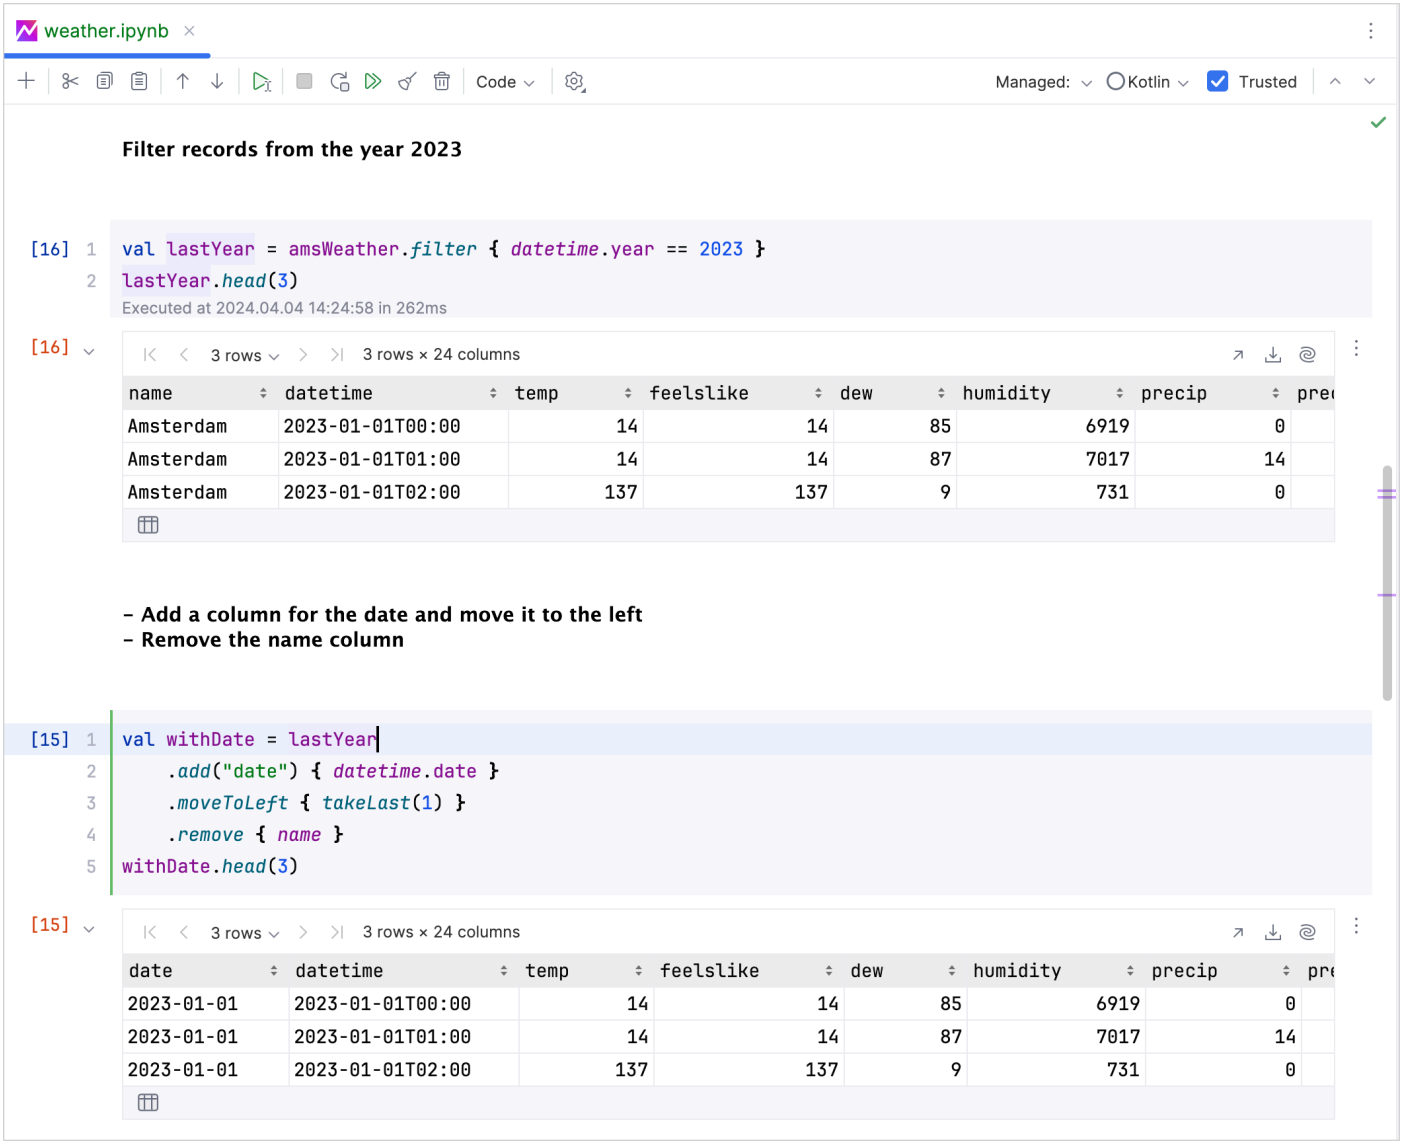
Exploring and analyzing data is something you may not do every day, but it's a crucial skill you need as a software developer.

Let's think about software development duties where data analysis is key: analyzing what's actually inside collections when debugging, digging into memory dumps or databases, or receiving JSON files with large amounts of data when working with REST APIs, to mention some.

With Kotlin's Exploratory Data Analysis (EDA) tools, such as Kotlin DataFrame and Kandy, you have at your disposal a rich set of capabilities to enhance your analytics skills and support you across different scenarios:

- **Load, transform, and visualize data in various formats:** with our Kotlin EDA tools, you can perform tasks like filtering, sorting, and aggregating data. Our tools can seamlessly read data right in the IDE from different data sources, such as CSV, JSON, SQL Databases, or Parquet files. See all supported formats in the DataFrame documentation.

  Kandy, our plotting tool, allows you to create a wide range of charts to visualize and gain insights from the dataset.



- **Efficiently analyze data stored in relational databases:** Kotlin DataFrame seamlessly integrates with databases and provides capabilities similar to SQL queries. You can retrieve, manipulate, and visualize data directly from various databases.

- **Fetch and analyze real-time and dynamic datasets from web APIs:** the EDA tools' flexibility allows integration with external APIs via protocols like OpenAPI. This feature helps you fetch data from web APIs, to then clean and transform the data to your needs.

Kotlin DataFrame

The Kotlin DataFrame library lets you manipulate structured data in your Kotlin projects. From data creation and cleaning to in-depth analysis and feature engineering, this library has you covered.

With the Kotlin DataFrame library, you can work with different file formats, including CSV, JSON, XLS, and XLSX. This library also facilitates the data retrieval process with its ability to connect with SQL databases or APIs. See all supported formats in the DataFrame documentation.

Kotlin DataFrame

Kandy

Kandy is an open-source Kotlin library that provides a powerful and flexible DSL for plotting charts of various types. This library is a simple, idiomatic, readable, and type-safe tool to visualize data. You can also easily combine Kandy with Kotlin Dataframe to complete different data-related tasks.

Kandy

What's next

- Retrieve and transform data using the Kotlin DataFrame library
- Visualize data using the Kandy library
- Learn more about Kotlin and Java libraries for data analysis

Retrieve data from files

Kotlin DataFrame library enables you to work with both non-structured and structured data. For data transformations, you can use such methods as `.add()`, `.split()`, `.convert()`, and `.parse()`. Additionally, this toolset enables the retrieval and manipulation of data from various structured file formats, including CSV, JSON, XLS, Parquet, and Apache Arrow. See all supported formats in the DataFrame documentation.

In this guide, you can learn how to retrieve, refine, and handle data through multiple examples.

Before you start

Starting with IntelliJ IDEA 2026.2, Kotlin Notebook will no longer be bundled with the IDE or officially supported by JetBrains. The source code will remain available on GitHub.

Learn more in the blog post.

To follow this tutorial:

1. Select **File** | **New** | **Kotlin Notebook**.
2. Import Kotlin DataFrame:

   ```
   %use dataframe
   ```

   Run the code cell with the `%use dataframe` line before any other code cells to make sure the DataFrame library and its APIs are available in the notebook.

To follow the tutorial, you can also use DataFrame as a Gradle or Maven dependency.

Retrieve data

To retrieve data from a file, use the `DataFrame.read()` function:

```
val movies = DataFrame.read("movies.csv")
```

The `DataFrame.read()` function detects the input format based on the file extension and content.

You can also pass additional arguments to control how the DataFrame library reads the input data. For example, the following code specifies a custom delimiter (`;`) for a CSV file:

```
val movies = DataFrame.read("movies.csv", delimiter = ';')
```

For a comprehensive overview of additional file formats and a variety of read functions, see the Kotlin DataFrame library documentation.

Display data

Once you have the data, you can display it. The easiest way is to store your data in a variable and then return it:

```
val jsonDf = DataFrame.read("jsonFile.json")
jsonDf
```

This code displays the data from your file as an interactive table:

```
1 val jsonDf = DataFrame.read("jsonFile.json")
2 jsonDf
```

✓ [8] 254ms

4 rows 4 rows × 6 cols

id	first_name	last_name	email	gender	ip_address
1	Jeanette	Penddreth	jpenddreth0@census.gov	Female	26.58.193.2
2	Giavani	Frediani	gfrediani1@senate.gov	Male	229.179.4.212
3	Noell	Bea	nbea2@imageshack.us	Female	180.66.162.255
4	Willard	Valek	wvalek3@vk.com	Male	67.76.188.26

Display data

You can use this view to inspect values, check column names, and easily understand the state of your dataset.

Inspect data structure

To gain insights into the structure or schema of your data, use the `.schema()` function on your DataFrame variable.

For example, run `jsonDf.schema()` to list the type of each column in your JSON dataset:

```
jsonDf.schema()
```

✓ [9] 37ms

```
id: Int
first_name: String
last_name: String
email: String
gender: String
ip_address: String
```

Schema example

You can also use the autocompletion feature. It allows you to quickly access and manipulate the properties of your DataFrame. After loading your data, simply type the DataFrame variable followed by a period (`.`) to see a list of available columns and their types.

```
jsonDf.
```

```
first_name for ColumnsScope<Line_17_jupyter._DataFrameTy…  DataColumn<String>
id for ColumnsScope<Line_17_jupyter._DataFrameType> in Line…  DataColumn<Int>
gender for ColumnsScope<Line_17_jupyter._DataFrameType> …  DataColumn<String>
email for ColumnsScope<Line_17_jupyter._DataFrameType> i…  DataColumn<String>
last_name for ColumnsScope<Line_17_jupyter._DataFrameTyp…  DataColumn<String>
```

Available properties

Refine data

Kotlin DataFrame provides various operations for refining your dataset. For example, grouping, filtering, updating, or adding new columns. These functions are essential for data analysis, allowing you to organize, clean, and transform your data effectively.

For example, let's look at the `movies.csv` dataset. It stores movie titles and release years in the same cell. The goal is to refine this dataset for easier analysis:

1. **Load the data**

   Load the file into a `DataFrame` using the `.read()` function:

   ```
   val movies = DataFrame.read("movies.csv")
   ```

2. **Add a column**

   To extract the release year from the `title` column, add a new `year` column:

   ```
   val moviesWithYear = movies
       .add("year") {
           "\\d{4}".toRegex()
               .findAll(title)
               .lastOrNull()
               ?.value
               ?.toInt()
               ?: -1
       }

   moviesWithYear
   ```

3. **Update values**

   To remove the release year from the movie title, update the `title` column:

   ```
   val moviesTitle = moviesWithYear
       .update("title") {
           "\\s*\\(\\d{4}\\)\\s*$".toRegex().replace(title, "")
   }

   moviesTitle
   ```

   The code keeps the movie titles in one column and moves the release years into another column.

4. **Filter rows**

   To focus on specific data, use the `.filter()` function. For example, to keep only the movies released after 1986, run:

   ```
   val newMovies = moviesTitle.filter {
       year ≥ 1996
   }

   newMovies
   ```

5. **Remove column**

   To remove a column that you do not need, use the `.remove()` function:

```
val refinedMovies = newMovies.remove {
    movieID
}

refinedMovies
```

For comparison, here is the dataset before refinement:

movieId	title	genres
1	Toy Story (1995)	Adventure|Animation|Children|Comedy|Fantasy
2	Jumanji (1995)	Adventure|Children|Fantasy
3	Grumpier Old Men (1995)	Comedy|Romance
4	Waiting to Exhale (1995)	Comedy|Drama|Romance
5	Father of the Bride Part II (1995)	Comedy
6	Heat (1995)	Action|Crime|Thriller
7	Sabrina (1995)	Comedy|Romance
8	Tom and Huck (1995)	Adventure|Children
9	Sudden Death (1995)	Action
10	GoldenEye (1995)	Action|Adventure|Thriller

Original dataset

The dataset after refinement:

title	genres	year
Eye for an Eye	Drama|Thriller	1996
Don't Be a Menace to South Central While Drink…	Comedy|Crime	1996
Two if by Sea	Comedy|Romance	1996
Bio-Dome	Comedy	1996
Lawnmower Man 2: Beyond Cyberspace	Action|Sci-Fi|Thriller	1996
From Dusk Till Dawn	Action|Comedy|Horror|Thriller	1996
Bed of Roses	Drama|Romance	1996
Big Bully	Comedy|Drama	1996
Juror, The	Drama|Thriller	1996
White Squall	Action|Adventure|Drama	1996

Data refinement result

For additional use cases and detailed examples, see Examples of Kotlin Dataframe.

Export data

After refining the data, you can easily export it.

You can utilize a variety of `.write()` functions for this purpose. It supports saving in multiple formats, including CSV, JSON, XLS, XLSX, Apache Arrow, and even HTML tables. See all supported formats in the DataFrame documentation. This can be particularly useful for sharing your findings, creating reports, or making your data available for further analysis.

For example, let's save the result as:

- JSON file using the `.writeJson()` function:

```
refinedMovies.writeJson("movies.json")
```

- CSV file using the `.writeCsv()` function:

```
refinedMovies.writeCsv("movies.csv")
```

- Apache Arrow files using the `.writeArrorIPC()` and `.writeArrorFeather()` functions:

```
refinedMovies.writeArrowIPC("movies.arrow")
refinedMovies.writeArrowFeather("movies.feather")
```

You can also open a standalone HTML table in your browser with the `.toStandaloneHTML()` function:

```
refinedMoviesDf
    .toStandaloneHTML(DisplayConfiguration(rowsLimit = null))
    .openInBrowser()
```

Retrieve data from web sources and APIs

With Kotlin DataFrame library, you can access and manipulate data from various web sources and APIs. It also assists in reshaping this data for comprehensive analysis and visualization.

Explore DataFrame examples on GitHub.

Before you start

Starting with IntelliJ IDEA 2026.2, Kotlin Notebook will no longer be bundled with the IDE or officially supported by JetBrains. The source code will remain available on GitHub.

Learn more in the blog post.

Create a new Kotlin Notebook:

1. Select **File** | **New** | **Kotlin Notebook**.
2. Import the Kotlin DataFrame library by running the following command:

```
%use dataframe
```

To follow the tutorial, you can also use DataFrame as a Gradle or Maven dependency.

Fetch data from an API

Fetching data from APIs using the Kotlin DataFrame library is achieved through the `.read()` function, which is similar to retrieving data from files, such as CSV or JSON. However, when working with web-based sources, you might require additional formatting to transform the raw API data into a structured format.

Let's look at an example of fetching data from the YouTube Data API:

1. Securely add your API key in a new code cell, which is necessary for authenticating requests to the YouTube Data API. You can obtain your API key from the credentials tab:

```
val apiKey = "YOUR-API_KEY"
```

2. Create a load function that takes a path as a string and uses the DataFrame's `.read()` function to fetch data from the YouTube Data API:

```
fun load(path: String): AnyRow =
DataRow.read("https://www.googleapis.com/youtube/v3/$path&key=$apiKey")
```

3. Organize the fetched data into rows and handle the YouTube API's pagination through the `nextPageToken`. This ensures you gather data across multiple pages:

```
fun load(path: String, maxPages: Int): AnyFrame {
    // Initializes a mutable list to store rows of data.
    val rows = mutableListOf<AnyRow>()

    // Sets the initial page path for data loading.
    var pagePath = path
    do {
        // Loads data from the current page path.
        val row = load(pagePath)
        // Adds the loaded data as a row to the list.
        rows.add(row)

        // Retrieves the token for the next page, if available.
        val next = row.getValueOrNull<String>("nextPageToken")
        // Updates the page path for the next iteration, including the new token.
        pagePath = path + "&pageToken=" + next

        // Continues loading pages until there's no next page.
    } while (next != null && rows.size < maxPages)

    // Concatenates and returns all loaded rows as a DataFrame.
    return rows.concat()
}
```

4. Use the previously defined `load()` function to fetch data and create a DataFrame in a new code cell. This example fetches data, or in this case, videos related to Kotlin, with a maximum of 50 results per page, up to a maximum of 5 pages. The result is stored in the `df` variable:

```
val df = load("search?q=kotlin&maxResults=50&part=snippet", 5)
df
```

5. Finally, extract and concatenate items from the DataFrame:

```
val items = df.items.concat()
items
```

Clean and refine data

Cleaning and refining data are crucial steps in preparing your dataset for analysis. The Kotlin DataFrame library offers powerful functionalities for these tasks. Methods like `move`, `concat`, `select`, `parse`, and `join` are instrumental in organizing and transforming your data.

Let's explore an example where the data is already fetched using YouTube's data API. The goal is to clean and restructure the dataset to prepare for in-depth analysis:

1. You can start by reorganizing and cleaning your data. This involves moving certain columns under new headers and removing unnecessary ones for clarity:

```
val videos = items.dropNulls { id.videoId }
    .select { id.videoId named "id" and snippet }
    .distinct()
videos
```

2. Chunk IDs from the cleaned data and load corresponding video statistics. This involves breaking the data into smaller batches and fetching additional details:

```
val statPages = clean.id.chunked(50).map {
    val ids = it.joinToString("%2C")
    load("videos?part=statistics&id=$ids")
}
statPages
```

3. Concatenate the fetched statistics and select relevant columns:

```
val stats = statPages.items.concat().select { id and statistics.all() }.parse()
stats
```

4. Join the existing cleaned data with the newly fetched statistics. This merges two sets of data into a comprehensive DataFrame:

```
val joined = clean.join(stats)
joined
```

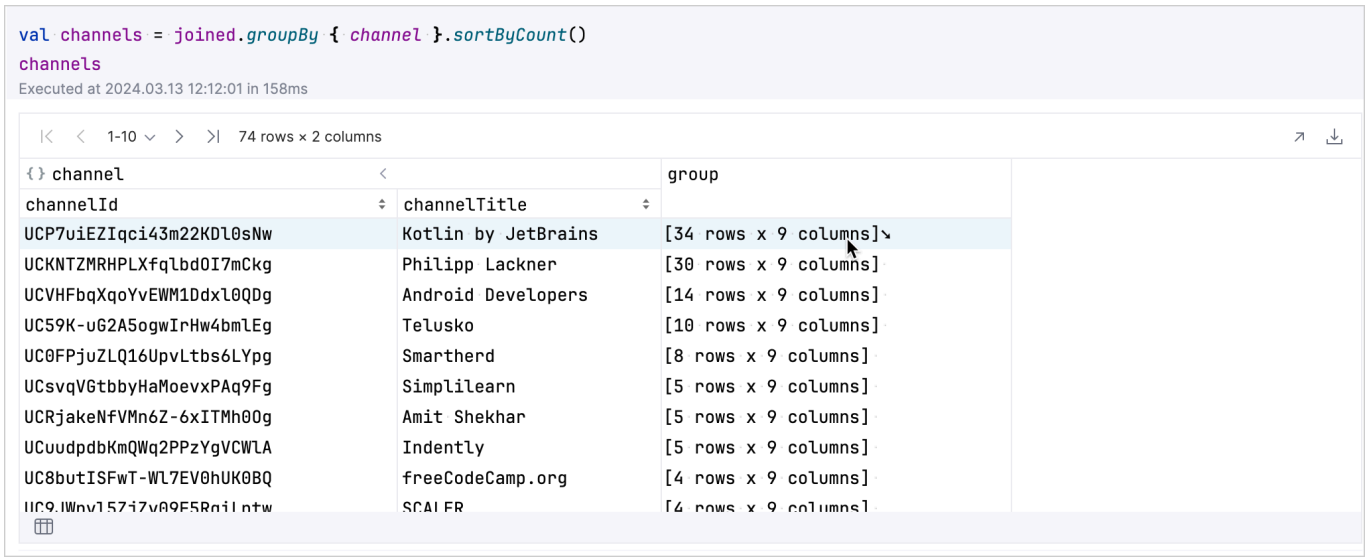
This example demonstrates how to clean, reorganize, and enhance your dataset using Kotlin DataFrame's various functions. Each step is designed to refine the data, making it more suitable for in-depth analysis.

Analyze data in Kotlin Notebook

After you've successfully fetched and cleaned and refined your data using functions from the Kotlin DataFrame library, the next step is to analyze this prepared dataset to extract meaningful insights.

Methods such as `groupBy` for categorizing data, `sum` and `maxBy` for summary statistics, and `sortBy` for ordering data are particularly useful. These tools allow you to perform complex data analysis tasks efficiently.

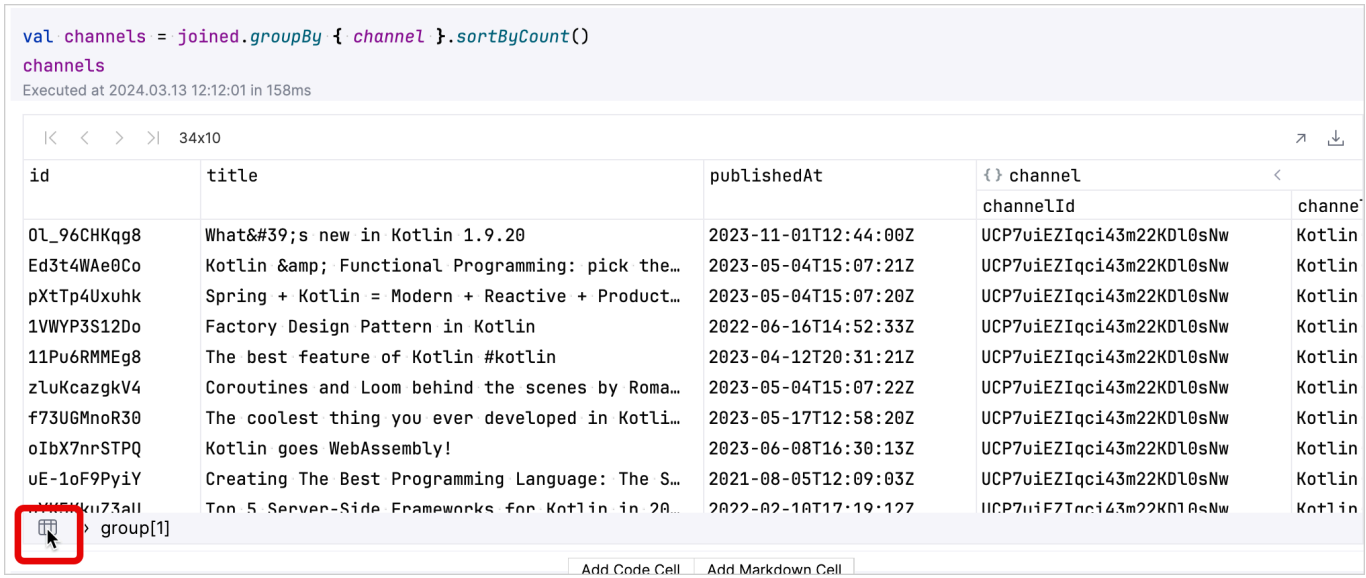
Let's look at an example, using `groupBy` to categorize videos by channel, `sum` to calculate total views per category, and `maxBy` to find the latest or most viewed video in each group:



1. Simplify the access to specific columns by setting up references:

```
val view by column<Int>()
```

2. Use the `groupBy` method to group the data by the `channel` column and sort it.



```
val channels = joined.groupBy { channel }.sortByCount()
```

In the resulting table, you can interactively explore the data. Clicking on the `group` field of a row corresponding to a channel expands that row to reveal more details about that channel's videos.

Expanding a row to reveal more details

You can click the table icon in the bottom left to return to the grouped dataset.

Click on the table icon in the bottom left to return

3. Use `aggregate`, `sum`, `maxBy`, and `flatten` to create a DataFrame summarizing each channel's total views and details of its latest or most viewed video:

```
val aggregated = channels.aggregate {
    viewCount.sum() into view

    val last = maxBy { publishedAt }
    last.title into "last title"
    last.publishedAt into "time"
    last.viewCount into "viewCount"
    // Sorts the DataFrame in descending order by view count and transform it into a flat
structure.
}.sortByDesc(view).flatten()
aggregated
```

The results of the analysis:

```
val view by column<Int>() // Simplify column access by setting up references, making subsequent operations more intuitive.

val channels = joined.groupBy { channel }.sortByCount().aggregate
 { this: AggregateGroupedDsl<_DataFrameType33>  it: AggregateGroupedDsl<_DataFrameType33>
    viewCount.sum() into view

    val last = maxBy { publishedAt }
    last.title into "last title"
    last.publishedAt into "time"
    last.viewCount into "viewCount" ^aggregate
}.sortByDesc(view).flatten() // Sort the DataFrame in descending order based on the values in the view column and transform it into
 a flat structure.
channels
Executed at 2024.03.04 10:53:40 in 127ms
```

1-10 78 rows × 6 columns

Connect and retrieve data from databases

Kotlin DataFrame library provides support for the most common SQL databases:

- DuckDB
- H2
- MariaDB
- Microsoft SQL Server
- MySQL
- PostgreSQL
- SQLite

Explore the Kotlin DataFrame SQL Examples on GitHub.

Before you start

> Starting with IntelliJ IDEA 2026.2, Kotlin Notebook will no longer be bundled with the IDE or officially supported by JetBrains. The source code will remain available on GitHub.
>
> Learn more in the blog post.

To follow this tutorial:

1. Select **File** | **New** | **Kotlin Notebook**.
2. Add the Java Database Connectivity (JDBC) driver dependency for your database in the first cell of your notebook.

   For example, to connect to a MariaDB database, add:

   ```
   USE {
       dependencies("org.mariadb.jdbc:mariadb-java-client:$version")
   }
   ```

3. Import Kotlin DataFrame:

   ```
   %use dataframe
   ```

   Run the code cell with the `%use dataframe` line before any other code cells to make sure the DataFrame library and its APIs are available in the notebook.

To follow the tutorial, you can also use DataFrame as a Gradle or Maven dependency.

Connect to a database

To connect to a database, create a connection configuration using the `DbConnectionConfig()` function:

1. Import the following functionality:

   ```
   import org.jetbrains.kotlinx.dataframe.io.DbConnectionConfig
   import org.jetbrains.kotlinx.dataframe.schema.DataFrameSchema
   ```

2. Define connection parameters (URL, username, password) using the `DbConnectionConfig()` function:

```
val URL = "YOUR_URL"
val USER_NAME = "YOUR_USERNAME"
val PASSWORD = "YOUR_PASSWORD"

val dbConfig = DbConnectionConfig(URL, USER_NAME, PASSWORD)
```

For more information on connecting to SQL databases, see Read from SQL databases in the Kotlin DataFrame documentation.

Inspect database schema

Before loading the data, inspect the database schemas to understand what tables you have and what columns they contain. You can use the schemas to decide which table to load into a DataFrame.

To retrieve schemas for all user-created tables in your database, use the `DataFrameSchema.readAllSqlTables()` function:

```
val dataSchemas = DataFrameSchema.readAllSqlTables(dbConfig)

dataSchemas.forEach { (tableName, schema) ->
    println("---Schema for table: $tableName---")
    println(schema)
    println()
}
```

Load data

After you inspect the database schemas and select the data, load the data into a DataFrame.

Kotlin DataFrame provides two ways to load data from a database:

- Load data directly from a table.
- Load the result of a custom SQL query.

Both approaches return a DataFrame that you can inspect, transform, and analyze.

Load data from a table

To load data from a table, use the `DataFrame.readSqlTable()` function.

The following example loads the first 100 rows from the `movies` table:

```
val moviesDf = DataFrame.readSqlTable(
    dbConfig = dbConfig,
    tableName = "movies",
    limit = 100
)

moviesDf
```

Load data with an SQL query

To execute a specific SQL query on your database, use the `DataFrame.readSqlQuery()` function. This approach is useful when you need to load specific columns, join tables, filter rows, or aggregate data in a database.

Let's retrieve a specific dataset related to movies directed by Quentin Tarantino. This query selects movie details and combines genres for each movie:

```
val TARANTINO_FILMS_SQL_QUERY = """
    SELECT name, year, rank, GROUP_CONCAT(genre) as "genres"
    FROM movies JOIN movies_directors ON movie_id = movies.id
    JOIN directors ON directors.id=director_id LEFT JOIN movies_genres ON movies.id =
movies_genres.movie_id
    WHERE directors.first_name = "Quentin" AND directors.last_name = "Tarantino"
    GROUP BY name, year, rank
    ORDER BY year
    """

val tarantinoMoviesDf = DataFrame.readSqlQuery(dbConfig, TARANTINO_FILMS_SQL_QUERY)

tarantinoMoviesDf
```

Process data

After loading your database into a DataFrame, you can use DataFrame operations to process retrieved data.

For example, let's manipulate data from the previous section. The following code:

1. Replaces missing values in the `year` column using the `.fillNA()` function.
2. Converts the column to `Int` using the `.convert()` function.
3. Keeps only films released after 2000 using the `.filter()` function.

```
val filteredTarantinoMovies = tarantinoMoviesDf
    .fillNA { year }.with { 0 }
    .convert { year }.toInt()
    .filter { year > 2000 }

filteredTarantinoMovies
```

Analyze data

Use the DataFrame library to group, sort, and aggregate data so you can uncover and understand patterns in your data.

For example, let's read actor data from the `actors` table and find the 20 most common first names:

```
// Extract data from the actors table
val actorDf = DataFrame.readSqlTable(dbConfig, "actors", 10000)
val top20ActorNames = actorDf
   // Groups the data by the first_name column
   .groupBy { first_name }

   // Counts the occurrences of each unique first name
   .count()

    // Sorts the results in descending order of count
   .sortByDesc("count")

   // Selects the top 20 most frequent names for analysis.
   .take(20)
```

Data visualization with Kandy

Kotlin offers an all-in-one-place solution for powerful and flexible data visualization, providing an intuitive way to present and explore data before diving into complex models.

This tutorial demonstrates how to create different chart types in IntelliJ IDEA using the Kandy and Kotlin DataFrame libraries.

Before you start

Starting with IntelliJ IDEA 2026.2, Kotlin Notebook will no longer be bundled with the IDE or officially supported by JetBrains. The source code will remain available on GitHub.

Learn more in the blog post.

To follow this tutorial:

1. Select **File** | **New** | **Kotlin Notebook**.
2. In your notebook, import Kandy and Kotlin DataFrame:

   ```
   %use kandy
   %use dataframe
   ```

   Run the code cell with the `%use dataframe` line before any other code cells to make sure the DataFrame library and its APIs are available in the notebook.

To follow the tutorial, you can also use DataFrame as a Gradle or Maven dependency.

Create a DataFrame

To start, let's create a DataFrame with data to visualize. This DataFrame stores simulated monthly average temperatures for Berlin, Madrid, and Caracas:

```
// The months variable stores a list with the 12 months of the year
val months = listOf(
    "January", "February",
    "March", "April", "May",
    "June", "July", "August",
    "September", "October", "November",
    "December"
)
// The tempBerlin, tempMadrid, and tempCaracas variables store a list
// with temperature values for each month
val tempBerlin =
    listOf(-0.5, 0.0, 4.8, 9.0, 14.3, 17.5, 19.2, 18.9, 14.5, 9.7, 4.7, 1.0)
val tempMadrid =
    listOf(6.3, 7.9, 11.2, 12.9, 16.7, 21.1, 24.7, 24.2, 20.3, 15.4, 9.9, 6.6)
val tempCaracas =
    listOf(27.5, 28.9, 29.6, 30.9, 31.7, 35.1, 33.8, 32.2, 31.3, 29.4, 28.9, 27.6)
```

Now let's create a new variable (`df`) and use the `dataFrameOf()` function to generate a DataFrame of three columns (Month, Temperature, and City):

```
val df = dataFrameOf(
    "Month" to months + months + months,
    "Temperature" to tempBerlin + tempMadrid + tempCaracas,
    "City" to List(12) { "Berlin" } + List(12) { "Madrid" } + List(12) { "Caracas" }
)
```

To preview the data, use the `.head()` function:

```
df.head(4) // Returns the first four rows
```

In our dataset, the first four rows store temperature in Berlin from January to April:

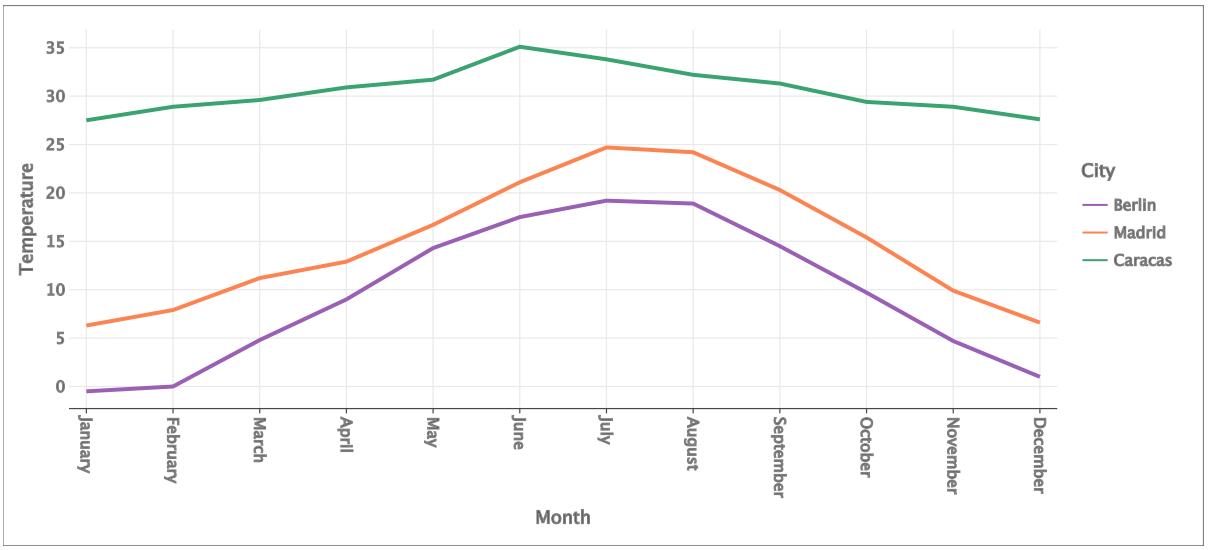
4 rows 4 rows × 3 columns

Month	Temperature	City
January	-0.5	Berlin
February	0	Berlin
March	4.8	Berlin
April	9	Berlin

Dataframe exploration

There are different options to access a column's records that can help you increase type safety when working with the Kandy and Kotlin DataFrame libraries together. For more information, see Access APIs.

Create a line chart



Let's create a line chart using the `df` DataFrame from the previous section:

1. Call the `.plot()` function from the Kandy library.
2. Apply the `line()` layer.
3. Map the `Month` and `Temperature` columns to the `X` and `Y` axes accordingly.
4. (Optional) Customize colors and sizes.

```
df.plot {
    line {
        x(Month)
        y(Temperature)

        color(City) {
            scale = categorical(
                "Berlin" to Color.hex("#6F4E37"),
                "Madrid" to Color.hex("#C2D4AB"),
                "Caracas" to Color.hex("#B5651D")
            )
        }
        width = 1.5
    }
    layout {
        size = 1000 to 450
    }
}
```

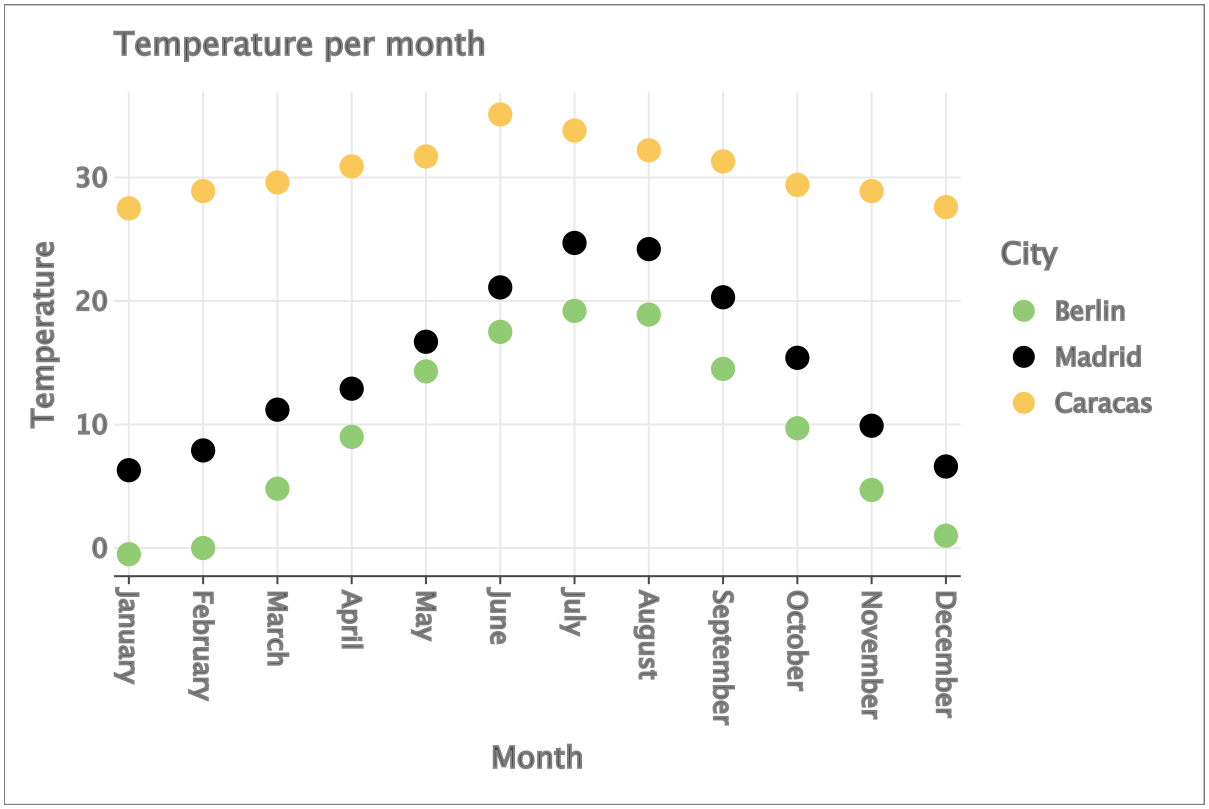
Here's the result:

Line chart

Create a points chart

Now, let's visualize the `df` DataFrame in a points (scatter) chart:

1. Call the `.plot()` function from the Kandy library.
2. Apply the `points()` layer.



3. Map the `Month` and `Temperature` columns to the `X` and `Y` axes accordingly.

4. (Optional) Customize colors, axis labels, point sizes, and chart title.

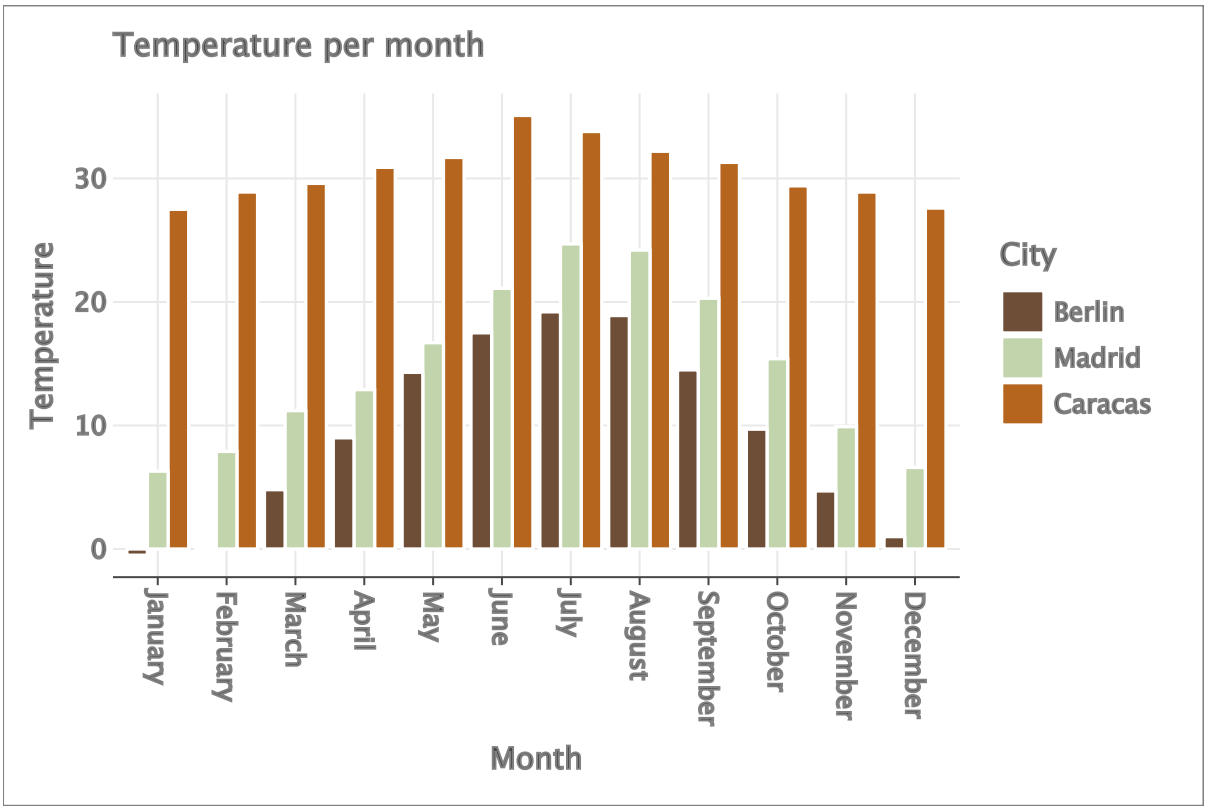
```
df.plot {
   points {
      x(Month) {
         axis.name = "Month"
      }
      y(Temperature) {
         axis.name = "Temperature"
      }

      color(City) {
         scale = categorical(
            "Berlin" to Color.hex("#6F4E37"),
            "Madrid" to Color.hex("#C2D4AB"),
            "Caracas" to Color.hex("#B5651D")
         )
      }
      size = 5.5
   }
   layout {
      title = "Temperature per month"
   }
}
```

Here's the result:

Points chart

Create a bar chart



Finally, let's create a bar chart for each city:

1. Use the `.groupBy()` function to group the DataFrame by the `City` column.
2. Call the `plot()` function from the Kandy library.
3. Apply the `bars()` layer.
4. (Optional) Add a title for the chart, customize colors.

```
df.groupBy { City }.plot {
    bars {
        x(Month)
        y(Temperature)

        fillColor(City) {
            scale = categorical(
                "Berlin" to Color.hex("#6F4E37"),
                "Madrid" to Color.hex("#C2D4AB"),
                "Caracas" to Color.hex("#B5651D")
            )
        }
    }
    layout.title {
       title = "Temperature per month"
    }
}
```

Here's the result:

Bar chart

Data visualization with Lets-Plot for Kotlin

Lets-Plot for Kotlin (LPK) is a multiplatform plotting library that ports the R's ggplot2 library to Kotlin. LPK brings the feature-rich ggplot2 API to the Kotlin ecosystem, making it suitable for scientists and statisticians who require sophisticated data visualization capabilities.

LPK targets various platforms, including Kotlin/JS, JVM's Swing, JavaFX, and Compose Multiplatform. Additionally, LPK has seamless integration with IntelliJ, DataGrip, DataSpell, and PyCharm.

Lets-Plot

This tutorial demonstrates how to create different plot types with the LPK and Kotlin DataFrame libraries in IntelliJ IDEA.

Before you start

Starting with IntelliJ IDEA 2026.2, Kotlin Notebook will no longer be bundled with the IDE or officially supported by JetBrains. The source code will remain available on GitHub.

Learn more in the blog post.

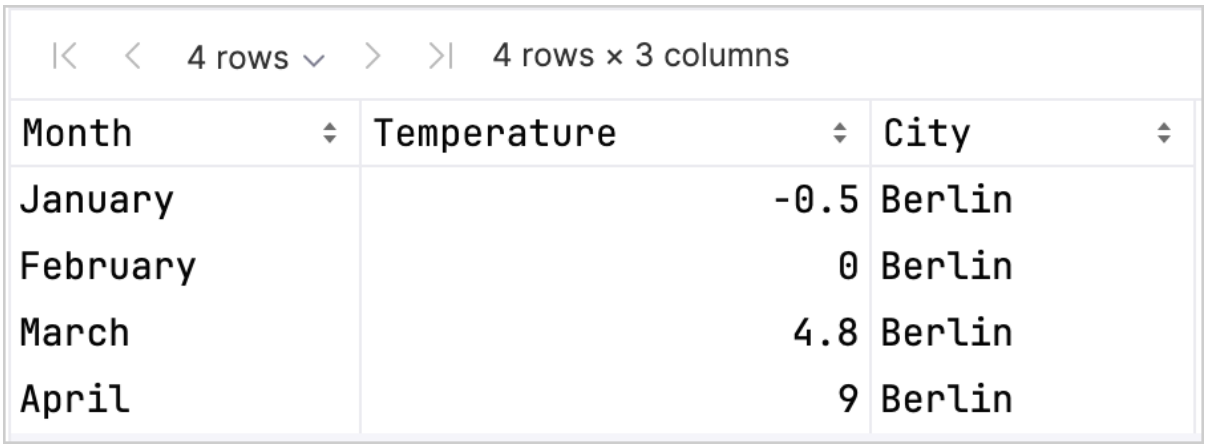
Create a new Kotlin Notebook to work with Lets-Plot:

1. Select **File** | **New** | **Kotlin Notebook**.
2. In your notebook, import the LPK and Kotlin DataFrame libraries by running the following command:

```
%use lets-plot
%use dataframe
```

To follow the tutorial, you can also use DataFrame as a Gradle or Maven dependency.

Prepare the data



Let's create a DataFrame that stores simulated numbers of the monthly average temperature in three cities: Berlin, Madrid, and Caracas.

Use the `dataFrameOf()` function from the Kotlin DataFrame library to generate the DataFrame. Paste and run the following code snippet:

```
// The months variable stores a list with 12 months of the year
val months = listOf(
    "January", "February",
    "March", "April", "May",
    "June", "July", "August",
    "September", "October", "November",
    "December"
)
// The tempBerlin, tempMadrid, and tempCaracas variables store a list with temperature values for each
month
val tempBerlin =
    listOf(-0.5, 0.0, 4.8, 9.0, 14.3, 17.5, 19.2, 18.9, 14.5, 9.7, 4.7, 1.0)
val tempMadrid =
    listOf(6.3, 7.9, 11.2, 12.9, 16.7, 21.1, 24.7, 24.2, 20.3, 15.4, 9.9, 6.6)
val tempCaracas =
    listOf(27.5, 28.9, 29.6, 30.9, 31.7, 35.1, 33.8, 32.2, 31.3, 29.4, 28.9, 27.6)

// The df variable stores a DataFrame of three columns, including monthly records, temperature, and
cities
val df = dataFrameOf(
    "Month" to months + months + months,
    "Temperature" to tempBerlin + tempMadrid + tempCaracas,
    "City" to List(12) { "Berlin" } + List(12) { "Madrid" } + List(12) { "Caracas" }
)
df.head(4)
```

You can see that the DataFrame has three columns: Month, Temperature, and City. The first four rows of the DataFrame contain records of the temperature in Berlin from January to April:

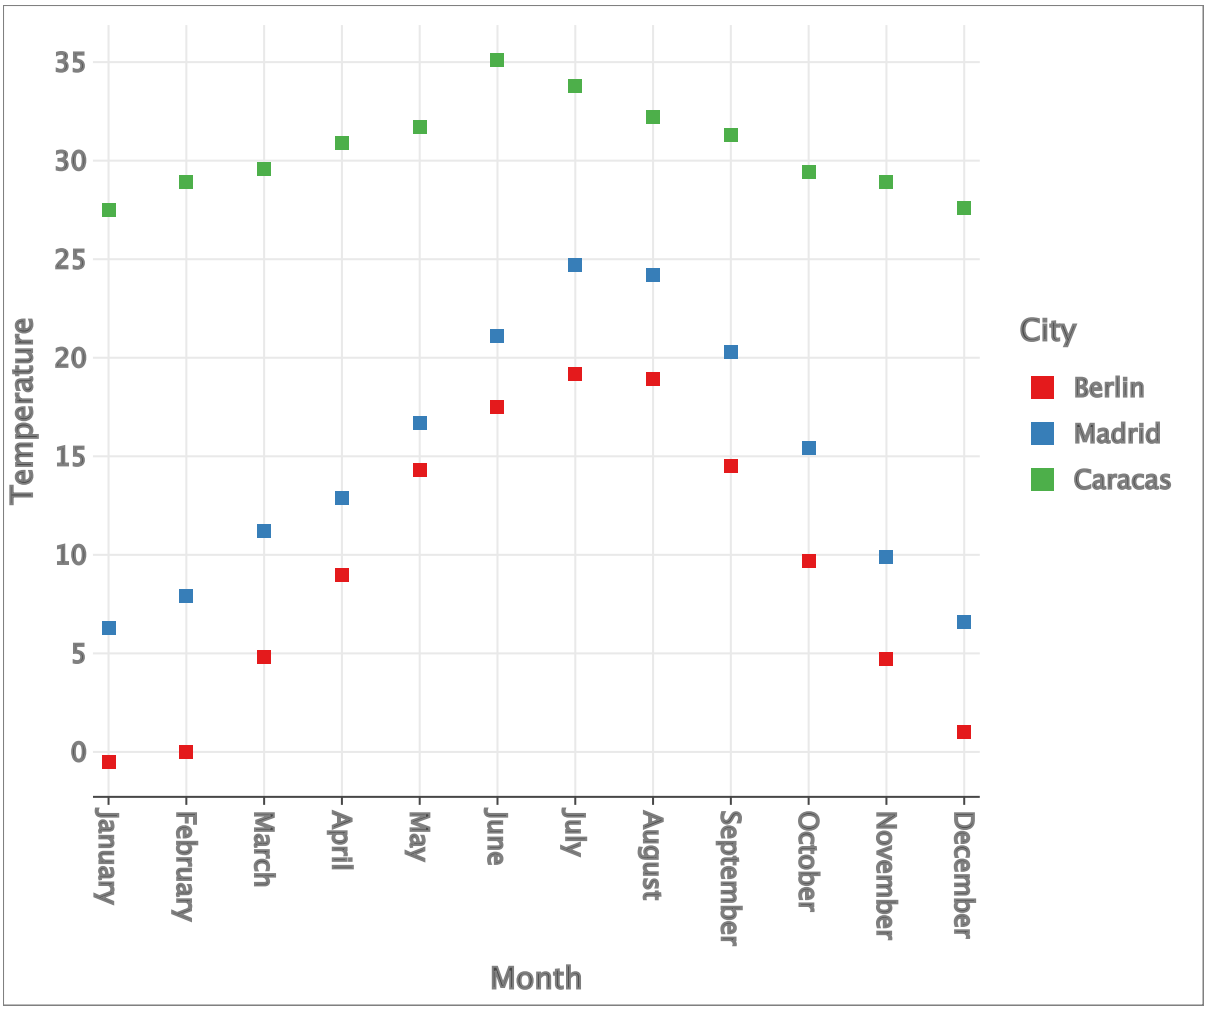
4 rows 4 rows × 3 columns

Month	Temperature	City
January	-0.5	Berlin
February	0	Berlin
March	4.8	Berlin
April	9	Berlin

Dataframe exploration

To create a plot using the LPK library, you need to convert your data (`df`) into a `Map` type that stores the data in key-value pairs. You can easily convert a DataFrame into a `Map` using the `.toMap()` function:

```
val data = df.toMap()
```



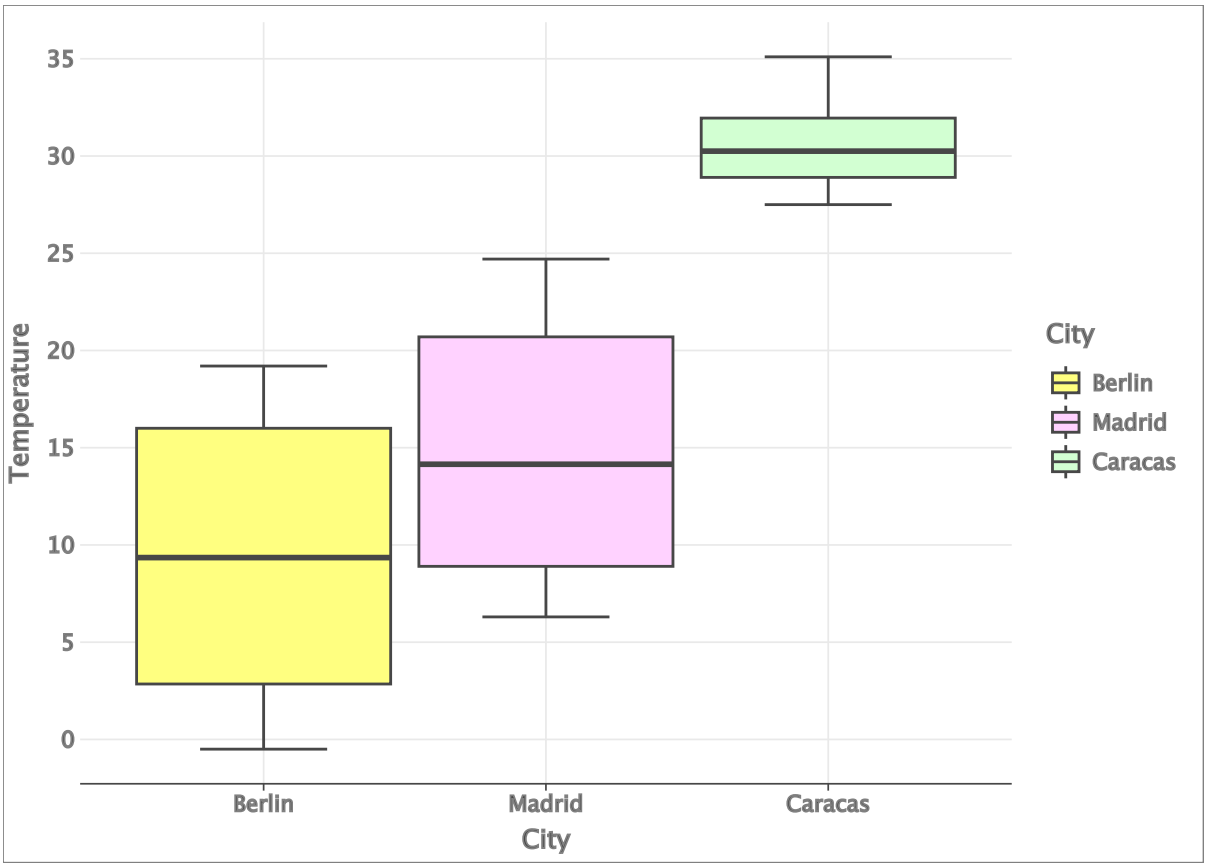
Create a scatter plot

Let's create a scatter plot with the LPK library.

Once you have your data in the `Map` format, use the `geomPoint()` function from the LPK library to generate the scatter plot. You can specify the values for the X and Y axes, as well as define categories and their color. Additionally, you can customize the plot's size and point shapes to suit your needs:

```
// Specifies X and Y axes, categories and their color, plot size, and plot type
val scatterPlot =
    letsPlot(data) { x = "Month"; y = "Temperature"; color = "City" } + ggsize(600, 500) +
geomPoint(shape = 15)
scatterPlot
```

Here's the result:



Scatter plot

Create a box plot

Let's visualize the data in a box plot. Use the `geomBoxplot()` function from the LPK library to generate the plot and customize colors with the `scaleFillManual()` function:

```
// Specifies X and Y axes, categories, plot size, and plot type
val boxPlot = ggplot(data) { x = "City"; y = "Temperature" } + ggsize(700, 500) + geomBoxplot { fill =
"City" } +
    // Customizes colors
    scaleFillManual(values = listOf("light_yellow", "light_magenta", "light_green"))
boxPlot
```

Here's the result:

Box plot

Create a 2D density plot

Now, let's create a 2D density plot to visualize the distribution and concentration of some random data.

Prepare the data for the 2D density plot

1. Import the dependencies to process the data and generate the plot:

```
%use lets-plot

@file:DependsOn("org.apache.commons:commons-math3:3.6.1")
import org.apache.commons.math3.distribution.MultivariateNormalDistribution
```

2. Paste and run the following code snippet to create sets of 2D data points:

```
// Defines covariance matrices for three distributions
val cov0: Array<DoubleArray> = arrayOf(
    doubleArrayOf(1.0, -.8),
    doubleArrayOf(-.8, 1.0)
)

val cov1: Array<DoubleArray> = arrayOf(
    doubleArrayOf(1.0, .8),
    doubleArrayOf(.8, 1.0)
)

val cov2: Array<DoubleArray> = arrayOf(
    doubleArrayOf(10.0, .1),
    doubleArrayOf(.1, .1)
)

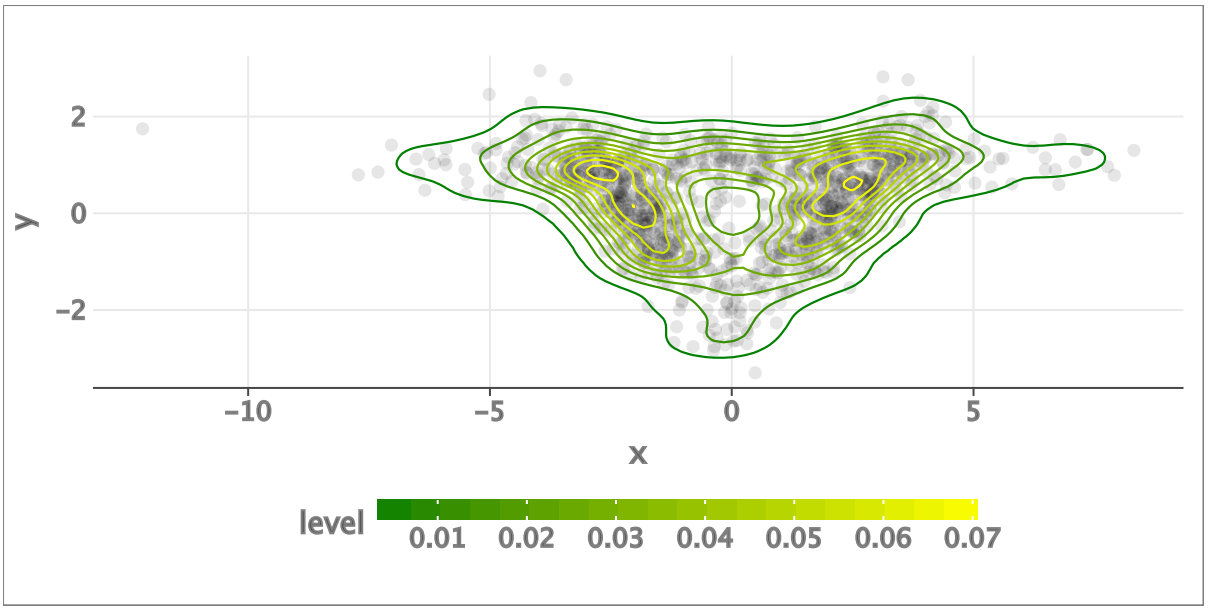
// Defines the number of samples
val n = 400

// Defines means for three distributions
val means0: DoubleArray = doubleArrayOf(-2.0, 0.0)
val means1: DoubleArray = doubleArrayOf(2.0, 0.0)
val means2: DoubleArray = doubleArrayOf(0.0, 1.0)

// Generates random samples from three multivariate normal distributions
val xy0 = MultivariateNormalDistribution(means0, cov0).sample(n)
val xy1 = MultivariateNormalDistribution(means1, cov1).sample(n)
val xy2 = MultivariateNormalDistribution(means2, cov2).sample(n)
```

From the code above, the `xy0`, `xy1`, and `xy2` variables store arrays with 2D (`x, y`) data points.

3. Convert your data into a `Map` type:



```
val data = mapOf(
    "x" to (xy0.map { it[0] } + xy1.map { it[0] } + xy2.map { it[0] }).toList(),
    "y" to (xy0.map { it[1] } + xy1.map { it[1] } + xy2.map { it[1] }).toList()
)
```

Generate the 2D density plot

Using the `Map` from the previous step, create a 2D density plot (`geomDensity2D`) with a scatter plot (`geomPoint`) in the background to better visualize the data points and outliers. You can use the `scaleColorGradient()` function to customize the scale of colors:

```
val densityPlot = letsPlot(data) { x = "x"; y = "y" } + ggsize(600, 300) + geomPoint(
    color = "black",
    alpha = .1
) + geomDensity2D { color = "..level.." } +
        scaleColorGradient(low = "dark_green", high = "yellow", guide = guideColorbar(barHeight = 10,
barWidth = 300)) +
        theme().legendPositionBottom()
densityPlot
```

Here's the result:

2D density plot

- Check the Lets-Plot for Kotlin's API reference.
- Learn about transforming and visualizing data with Kotlin in the Kotlin DataFrame and Kandy library documentation.

Kotlin and Java libraries for data analysis

From data collection to model building, Kotlin offers robust libraries facilitating different tasks in the data pipeline.

In addition to its own libraries, Kotlin is 100% interoperable with Java. This interoperability helps to leverage the entire ecosystem of tried-and-true Java libraries with excellent performance. With this perk, you can easily use either Kotlin or Java libraries when working on Kotlin data projects.

Kotlin libraries

Library	Purpose	Features
Kotlin DataFrame	• Data collection • Data cleaning and processing	• Operations for creating, sorting, and cleaning data frames, feature engineering, and more • Processing of structured data • Support for CSV, JSON, and other input formats • Reading from SQL databases • Connecting with different APIs to access data and increase type safety

Library	Purpose	Features
Kandy	• Data exploration and visualization	• Powerful, readable, and typesafe DSL for plotting charts of various types • Open-source library written in Kotlin for the JVM • Support for Datalore • Seamless integration with Kotlin DataFrame
KotlinDL	• Model building	• Deep learning API written in Kotlin and inspired by Keras • Training deep learning models from scratch or importing existing Keras and ONNX models for inference • Transferring learning for tailoring existing pre-trained models to your tasks • Support for the Android platform
Multik	• Data cleaning and processing • Model building	• Mathematical operations over multidimensional arrays (linear algebra, statistics, arithmetics, and other calculations) • Creating, copying, indexing, slicing, and other array operations • Kotlin-idiomatic library with benefits such as type and dimension safety and swappable computational engines, running on the JVM or as native code
Kotlin for Apache Spark	• Data collection • Data cleaning and processing • Data exploration and visualization • Model building	• Layer of compatibility between Apache Spark and Kotlin • Apache Spark data transformation operations in Kotlin-idiomatic code • Simple usage of Kotlin features, such as data classes and lambda expressions, in curly braces or method reference
Lets-Plot	• Data exploration and visualization	• Plotting statistical data written in Kotlin • Support for Datalore • Compatible with the JVM, JS, and Python • Embedding charts in Compose Multiplatform applications
KMath	• Data cleaning and processing • Data exploration and visualization • Model building	• Modular library to work with mathematical abstractions in Kotlin Multiplatform (JVM, JS, Native, and Wasm) • APIs for algebraic structures, mathematical expressions, histograms, and streaming operations • Interchangeable wrappers over existing Java and Kotlin libraries, including ND4J, Apache Commons Math, and Multik •

Library	Purpose	Features
		Inspired by Python's NumPy but with other additional features like type safety
kravis	• Data exploration and visualization	• Visualization of tabular data • Inspired by R's ggplot

Java libraries

Since Kotlin provides first-class interoperability with Java, you can use Java libraries for data tasks in your Kotlin code. Here are some examples of such libraries:

Library	Purpose	Features
Tablesaw	• Data collection • Data cleaning and processing • Data exploration and visualization	• Tools for loading, cleaning, transforming, filtering, and summarizing data • Inspired by Plot.ly
CoreNLP	• Data cleaning and processing	• Natural language processing toolkit • Linguistic annotations for text, such as sentiment and quote attributions • Support for eight languages
Smile	• Data cleaning and processing • Data exploration and visualization • Model building	• Ready-made algorithms for machine learning and natural language processing • Linear algebra, graph, interpolation, and visualization tools • Provides functional Kotlin API, Scala API, Clojure API, and more
Smile-NLP-kt	• Data cleaning and processing	• Kotlin rewrite of the Scala implicits for the natural language processing part of Smile • Operations in the format of Kotlin extension functions and interfaces • Sentence breaking, stemming, bag of words, and other tasks

Library	Purpose	Features
ND4J	• Data cleaning and processing • Model building	• Matrix mathematics library for the JVM • Over 500 mathematical, linear algebra, and deep learning operations
Apache Commons Math	• Data cleaning and processing • Model building	• Mathematics and statistics operations for Java • Correlations, distributions, linear algebra, geometry, and other operations • Machine learning models
NM Dev	• Data cleaning and processing • Model building	• Java math library of numerical algorithms • Object-oriented numerical methods • Linear algebra, optimization, statistics, calculus, and more operations
Apache OpenNLP	• Data cleaning and processing • Model building	• Machine-learning-based toolkit for the processing of natural language text • Tokenization, sentence segmentation, part-of-speech tagging, and other tasks • Built-in tools for data modeling and model validation
Charts	• Data exploration and visualization	• JavaFX library for scientific charts • Complex charts, such as logarithmic, heatmap, and force-directed graph
DeepLearning4J	• Model building	• Deep learning library for Java • Importing and retraining models (Pytorch, Tensorflow, Keras) • Deploying in JVM microservice environments, mobile devices, IoT, and Apache Spark
Timefold	• Model building	• Solver utility for optimization planning problems • Compatible with object-oriented and functional programming

Collections overview

The Kotlin Standard Library provides a comprehensive set of tools for managing *collections* – groups of a variable number of items (possibly zero) that are significant to the problem being solved and are commonly operated on.

Collections are a common concept for most programming languages, so if you're familiar with, for example, Java or Python collections, you can skip this introduction and proceed to the detailed sections.

A collection usually contains a number of objects of the same type (and its subtypes). Objects in a collection are called *elements* or *items*. For example, all the students in a department form a collection that can be used to calculate their average age.

The following collection types are relevant for Kotlin:

- *List* is an ordered collection with access to elements by indices – integer numbers that reflect their position. Elements can occur more than once in a list. An example of a list is a telephone number: it's a group of digits, their order is important, and they can repeat.
- *Set* is a collection of unique elements. It reflects the mathematical abstraction of set: a group of objects without repetitions. Generally, the order of set elements has no significance. For example, the numbers on lottery tickets form a set: they are unique, and their order is not important.
- *Map* (or *dictionary*) is a set of key-value pairs. Keys are unique, and each of them maps to exactly one value. The values can be duplicates. Maps are useful for storing logical connections between objects, for example, an employee's ID and their position.

Kotlin lets you manipulate collections independently of the exact type of objects stored in them. In other words, you add a `String` to a list of `String`s the same way as you would do with `Int`s or a user-defined class. So, the Kotlin Standard Library offers generic interfaces, classes, and functions for creating, populating, and managing collections of any type.

The collection interfaces and related functions are located in the `kotlin.collections` package. Let's get an overview of its contents.

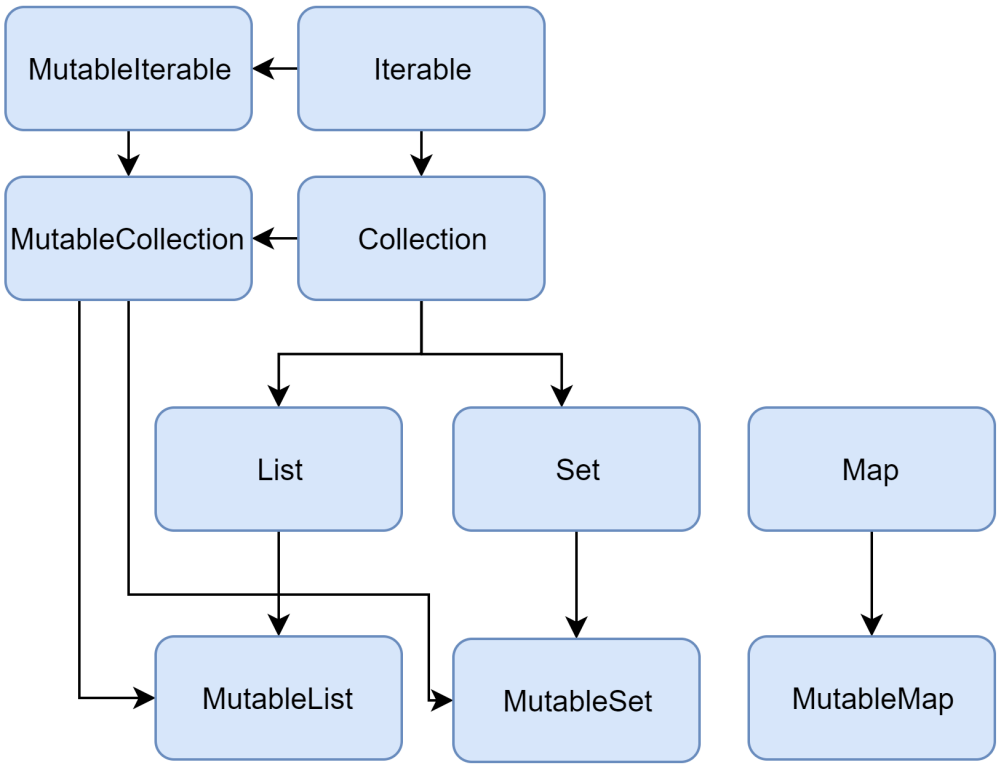
Arrays are not a type of collection. For more information, see Arrays.

Collection types

The Kotlin Standard Library provides implementations for basic collection types: sets, lists, and maps. A pair of interfaces represent each collection type:

- A *read-only* interface that provides operations for accessing collection elements.
- A *mutable* interface that extends the corresponding read-only interface with write operations: adding, removing, and updating its elements.

Note that a mutable collection doesn't have to be assigned to a `var`. Write operations with a mutable collection are still possible even if it is assigned to a `val`. The benefit of assigning mutable collections to `val` is that you protect the reference to the mutable collection from modification. Over time, as your code grows and becomes more complex, it becomes even more important to prevent unintentional modification to references. Use `val` as much as possible for safer and more robust code. If you try to reassign a `val` collection, you get a compilation error:



```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")
    numbers.add("five")   // this is OK
    println(numbers)
    //numbers = mutableListOf("six", "seven")      // compilation error

}
```

The read-only collection types are covariant. This means that if a `Rectangle` class inherits from `Shape`, you can use a `List<Rectangle>` anywhere the `List<Shape>` is required. In other words, the collection types have the same subtyping relationship as the element types. Maps are covariant on the value type, but not on the key type.

In turn, mutable collections aren't covariant; otherwise, this would lead to runtime failures. If `MutableList<Rectangle>` was a subtype of `MutableList<Shape>`, you could insert other `Shape` inheritors (for example, `Circle`) into it, thus violating its `Rectangle` type argument.

Below is a diagram of the Kotlin collection interfaces:

Collection interfaces hierarchy

Let's walk through the interfaces and their implementations. To learn about `Collection`, read the section below. To learn about `List`, `Set`, and `Map`, you can either read the corresponding sections or watch a video by Sebastian Aigner, Kotlin Developer Advocate:

Watch video online.

Collection

`Collection<T>` is the root of the collection hierarchy. This interface represents the common behavior of a read-only collection: retrieving size, checking item membership, and so on. `Collection` inherits from the `Iterable<T>` interface that defines the operations for iterating elements. You can use `Collection` as a parameter of a function that applies to different collection types. For more specific cases, use the `Collection`'s inheritors: `List` and `Set`.

```
fun printAll(strings: Collection<String>) {
    for(s in strings) print("$s ")
    println()
}

fun main() {
    val stringList = listOf("one", "two", "one")
    printAll(stringList)

    val stringSet = setOf("one", "two", "three")
    printAll(stringSet)
}
```

`MutableCollection<T>` is a `Collection` with write operations, such as `add` and `remove`.

```
fun List<String>.getShortWordsTo(shortWords: MutableList<String>, maxLength: Int) {
    this.filterTo(shortWords) { it.length <= maxLength }
    // throwing away the articles
    val articles = setOf("a", "A", "an", "An", "the", "The")
    shortWords -= articles
}

fun main() {
    val words = "A long time ago in a galaxy far far away".split(" ")
    val shortWords = mutableListOf<String>()
    words.getShortWordsTo(shortWords, 3)
    println(shortWords)
}
```

List

`List<T>` stores elements in a specified order and provides indexed access to them. Indices start from zero – the index of the first element – and go to `lastIndex` which is the `(list.size - 1)`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println("Number of elements: ${numbers.size}")
    println("Third element: ${numbers.get(2)}")
    println("Fourth element: ${numbers[3]}")
    println("Index of element \"two\" ${numbers.indexOf("two")}")
}
```

List elements (including nulls) can duplicate: a list can contain any number of equal objects or occurrences of a single object. Two lists are considered equal if they have the same sizes and structurally equal elements at the same positions.

```
data class Person(var name: String, var age: Int)

fun main() {
    val bob = Person("Bob", 31)
    val people = listOf(Person("Adam", 20), bob, bob)
    val people2 = listOf(Person("Adam", 20), Person("Bob", 31), bob)
    println(people == people2)
    bob.age = 32
    println(people == people2)
}
```

`MutableList<T>` is a `List` with list-specific write operations, for example, to add or remove an element at a specific position.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4)
    numbers.add(5)
    numbers.removeAt(1)
    numbers[0] = 0
    numbers.shuffle()
    println(numbers)
}
```

As you see, in some aspects lists are very similar to arrays. However, there is one important difference: an array's size is defined upon initialization and is never changed; in turn, a list doesn't have a predefined size; a list's size can be changed as a result of write operations: adding, updating, or removing elements.

In Kotlin, the default implementation of `MutableList` is `ArrayList` which you can think of as a resizable array.

Set

`Set<T>` stores unique elements; their order is generally undefined. `null` elements are unique as well: a `Set` can contain only one `null`. Two sets are equal if they have the same size, and for each element of a set there is an equal element in the other set.

```
fun main() {
    val numbers = setOf(1, 2, 3, 4)
    println("Number of elements: ${numbers.size}")
    if (numbers.contains(1)) println("1 is in the set")

    val numbersBackwards = setOf(4, 3, 2, 1)
    println("The sets are equal: ${numbers == numbersBackwards}")
}
```

`MutableSet` is a `Set` with write operations from `MutableCollection`.

The default implementation of `MutableSet` – `LinkedHashSet` – preserves the order of elements insertion. Hence, the functions that rely on the order, such as `first()` or `last()`, return predictable results on such sets.

```
fun main() {
    val numbers = setOf(1, 2, 3, 4)  // LinkedHashSet is the default implementation
    val numbersBackwards = setOf(4, 3, 2, 1)

    println(numbers.first() == numbersBackwards.first())
    println(numbers.first() == numbersBackwards.last())
}
```

An alternative implementation – `HashSet` – says nothing about the elements order, so calling such functions on it returns unpredictable results. However, `HashSet` requires less memory to store the same number of elements.

Map

`Map<K, V>` is not an inheritor of the `Collection` interface; however, it's a Kotlin collection type as well. A `Map` stores *key-value* pairs (or *entries*); keys are unique, but different keys can be paired with equal values. The `Map` interface provides specific functions, such as access to value by key, searching keys and values, and so on.

```
fun main() {
    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key4" to 1)

    println("All keys: ${numbersMap.keys}")
    println("All values: ${numbersMap.values}")
    if ("key2" in numbersMap) println("Value by key \"key2\": ${numbersMap["key2"]}")
    if (1 in numbersMap.values) println("The value 1 is in the map")
    if (numbersMap.containsValue(1)) println("The value 1 is in the map") // same as previous
}
```

Two maps containing the equal pairs are equal regardless of the pair order.

```
fun main() {
    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key4" to 1)
    val anotherMap = mapOf("key2" to 2, "key1" to 1, "key4" to 1, "key3" to 3)

    println("The maps are equal: ${numbersMap == anotherMap}")
}
```

`MutableMap` is a `Map` with map write operations, for example, you can add a new key-value pair or update the value associated with the given key.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2)
    numbersMap.put("three", 3)
    numbersMap["one"] = 11

    println(numbersMap)
}
```

The default implementation of `MutableMap` – `LinkedHashMap` – preserves the order of elements insertion when iterating the map. In turn, an alternative implementation – `HashMap` – says nothing about the elements order.

ArrayDeque

`ArrayDeque<T>` is an implementation of a double-ended queue, which allows you to add or remove elements both at the beginning or end of the queue. As such, `ArrayDeque` also fills the role of both a Stack and Queue data structure in Kotlin. Behind the scenes, `ArrayDeque` is realized using a resizable array that automatically adjusts in size when required:

```
fun main() {
    val deque = ArrayDeque(listOf(1, 2, 3))

    deque.addFirst(0)
    deque.addLast(4)
    println(deque) // [0, 1, 2, 3, 4]

    println(deque.first()) // 0
    println(deque.last()) // 4

    deque.removeFirst()
    deque.removeLast()
    println(deque) // [1, 2, 3]
}
```

Constructing collections

Construct from elements

The most common way to create a collection is with the standard library functions `listOf<T>()`, `setOf<T>()`, `mutableListOf<T>()`, `mutableSetOf<T>()`. If you provide a comma-separated list of collection elements as arguments, the compiler detects the element type automatically. When creating empty collections, specify the type explicitly.

```
val numbersSet = setOf("one", "two", "three", "four")
val emptySet = mutableSetOf<String>()
```

The same is available for maps with the functions `mapOf()` and `mutableMapOf()`. The map's keys and values are passed as `Pair` objects (usually created with `to` infix function).

```
val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key4" to 1)
```

Note that the `to` notation creates a short-living `Pair` object, so it's recommended that you use it only if performance isn't critical. To avoid excessive memory usage, use alternative ways. For example, you can create a mutable map and populate it using the write operations. The `apply()` function can help to keep the initialization fluent here.

```
val numbersMap = mutableMapOf<String, String>().apply { this["one"] = "1"; this["two"] = "2" }
```

Create with collection builder functions

Another way of creating a collection is to call a builder function – `buildList()`, `buildSet()`, or `buildMap()`. They create a new, mutable collection of the corresponding type, populate it using write operations, and return a read-only collection with the same elements:

```
val map = buildMap { // this is MutableMap<String, Int>, types of key and value are inferred from the
`put()` calls below
    put("a", 1)
    put("b", 0)
    put("c", 4)
}

println(map) // {a=1, b=0, c=4}
```

Empty collections

There are also functions for creating collections without any elements: `emptyList()`, `emptySet()`, and `emptyMap()`. When creating empty collections, you should specify the type of elements that the collection will hold.

```
val empty = emptyList<String>()
```

Initializer functions for lists

For lists, there is a constructor-like function that takes the list size and the initializer function that defines the element value based on its index.

```
fun main() {
    val doubled = List(3, { it * 2 })  // or MutableList if you want to change its content later
    println(doubled)
}
```

Concrete type constructors

To create a concrete type collection, such as an `ArrayList` or `LinkedList`, you can use the available constructors for these types. Similar constructors are available for implementations of `Set` and `Map`.

```
val linkedList = LinkedList<String>(listOf("one", "two", "three"))
val presizedSet = HashSet<Int>(32)
```

Copy

To create a collection with the same elements as an existing collection, you can use copying functions. Collection copying functions from the standard library create *shallow* copy collections with references to the same elements. Thus, a change made to a collection element reflects in all its copies.

Collection copying functions, such as `toList()`, `toMutableList()`, `toSet()` and others, create a snapshot of a collection at a specific moment. Their result is a new collection of the same elements. If you add or remove elements from the original collection, this won't affect the copies. Copies may be changed independently of the source as well.

```
class Person(var name: String)
fun main() {
    val alice = Person("Alice")
    val sourceList = mutableListOf(alice, Person("Bob"))
    val copyList = sourceList.toList()
    sourceList.add(Person("Charles"))
    alice.name = "Alicia"
    println("First item's name is: ${sourceList[0].name} in source and ${copyList[0].name} in copy")
    println("List size is: ${sourceList.size} in source and ${copyList.size} in copy")
}
```

These functions can also be used for converting collections to other types, for example, build a set from a list or vice versa.

```
fun main() {
    val sourceList = mutableListOf(1, 2, 3)
    val copySet = sourceList.toMutableSet()
    copySet.add(3)
    copySet.add(4)
    println(copySet)
}
```

Alternatively, you can create new references to the same collection instance. New references are created when you initialize a collection variable with an existing collection. So, when the collection instance is altered through a reference, the changes are reflected in all its references.

```
fun main() {
    val sourceList = mutableListOf(1, 2, 3)
    val referenceList = sourceList
    referenceList.add(4)
    println("Source size: ${sourceList.size}")
}
```

Collection initialization can be used for restricting mutability. For example, if you create a `List` reference to a `MutableList`, the compiler will produce errors if you try to modify the collection through this reference.

```
fun main() {
//sampleStart
    val sourceList = mutableListOf(1, 2, 3)
    val referenceList: List<Int> = sourceList
    //referenceList.add(4)            //compilation error
    sourceList.add(4)
    println(referenceList) // shows the current state of sourceList
}
```

Invoke functions on other collections

Collections can be created as a result of various operations on other collections. For example, filtering a list creates a new list of elements that match the filter:

```
fun main() {
//sampleStart
    val numbers = listOf("one", "two", "three", "four")
    val longerThan3 = numbers.filter { it.length > 3 }
    println(longerThan3)
}
```

Mapping produces a list from a transformation's results:

```
fun main() {
//sampleStart
    val numbers = setOf(1, 2, 3)
    println(numbers.map { it * 3 })
    println(numbers.mapIndexed { idx, value -> value * idx })
}
```

Association produces maps:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.associateWith { it.length })
}
```

For more information about operations on collections in Kotlin, see Collection operations overview.

Iterators

For traversing collection elements, the Kotlin standard library supports the commonly used mechanism of *iterators* – objects that provide access to the elements sequentially without exposing the underlying structure of the

collection. Iterators are useful when you need to process all the elements of a collection one-by-one, for example, print values or make similar updates to them.

Iterators can be obtained for inheritors of the `Iterable<T>` interface, including `Set` and `List`, by calling the `iterator()` function.

Once you obtain an iterator, it points to the first element of a collection; calling the `next()` function returns this element and moves the iterator position to the following element if it exists.

Once the iterator passes through the last element, it can no longer be used for retrieving elements; neither can it be reset to any previous position. To iterate through the collection again, create a new iterator.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val numbersIterator = numbers.iterator()
    while (numbersIterator.hasNext()) {
        println(numbersIterator.next())
        // one
        // two
        // three
        // four
    }
}
```

Another way to go through an `Iterable` collection is the well-known `for` loop. When using `for` on a collection, you obtain the iterator implicitly. So, the following code is equivalent to the example above:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    for (item in numbers) {
        println(item)
        // one
        // two
        // three
        // four
    }
}
```

Finally, there is a useful `forEach()` function that lets you automatically iterate a collection and execute the given code for each element. So, the same example would look like this:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    numbers.forEach {
        println(it)
        // one
        // two
        // three
        // four
    }
}
```

List iterators

For lists, there is a special iterator implementation: `ListIterator`. It supports iterating lists in both directions: forwards and backwards.

Backward iteration is implemented by the functions `hasPrevious()` and `previous()`. Additionally, the `ListIterator` provides information about the element indices with the functions `nextIndex()` and `previousIndex()`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val listIterator = numbers.listIterator()
    while (listIterator.hasNext()) listIterator.next()
    println("Iterating backwards:")
    // Iterating backwards:
    while (listIterator.hasPrevious()) {
        print("Index: ${listIterator.previousIndex()}")
        println(", value: ${listIterator.previous()}")
        // Index: 3, value: four
        // Index: 2, value: three
        // Index: 1, value: two
        // Index: 0, value: one
    }
}
```

Having the ability to iterate in both directions, means the `ListIterator` can still be used after it reaches the last element.

Mutable iterators

For iterating mutable collections, there is `MutableIterator` that extends `Iterator` with the element removal function `remove()`. So, you can remove elements from a collection while iterating it.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")
    val mutableIterator = numbers.iterator()

    mutableIterator.next()
    mutableIterator.remove()
    println("After removal: $numbers")
    // After removal: [two, three, four]
}
```

In addition to removing elements, the `MutableListIterator` can also insert and replace elements while iterating the list by using the `add()` and `set()` functions.

```
fun main() {
    val numbers = mutableListOf("one", "four", "four")
    val mutableListIterator = numbers.listIterator()

    mutableListIterator.next()
    mutableListIterator.add("two")
    println(numbers)
    // [one, two, four, four]
    mutableListIterator.next()
    mutableListIterator.set("three")
    println(numbers)
    // [one, two, three, four]
}
```

Ordering

The order of elements is an important aspect of certain collection types. For example, two lists of the same elements are not equal if their elements are ordered differently.

In Kotlin, the orders of objects can be defined in several ways.

First, there is *natural* order. It is defined for implementations of the `Comparable` interface. Natural order is used for sorting them when no other order is specified.

Most built-in types are comparable:

- Numeric types use the traditional numerical order: `1` is greater than `0`; `-3.4f` is greater than `-5f`, and so on.
- `Char` and `String` use the lexicographical order: `b` is greater than `a`; `world` is greater than `hello`.

To define a natural order for a user-defined type, make the type an implementer of `Comparable`. This requires implementing the `compareTo()` function. `compareTo()` must take another object of the same type as an argument and return an integer value showing which object is greater:

- Positive values show that the receiver object is greater.
- Negative values show that it's less than the argument.
- Zero shows that the objects are equal.

Below is a class for ordering versions that consist of the major and the minor part.

```
class Version(val major: Int, val minor: Int): Comparable<Version> {
    override fun compareTo(other: Version): Int = when {
        this.major != other.major -> this.major compareTo other.major // compareTo() in the infix form
        this.minor != other.minor -> this.minor compareTo other.minor
        else -> 0
    }
}

fun main() {
    println(Version(1, 2) > Version(1, 3))
    println(Version(2, 0) > Version(1, 5))
}
```

Custom orders let you sort instances of any type in a way you like. Particularly, you can define an order for non-comparable objects or define an order other than natural for a comparable type. To define a custom order for a type, create a `Comparator` for it. `Comparator` contains the `compare()` function: it takes two instances of a class and returns the integer result of the comparison between them. The result is interpreted in the same way as the result of a `compareTo()` as is described above.

```
fun main() {
    val lengthComparator = Comparator { str1: String, str2: String -> str1.length - str2.length }
    println(listOf("aaa", "bb", "c").sortedWith(lengthComparator))
}
```

Having the `lengthComparator`, you are able to arrange strings by their length instead of the default lexicographical order.

A shorter way to define a `Comparator` is the `compareBy()` function from the standard library. `compareBy()` takes a lambda function that produces a `Comparable` value from an instance and defines the custom order as the natural order of the produced values.

With `compareBy()`, the length comparator from the example above looks like this:

```
fun main() {
//sampleStart
    println(listOf("aaa", "bb", "c").sortedWith(compareBy { it.length }))
}
```

You can also define an order based on multiple criteria. For example, to sort strings by their length and alphabetically when the lengths are equal, you can write:

```
fun main() {
    val sortedStrings = listOf("aaa", "bb", "c", "b", "a", "aa", "ccc")
        .sortedWith { a, b ->
           when (val compareLengths = a.length.compareTo(b.length)) {
             0 -> a.compareTo(b)
             else -> compareLengths
           }
         }

    println(sortedStrings)
    // [a, b, c, aa, bb, aaa, ccc]
}
```

Since sorting by multiple criteria is a common scenario, the Kotlin standard library provides the `.thenBy()` function that you can use to add a secondary sorting rule.

For example, you can combine `compareBy()` with `.thenBy()` to sort strings by their length first and alphabetically second, just like in the previous example:

```
fun main() {
    val sortedStrings = listOf("aaa", "bb", "c", "b", "a", "aa", "ccc")
        .sortedWith(compareBy<String> { it.length }.thenBy { it })

    println(sortedStrings)
    // [a, b, c, aa, bb, aaa, ccc]
}
```

The Kotlin collections package provides functions for sorting collections in natural, custom, and even random orders. On this page, we'll describe sorting functions that apply to read-only collections. These functions return their result as a new collection containing the elements of the original collection in the requested order. To learn about functions for sorting mutable collections in place, see the List-specific operations.

Natural order

The basic functions `.sorted()` and `.sortedDescending()` return elements of a collection sorted into ascending and descending sequence according to their natural order. These functions apply to collections of `Comparable` elements.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    println("Sorted ascending: ${numbers.sorted()}")
    println("Sorted descending: ${numbers.sortedDescending()}")
}
```

Custom orders

For sorting in custom orders or sorting non-comparable objects, there are the functions `.sortedBy()` and `.sortedByDescending()`. They take a selector function that maps collection elements to `Comparable` values and sort the collection in natural order of that values.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    val sortedNumbers = numbers.sortedBy { it.length }
    println("Sorted by length ascending: $sortedNumbers")
    val sortedByLast = numbers.sortedByDescending { it.last() }
    println("Sorted by the last letter descending: $sortedByLast")
}
```

To define a custom order for the collection sorting, you can provide your own `Comparator`. To do this, call the `.sortedWith()` extension function passing in your `Comparator`. With this function, sorting strings by their length looks like this:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println("Sorted by length ascending: ${numbers.sortedWith(compareBy { it.length })}")
}
```

Check sorted order

You can use the following extension functions to check whether elements already follow a specified order:

- `.isSorted()`
- `.isSortedDescending()`
- `.isSortedWith(comparator)`
- `.isSortedBy(selector)`
- `.isSortedByDescending(selector)`

These extension functions return `true` if the elements are in the specified order or if there are fewer than two elements. They return `false` and stop checking as soon as they find an out-of-order pair.

For collections without a guaranteed iteration order, such as `HashSet`, the result may vary across calls. The same applies to sequences that don't produce elements in a consistent order. To get the same result across calls, use these functions only on collections with a guaranteed iteration order, such as `List`.

When checking `Double` and `Float` values, these functions treat `NaN` as greater than any other value and `-0.0` as less than `0.0`. Additionally, the `.isSortedBy()` and `.isSortedByDescending()` functions treat `null` selector results as less than any non-null value.

When you call these functions on a sequence, the operation is terminal. It consumes the sequence to produce a `Boolean` value instead of returning another sequence.

> These sorted-order functions are also available for arrays, primitive arrays, and unsigned arrays. Unsigned arrays and operations on them are Experimental and require opt-in with the `@ExperimentalUnsignedTypes` annotation.

Here's an example of checking sorted order with the `.isSorted()` and `.isSortedBy()` functions:

```
data class User(val name: String, val age: Int)

fun main() {
    val numbers = listOf(1, 2, 3, 4)
    println(numbers.isSorted())
    // true

    val users = listOf(
        User("Alice", 24),
        User("Bob", 31),
        User("Charlie", 29),
    )
    println(users.isSortedBy(User::age))
    // false

    val descending = listOf(4, 3, 2, 1)
    println(descending.isSortedDescending())
    // true

}
```

Reverse order

You can retrieve the collection in the reversed order using the `.reversed()` function.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.reversed())
}
```

The `.reversed()` extension function returns a new collection with the copies of the elements. So, if you change the original collection later, this won't affect the previously obtained results of `.reversed()`.

Another reversing function - `.asReversed()`

- returns a reversed view of the same collection instance, so it may be more lightweight and preferable than `.reversed()` if the original list is not going to change.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val reversedNumbers = numbers.asReversed()
    println(reversedNumbers)
}
```

If the original list is mutable, all its changes reflect in its reversed views and vice versa.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")
    val reversedNumbers = numbers.asReversed()
    println(reversedNumbers)
    numbers.add("five")
    println(reversedNumbers)
}
```

However, if the mutability of the list is unknown or the source is not a list at all, `.reversed()` is more preferable since its result is a copy that won't change in the future.

Random order

Finally, there is a function that returns a new `List` containing the collection elements in a random order - `.shuffled()`. You can call it without arguments or with a `Random` object.

```
fun main() {
     val numbers = listOf("one", "two", "three", "four")
     println(numbers.shuffled())
}
```

Grouping

The Kotlin standard library provides extension functions for grouping collection elements. The basic function `groupBy()` takes a lambda function and returns a `Map`. In this map, each key is the lambda result, and the corresponding value is the `List` of elements on which this result is returned. This function can be used, for example, to group a list of `String`s by their first letter.

You can also call `groupBy()` with a second lambda argument – a value transformation function. In the result map of `groupBy()` with two lambdas, the keys produced by `keySelector` function are mapped to the results of the value transformation function instead of the original elements.

This example illustrates using the `groupBy()` function to group the strings by their first letter, iterating through the groups on the resulting `Map` with the `for` operator, and then transforming the values to uppercase using the `valueTransform` function:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")

    // Groups the strings by their first letter using groupBy()
    val groupedByFirstLetter = numbers.groupBy { it.first().uppercase() }
    println(groupedByFirstLetter)
    // {O=[one], T=[two, three], F=[four, five]}

    // Iterates through each group and prints the key and its associated values
    for ((key, value) in groupedByFirstLetter) {
        println("Key: $key, Values: $value")
    }
    // Key: O, Values: [one]
    // Key: T, Values: [two, three]
    // Key: F, Values: [four, five]

    // Groups the strings by their first letter and transforms the values to uppercase
    val groupedAndTransformed = numbers.groupBy(keySelector = { it.first() }, valueTransform = {
it.uppercase() })
    println(groupedAndTransformed)
    // {o=[ONE], t=[TWO, THREE], f=[FOUR, FIVE]}
}
```

If you want to group elements and then apply an operation to all groups at one time, use the function `groupingBy()`. It returns an instance of the `Grouping` type. The `Grouping` instance lets you apply operations to all groups in a lazy manner: the groups are actually built right before the operation execution.

Namely, `Grouping` supports the following operations:

- `eachCount()` counts the elements in each group.

- `fold()` and `reduce()` perform fold and reduce operations on each group as a separate collection and return the results.
- `aggregate()` applies a given operation subsequently to all the elements in each group and returns the result. This is the generic way to perform any operations on a `Grouping`. Use it to implement custom operations when fold or reduce are not enough.

You can use the `for` operator on the resulting `Map` to iterate through the groups created by the `groupingBy()` function. This allows you to access each key and the count of elements associated with that key.

The following example demonstrates how to group strings by their first letter using the `groupingBy()` function, count the elements in each group, and then iterate through each group to print the key and count of elements:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")

    // Groups the strings by their first letter using groupingBy() and counts the elements in each
group
    val grouped = numbers.groupingBy { it.first() }.eachCount()

    // Iterates through each group and prints the key and its associated values
    for ((key, count) in grouped) {
        println("Key: $key, Count: $count")
        // Key: o, Count: 1
        // Key: t, Count: 2
        // Key: f, Count: 2
    }
}
```

Collection transformation operations

The Kotlin standard library provides a set of extension functions for collection *transformations*. These functions build new collections from existing ones based on the transformation rules provided. In this page, we'll give an overview of the available collection transformation functions.

Map

The *mapping* transformation creates a collection from the results of a function on the elements of another collection. The basic mapping function is `map()`. It applies the given lambda function to each subsequent element and returns the list of the lambda results. The order of results is the same as the original order of elements. To apply a transformation that additionally uses the element index as an argument, use `mapIndexed()`.

```
fun main() {
    val numbers = setOf(1, 2, 3)
    println(numbers.map { it * 3 })
    println(numbers.mapIndexed { idx, value -> value * idx })
}
```

If the transformation produces `null` on certain elements, you can filter out the `null`s from the result collection by calling the `mapNotNull()` function instead of `map()`, or `mapIndexedNotNull()` instead of `mapIndexed()`.

```
fun main() {
    val numbers = setOf(1, 2, 3)
    println(numbers.mapNotNull { if ( it == 2) null else it * 3 })
    println(numbers.mapIndexedNotNull { idx, value -> if (idx == 0) null else value * idx })
}
```

When transforming maps, you have two options: transform keys leaving values unchanged and vice versa. To apply a given transformation to keys, use `mapKeys()`; in turn, `mapValues()` transforms values. Both functions use the transformations that take a map entry as an argument, so you can operate both its key and value.

```
fun main() {
    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key11" to 11)
    println(numbersMap.mapKeys { it.key.uppercase() })
    println(numbersMap.mapValues { it.value + it.key.length })
}
```

Zip

Zipping transformation is building pairs from elements with the same positions in both collections. In the Kotlin standard library, this is done by the `zip()` extension function.

When called on a collection or an array with another collection (or array) as an argument, `zip()` returns the `List` of `Pair` objects. The elements of the receiver collection are the first elements in these pairs.

If the collections have different sizes, the result of the `zip()` is the smaller size; the last elements of the larger collection are not included in the result.

`zip()` can also be called in the infix form `a zip b`.

```
fun main() {
    val colors = listOf("red", "brown", "grey")
    val animals = listOf("fox", "bear", "wolf")
    println(colors zip animals)

    val twoAnimals = listOf("fox", "bear")
    println(colors.zip(twoAnimals))
}
```

You can also call `zip()` with a transformation function that takes two parameters: the receiver element and the argument element. In this case, the result `List` contains the return values of the transformation function called on pairs of the receiver and the argument elements with the same positions.

```
fun main() {
    val colors = listOf("red", "brown", "grey")
    val animals = listOf("fox", "bear", "wolf")

    println(colors.zip(animals) { color, animal -> "The ${animal.replaceFirstChar { it.uppercase() }}
is $color"})
}
```

When you have a `List` of `Pair`s, you can do the reverse transformation – *unzipping* – that builds two lists from these pairs:

- The first list contains the first elements of each `Pair` in the original list.
- The second list contains the second elements.

To unzip a list of pairs, call `unzip()`.

```
fun main() {
    val numberPairs = listOf("one" to 1, "two" to 2, "three" to 3, "four" to 4)
    println(numberPairs.unzip())
}
```

Associate

Association transformations allow building maps from the collection elements and certain values associated with them. In different association types, the elements can be either keys or values in the association map.

The basic association function `associateWith()` creates a `Map` in which the elements of the original collection are keys, and values are produced from them by the given transformation function. If two elements are equal, only the last one remains in the map.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.associateWith { it.length })
}
```

For building maps with collection elements as values, there is the function `associateBy()`. It takes a function that returns a key based on an element's value. If two elements' keys are equal, only the last one remains in the map.

`associateBy()` can also be called with a value transformation function.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    println(numbers.associateBy { it.first().uppercaseChar() })
    println(numbers.associateBy(keySelector = { it.first().uppercaseChar() }, valueTransform = {
it.length }))
}
```

Another way to build maps in which both keys and values are somehow produced from collection elements is the function `associate()`. It takes a lambda function that returns a `Pair`: the key and the value of the corresponding map entry.

Note that `associate()` produces short-living `Pair` objects which may affect the performance. Thus, `associate()` should be used when the performance isn't critical or it's more preferable than other options.

An example of the latter is when a key and the corresponding value are produced from an element together.

```
fun main() {
data class FullName (val firstName: String, val lastName: String)

fun parseFullName(fullName: String): FullName {
    val nameParts = fullName.split(" ")
    if (nameParts.size == 2) {
        return FullName(nameParts[0], nameParts[1])
    } else throw Exception("Wrong name format")
}

    val names = listOf("Alice Adams", "Brian Brown", "Clara Campbell")
    println(names.associate { name -> parseFullName(name).let { it.lastName to it.firstName } })
}
```

Here we call a transform function on an element first, and then build a pair from the properties of that function's result.

Flatten

If you operate nested collections, you may find the standard library functions that provide flat access to nested collection elements useful.

The first function is `flatten()`. You can call it on a collection of collections, for example, a `List` of `Set`s. The function returns a single `List` of all the elements of the nested collections.

```
fun main() {
    val numberSets = listOf(setOf(1, 2, 3), setOf(4, 5, 6), setOf(1, 2))
    println(numberSets.flatten())
}
```

Another function – `flatMap()` provides a flexible way to process nested collections. It takes a function that maps a collection element to another collection. As a result, `flatMap()` returns a single list of its return values on all the elements. So, `flatMap()` behaves as a subsequent call of `map()` (with a collection as a mapping result) and `flatten()`.

```
data class StringContainer(val values: List<String>)

fun main() {
    val containers = listOf(
        StringContainer(listOf("one", "two", "three")),
        StringContainer(listOf("four", "five", "six")),
        StringContainer(listOf("seven", "eight"))
    )
    println(containers.flatMap { it.values })
}
```

String representation

If you need to retrieve the collection content in a readable format, use functions that transform the collections to strings: `joinToString()` and `joinTo()`.

`joinToString()` builds a single `String` from the collection elements based on the provided arguments. `joinTo()` does the same but appends the result to the given `Appendable` object.

When called with the parameters' default values, the functions return the result similar to calling `toString()` on the collection: a `String` of elements' string representations separated by commas with spaces.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    println(numbers)
    println(numbers.joinToString())

    val listString = StringBuffer("The list of numbers: ")
    numbers.joinTo(listString)
    println(listString)
}
```

To build a custom string representation, you can specify its parameters in function arguments `separator`, `prefix`, and `postfix`. The resulting string will start with the `prefix` and end with the `postfix`. The `separator` will come after each element except the last.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.joinToString(separator = " | ", prefix = "start: ", postfix = ": end"))
}
```

For bigger collections, you may want to specify the `limit` – a number of elements that will be included into result. If the collection size exceeds the `limit`, all the other elements will be replaced with a single value of the `truncated` argument.

```
fun main() {
    val numbers = (1..100).toList()
    println(numbers.joinToString(limit = 10, truncated = "<...>"))
}
```

Finally, to customize the representation of elements themselves, provide the `transform` function.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    println(numbers.joinToString { "Element: ${it.uppercase()}"})
}
```

Filtering collections

Filtering is one of the most popular tasks in collection processing. In Kotlin, filtering conditions are defined by *predicates* – lambda functions that take a collection element and return a boolean value: `true` means that the given element matches the predicate, `false` means the opposite.

The standard library contains a group of extension functions that let you filter collections in a single call. These functions leave the original collection unchanged, so they are available for both mutable and read-only collections. To operate the filtering result, you should assign it to a variable or chain the functions after filtering.

Filter by predicate

The basic filtering function is `filter()`. When called with a predicate, `filter()` returns the collection elements that match it. For both `List` and `Set`, the resulting collection is a `List`, for `Map` it's a `Map` as well.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val longerThan3 = numbers.filter { it.length > 3 }
    println(longerThan3)

    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key11" to 11)
    val filteredMap = numbersMap.filter { (key, value) -> key.endsWith("1") && value > 10}
    println(filteredMap)
}
```

The predicates in `filter()` can only check the values of the elements. If you want to use element positions in the filter, use `filterIndexed()`. It takes a predicate with two arguments: the index and the value of an element.

To filter collections by negative conditions, use `filterNot()`. It returns a list of elements for which the predicate yields `false`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    val filteredIdx = numbers.filterIndexed { index, s -> (index != 0) && (s.length < 5)  }
    val filteredNot = numbers.filterNot { it.length <= 3 }

    println(filteredIdx)
    println(filteredNot)
}
```

There are also functions that narrow the element type by filtering elements of a given type:

- `filterIsInstance()` returns collection elements of a given type. Being called on a `List<Any>`, `filterIsInstance<T>()` returns a `List<T>`, thus allowing you to call functions of the `T` type on its items.

```
fun main() {
    val numbers = listOf(null, 1, "two", 3.0, "four")
    println("All String elements in upper case:")
    numbers.filterIsInstance<String>().forEach {
        println(it.uppercase())
    }
}
```

- `filterNotNull()` returns all non-nullable elements. Being called on a `List<T?>`, `filterNotNull()` returns a `List<T: Any>`, thus allowing you to treat the elements as non-nullable objects.

```
fun main() {
    val numbers = listOf(null, "one", "two", null)
    numbers.filterNotNull().forEach {
        println(it.length)   // length is unavailable for nullable Strings
    }
}
```

Partition

Another filtering function – `partition()` – filters a collection by a predicate and keeps the elements that don't match it in a separate list. So, you have a `Pair` of `List`s as a return value: the first list containing elements that match the predicate and the second one containing everything else from the original collection.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val (match, rest) = numbers.partition { it.length > 3 }

    println(match)
    println(rest)
}
```

Test predicates

Finally, there are functions that simply test a predicate against collection elements:

- `any()` returns `true` if at least one element matches the given predicate.
- `none()` returns `true` if none of the elements match the given predicate.

- `all()` returns `true` if all elements match the given predicate. Note that `all()` returns `true` when called with any valid predicate on an empty collection. Such behavior is known in logic as *vacuous truth*.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    println(numbers.any { it.endsWith("e") })
    println(numbers.none { it.endsWith("a") })
    println(numbers.all { it.endsWith("e") })

    println(emptyList<Int>().all { it > 5 })   // vacuous truth
}
```

`any()` and `none()` can also be used without a predicate: in this case, they just check the collection emptiness. `any()` returns `true` if there are elements and `false` if there aren't; `none()` does the opposite.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val empty = emptyList<String>()

    println(numbers.any())
    println(empty.any())

    println(numbers.none())
    println(empty.none())
}
```

Retrieve collection parts

The Kotlin standard library contains extension functions for retrieving parts of a collection. These functions provide a variety of ways to select elements for the result collection: listing their positions explicitly, specifying the result size, and others.

Slice

`slice()` returns a list of the collection elements with given indices. The indices may be passed either as a range or as a collection of integer values.

```
fun main() {
//sampleStart
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.slice(1..3))
    println(numbers.slice(0..4 step 2))
    println(numbers.slice(setOf(3, 5, 0)))
}
```

Take and drop

To get the specified number of elements starting from the first, use the `take()` function. For getting the last elements, use `takeLast()` . When called with a number larger than the collection size, both functions return the whole collection.

To take all the elements except a given number of first or last elements, call the `drop()` and `dropLast()` functions respectively.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.take(3))
    println(numbers.takeLast(3))
    println(numbers.drop(1))
    println(numbers.dropLast(5))
}
```

You can also use predicates to define the number of elements for taking or dropping. There are four functions similar to the ones described above:

- `takeWhile()` is `take()` with a predicate: it takes the elements up to but excluding the first one not matching the predicate. If the first collection element doesn't match the predicate, the result is empty.
- `takeLastWhile()` is similar to `takeLast()`: it takes the range of elements matching the predicate from the end of the collection. The first element of the range is the element next to the last element not matching the predicate. If the last collection element doesn't match the predicate, the result is empty;
- `dropWhile()` is the opposite to `takeWhile()` with the same predicate: it returns the elements from the first one not matching the predicate to the end.
- `dropLastWhile()` is the opposite to `takeLastWhile()` with the same predicate: it returns the elements from the beginning to the last one not matching the predicate.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.takeWhile { !it.startsWith('f') })
    println(numbers.takeLastWhile { it != "three" })
    println(numbers.dropWhile { it.length == 3 })
    println(numbers.dropLastWhile { it.contains('i') })
}
```

Chunked

To break a collection into parts of a given size, use the `chunked()` function. `chunked()` takes a single argument – the size of the chunk – and returns a `List` of `List`s of the given size. The first chunk starts from the first element and contains the `size` elements, the second chunk holds the next `size` elements, and so on. The last chunk may have a smaller size.

```
fun main() {
    val numbers = (0..13).toList()
    println(numbers.chunked(3))
}
```

You can also apply a transformation for the returned chunks right away. To do this, provide the transformation as a lambda function when calling `chunked()`. The lambda argument is a chunk of the collection. When `chunked()` is called with a transformation, the chunks are short-living `List`s that should be consumed right in that lambda.

```
fun main() {
    val numbers = (0..13).toList()
    println(numbers.chunked(3) { it.sum() })  // `it` is a chunk of the original collection
}
```

Windowed

You can retrieve all possible ranges of the collection elements of a given size. The function for getting them is called `windowed()`: it returns a list of element ranges that you would see if you were looking at the collection through a sliding window of the given size. Unlike `chunked()`, `windowed()` returns element ranges (*windows*) starting from *each* collection element. All the windows are returned as elements of a single `List`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")
    println(numbers.windowed(3))
}
```

`windowed()` provides more flexibility regarding parameters with default values:

- `step` defines a distance between first elements of two adjacent windows. By default, the value is 1, so the result contains windows starting from all elements. If you increase the step to 2, you will receive only windows starting from odd elements: first, third, and so on.
- `partialWindows` includes windows of smaller sizes that start from the elements at the end of the collection. For example, if you request windows of three elements, you can't build them for the last two elements. Enabling `partialWindows` in this case includes two more lists of sizes 2 and 1.

Finally, you can apply a transformation to the returned ranges right away. To do this, provide the transformation as a lambda function when calling `windowed()`.

```
fun main() {
    val numbers = (1..10).toList()
    println(numbers.windowed(3, step = 2, partialWindows = true))
    println(numbers.windowed(3) { it.sum() })
}
```

To build two-element windows, there is a separate function - `zipWithNext()`. It creates pairs of adjacent elements of the receiver collection. Note that `zipWithNext()` doesn't break the collection into pairs; it creates a `Pair` for *each* element except the last one, so its result on `[1, 2, 3, 4]` is `[[1, 2], [2, 3], [3, 4]]`, not `[[1, 2], [3, 4]]`. `zipWithNext()` can be called with a transformation function as well; it should take two elements of the receiver collection as arguments.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")
    println(numbers.zipWithNext())
    println(numbers.zipWithNext() { s1, s2 -> s1.length > s2.length})
}
```

Retrieve single elements

Kotlin collections provide a set of functions for retrieving single elements from collections. Functions described on this page apply to both lists and sets.

As the definition of list says, a list is an ordered collection. Hence, every element of a list has its position that you can use for referring. In addition to functions described on this page, lists offer a wider set of ways to retrieve and search for elements by indices. For more details, see List-specific operations.

In turn, set is not an ordered collection by definition. However, the Kotlin `Set` stores elements in certain orders. These can be the order of insertion (in `LinkedHashSet`), natural sorting order (in `SortedSet`), or another order.

The order of a set of elements can also be unknown. In such cases, the elements are still ordered somehow, so the functions that rely on the element positions still return their results. However, such results are unpredictable to the caller unless they know the specific implementation of `Set` used.

Retrieve by position

For retrieving an element at a specific position, there is the function `elementAt()`. Call it with the integer number as an argument, and you'll receive the collection element at the given position. The first element has the position `0`, and the last one is `(size - 1)`.

`elementAt()` is useful for collections that do not provide indexed access, or are not statically known to provide one. In case of `List`, it's more idiomatic to use indexed access operator (`get()` or `[]`).

```
fun main() {
    val numbers = linkedSetOf("one", "two", "three", "four", "five")
    println(numbers.elementAt(3))

    val numbersSortedSet = sortedSetOf("one", "two", "three", "four")
    println(numbersSortedSet.elementAt(0)) // elements are stored in the ascending order
}
```

There are also useful aliases for retrieving the first and the last element of the collection: `first()` and `last()`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")
    println(numbers.first())
    println(numbers.last())
}
```

To avoid exceptions when retrieving element with non-existing positions, use safe variations of `elementAt()`:

- `elementAtOrNull()` returns null when the specified position is out of the collection bounds.
- `elementAtOrElse()` additionally takes a lambda function that maps an `Int` argument to an instance of the collection element type. When called with an out-of-bounds position, the `elementAtOrElse()` returns the result of the lambda on the given value.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five")
    println(numbers.elementAtOrNull(5))
    println(numbers.elementAtOrElse(5) { index -> "The value for index $index is undefined"})
}
```

Retrieve by condition

Functions `first()` and `last()` also let you search a collection for elements matching a given predicate. When you call `first()` with a predicate that tests a collection element, you'll receive the first element on which the predicate yields `true`. In turn, `last()` with a predicate returns the last element matching it.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.first { it.length > 3 })
    println(numbers.last { it.startsWith("f") })
}
```

If no elements match the predicate, both functions throw exceptions. To avoid them, use `firstOrNull()` and `lastOrNull()` instead: they return `null` if no matching elements are found.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.firstOrNull { it.length > 6 })
}
```

Use the aliases if their names suit your situation better:

- `find()` instead of `firstOrNull()`
- `findLast()` instead of `lastOrNull()`

```
fun main() {
    val numbers = listOf(1, 2, 3, 4)
    println(numbers.find { it % 2 == 0 })
    println(numbers.findLast { it % 2 == 0 })
}
```

Retrieve with selector

If you need to map the collection before retrieving the element, there is a function `firstNotNullOf()`. It combines 2 actions:

- Maps the collection with the selector function
- Returns the first non-null value in the result

`firstNotNullOf()` throws the `NoSuchElementException` if the resulting collection doesn't have a non-nullable element. Use the counterpart `firstNotNullOfOrNull()` to return null in this case.

```
fun main() {
    val list = listOf<Any>(0, "true", false)
    // Converts each element to string and returns the first one that has required length
    val longEnough = list.firstNotNullOf { item -> item.toString().takeIf { it.length >= 4 } }
    println(longEnough)
}
```

Random element

If you need to retrieve an arbitrary element of a collection, call the `random()` function. You can call it without arguments or with a `Random` object as a source of the randomness.

```
fun main() {
    val numbers = listOf(1, 2, 3, 4)
    println(numbers.random())
}
```

On empty collections, `random()` throws an exception. To receive `null` instead, use `randomOrNull()`

Check element existence

To check the presence of an element in a collection, use the `contains()` function. It returns `true` if there is a collection element that `equals()` the function argument. You can call `contains()` in the operator form with the `in` keyword.

To check the presence of multiple instances together at once, call `containsAll()` with a collection of these instances as an argument.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.contains("four"))
    println("zero" in numbers)

    println(numbers.containsAll(listOf("four", "two")))
    println(numbers.containsAll(listOf("one", "zero")))
}
```

Additionally, you can check if the collection contains any elements by calling `isEmpty()` or `isNotEmpty()`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four", "five", "six")
    println(numbers.isEmpty())
    println(numbers.isNotEmpty())

    val empty = emptyList<String>()
    println(empty.isEmpty())
    println(empty.isNotEmpty())
}
```

Collection operations overview

The Kotlin standard library offers a broad variety of functions for performing operations on collections. This includes simple operations, such as getting or adding elements, as well as more complex ones including search, sorting, filtering, transformations, and so on.

Extension and member functions

Collection operations are declared in the standard library in two ways: member functions of collection interfaces and extension functions.

Member functions define operations that are essential for a collection type. For example, `Collection` contains the function `isEmpty()` for checking its emptiness; `List` contains `get()` for index access to elements, and so on.

When you create your own implementations of collection interfaces, you must implement their member functions. To make the creation of new implementations easier, use the skeletal implementations of collection interfaces from the standard library: `AbstractCollection`, `AbstractList`, `AbstractSet`, `AbstractMap`, and their mutable counterparts.

Other collection operations are declared as extension functions. These are filtering, transformation, ordering, and other collection processing functions.

Common operations

Common operations are available for both read-only and mutable collections. Common operations fall into these groups:

- Transformations
- Filtering
- `plus` and `minus` operators
- Grouping
- Retrieving collection parts
- Retrieving single elements
- Ordering
- Aggregate operations

Operations described on these pages return their results without affecting the original collection. For example, a filtering operation produces a *new collection* that contains all the elements matching the filtering predicate. Results of such operations should be either stored in variables, or used in some other way, for example, passed in other functions.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    numbers.filter { it.length > 3 }  // nothing happens with `numbers`, result is lost
    println("numbers are still $numbers")
    val longerThan3 = numbers.filter { it.length > 3 } // result is stored in `longerThan3`
    println("numbers longer than 3 chars are $longerThan3")
}
```

For certain collection operations, there is an option to specify the *destination* object. Destination is a mutable collection to which the function appends its resulting items instead of returning them in a new object. For performing operations with destinations, there are separate functions with the `To` postfix in their names, for example, `filterTo()` instead of `filter()` or `associateTo()` instead of `associate()`. These functions take the destination collection as an additional parameter.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val filterResults = mutableListOf<String>()  //destination object
    numbers.filterTo(filterResults) { it.length > 3 }
    numbers.filterIndexedTo(filterResults) { index, _ -> index == 0 }
    println(filterResults) // contains results of both operations
}
```

For convenience, these functions return the destination collection back, so you can create it right in the corresponding argument of the function call:

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    // filter numbers right into a new hash set,
    // thus eliminating duplicates in the result
    val result = numbers.mapTo(HashSet()) { it.length }
    println("distinct item lengths are $result")
}
```

Functions with destination are available for filtering, association, grouping, flattening, and other operations. For the complete list of destination operations see the Kotlin collections reference.

Write operations

For mutable collections, there are also *write operations* that change the collection state. Such operations include adding, removing, and updating elements. Write operations are listed in the Write operations and corresponding sections of List-specific operations and Map specific operations.

For certain operations, there are pairs of functions for performing the same operation: one applies the operation in-place and the other returns the result as a separate collection. For example, `sort()` sorts a mutable collection in-place, so its state changes; `sorted()` creates a new collection that contains the same elements in the sorted order.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")
    val sortedNumbers = numbers.sorted()
    println(numbers == sortedNumbers)  // false
    numbers.sort()
    println(numbers == sortedNumbers)  // true
}
```

Aggregate operations

Kotlin collections contain functions for commonly used *aggregate operations* – operations that return a single value based on the collection content. Most of them are well known and work the same way as they do in other languages:

- `minOrNull()` and `maxOrNull()` return the smallest and the largest element respectively. On empty collections, they return `null`.
- `average()` returns the average value of elements in the collection of numbers.
- `sum()` returns the sum of elements in the collection of numbers.
- `count()` returns the number of elements in a collection.

```
fun main() {
    val numbers = listOf(6, 42, 10, 4)

    println("Count: ${numbers.count()}")
    println("Max: ${numbers.maxOrNull()}")
    println("Min: ${numbers.minOrNull()}")
    println("Average: ${numbers.average()}")
    println("Sum: ${numbers.sum()}")
}
```

There are also functions for retrieving the smallest and the largest elements by certain selector function or custom `Comparator`:

- `maxByOrNull()` and `minByOrNull()` take a selector function and return the element for which it returns the largest or the smallest value.
- `maxWithOrNull()` and `minWithOrNull()` take a `Comparator` object and return the largest or smallest element according to that `Comparator`.

- `maxOfOrNull()` and `minOfOrNull()` take a selector function and return the largest or the smallest return value of the selector itself.
- `maxOfWithOrNull()` and `minOfWithOrNull()` take a `Comparator` object and return the largest or smallest selector return value according to that `Comparator`.

These functions return `null` on empty collections. There are also alternatives – `maxOf`, `minOf`, `maxOfWith`, and `minOfWith` – which do the same as their counterparts but throw a `NoSuchElementException` on empty collections.

```
fun main() {
    val numbers = listOf(5, 42, 10, 4)
    val min3Remainder = numbers.minByOrNull { it % 3 }
    println(min3Remainder)

    val strings = listOf("one", "two", "three", "four")
    val longestString = strings.maxWithOrNull(compareBy { it.length })
    println(longestString)
}
```

Besides regular `sum()`, there is an advanced summation function `sumOf()` that takes a selector function and returns the sum of its application to all collection elements. Selector can return different numeric types: `Int`, `Long`, `Double`, `UInt`, and `ULong` (also `BigInteger` and `BigDecimal` on the JVM).

```
fun main() {
    val numbers = listOf(5, 42, 10, 4)
    println(numbers.sumOf { it * 2 })
    println(numbers.sumOf { it.toDouble() / 2 })
}
```

Fold and reduce

For more specific cases, there are the functions `reduce()` and `fold()` that apply the provided operation to the collection elements sequentially and return the accumulated result. The operation takes two arguments: the previously accumulated value and the collection element.

The difference between the two functions is that `fold()` takes an initial value and uses it as the accumulated value on the first step, whereas the first step of `reduce()` uses the first and the second elements as operation arguments on the first step.

```
fun main() {
    val numbers = listOf(5, 2, 10, 4)

    val simpleSum = numbers.reduce { sum, element -> sum + element }
    println(simpleSum)
    val sumDoubled = numbers.fold(0) { sum, element -> sum + element * 2 }
    println(sumDoubled)

    //incorrect: the first element isn't doubled in the result
    //val sumDoubledReduce = numbers.reduce { sum, element -> sum + element * 2 }
    //println(sumDoubledReduce)
}
```

The example above shows the difference: `fold()` is used for calculating the sum of doubled elements. If you pass the same function to `reduce()`, it will return another result because it uses the list's first and second elements as arguments on the first step, so the first element won't be doubled.

To apply a function to elements in the reverse order, use functions `reduceRight()` and `foldRight()`. They work in a way similar to `fold()` and `reduce()` but start from the last element and then continue to previous. Note that when folding or reducing right, the operation arguments change their order: first goes the element, and then the accumulated value.

```
fun main() {
    val numbers = listOf(5, 2, 10, 4)
    val sumDoubledRight = numbers.foldRight(0) { element, sum -> sum + element * 2 }
    println(sumDoubledRight)
}
```

You can also apply operations that take element indices as parameters. For this purpose, use functions `reduceIndexed()` and `foldIndexed()` passing element index as the first argument of the operation.

Finally, there are functions that apply such operations to collection elements from right to left - `reduceRightIndexed()` and `foldRightIndexed()`.

```
fun main() {
    val numbers = listOf(5, 2, 10, 4)
    val sumEven = numbers.foldIndexed(0) { idx, sum, element -> if (idx % 2 == 0) sum + element else
sum }
    println(sumEven)

    val sumEvenRight = numbers.foldRightIndexed(0) { idx, element, sum -> if (idx % 2 == 0) sum +
element else sum }
    println(sumEvenRight)
}
```

All reduce operations throw an exception on empty collections. To receive `null` instead, use their `*OrNull()` counterparts:

- `reduceOrNull()`
- `reduceRightOrNull()`
- `reduceIndexedOrNull()`
- `reduceRightIndexedOrNull()`

For cases where you want to save intermediate accumulator values, there are functions `runningFold()` (or its synonym `scan()`) and `runningReduce()`.

```
fun main() {
    val numbers = listOf(0, 1, 2, 3, 4, 5)
    val runningReduceSum = numbers.runningReduce { sum, item -> sum + item }
    val runningFoldSum = numbers.runningFold(10) { sum, item -> sum + item }
    val transform = { index: Int, element: Int -> "N = ${index + 1}: $element" }
    println(runningReduceSum.mapIndexed(transform).joinToString("\n", "Sum of first N elements with
runningReduce:\n"))
    println(runningFoldSum.mapIndexed(transform).joinToString("\n", "Sum of first N elements with
runningFold:\n"))
}
```

If you need an index in the operation parameter, use `runningFoldIndexed()` or `runningReduceIndexed()`.

Collection write operations

Mutable collections support operations for changing the collection contents, for example, adding or removing elements. On this page, we'll describe write operations available for all implementations of `MutableCollection`. For more specific operations available for `List` and `Map`, see List-specific Operations and Map Specific Operations respectively.

Adding elements

To add a single element to a list or a set, use the `add()` function. The specified object is appended to the end of the collection.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4)
    numbers.add(5)
    println(numbers)
}
```

`addAll()` adds every element of the argument object to a list or a set. The argument can be an `Iterable`, a `Sequence`, or an `Array`. The types of the receiver and the argument may be different, for example, you can add all items from a `Set` to a `List`.

When called on lists, `addAll()` adds new elements in the same order as they go in the argument. You can also call `addAll()` specifying an element position as the first argument. The first element of the argument collection will be inserted at this position. Other elements of the argument collection will follow it, shifting the receiver elements to the end.

```
fun main() {
    val numbers = mutableListOf(1, 2, 5, 6)
    numbers.addAll(arrayOf(7, 8))
    println(numbers)
    numbers.addAll(2, setOf(3, 4))
    println(numbers)
}
```

You can also add elements using the in-place version of the `plus` operator - `plusAssign` (`+=`) When applied to a mutable collection, `+=` appends the second operand (an element or another collection) to the end of the collection.

```
fun main() {
    val numbers = mutableListOf("one", "two")
    numbers += "three"
    println(numbers)
    numbers += listOf("four", "five")
    println(numbers)
}
```

Removing elements

To remove an element from a mutable collection, use the `remove()` function. `remove()` accepts the element value and removes one occurrence of this value.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4, 3)
    numbers.remove(3)                    // removes the first `3`
    println(numbers)
    numbers.remove(5)                    // removes nothing
    println(numbers)
}
```

For removing multiple elements at once, there are the following functions :

- `removeAll()` removes all elements that are present in the argument collection. Alternatively, you can call it with a predicate as an argument; in this case, the function removes all elements for which the predicate yields `true` .
- `retainAll()` is the opposite of `removeAll()` : it removes all elements except the ones from the argument collection. When used with a predicate, it leaves only elements that match it.
- `clear()` removes all elements from a list and leaves it empty.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4)
    println(numbers)
    numbers.retainAll { it >= 3 }
    println(numbers)
    numbers.clear()
    println(numbers)

    val numbersSet = mutableSetOf("one", "two", "three", "four")
    numbersSet.removeAll(setOf("one", "two"))
    println(numbersSet)
}
```

Another way to remove elements from a collection is with the `minusAssign` (`-=`) operator – the in-place version of `minus` . The second argument can be a single instance of the element type or another collection. With a single element on the right-hand side, `-=` removes the *first* occurrence of it. In turn, if it's a collection, *all* occurrences of its elements are removed. For example, if a list contains duplicate elements, they are removed at once. The second operand can contain elements that are not present in the collection. Such elements don't affect the operation execution.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "three", "four")
    numbers -= "three"
    println(numbers)
    numbers -= listOf("four", "five")
    //numbers -= listOf("four")    // does the same as above
    println(numbers)
}
```

Updating elements

Lists and maps also provide operations for updating elements. They are described in List-specific Operations and Map Specific Operations. For sets, updating doesn't make sense since it's actually removing an element and adding another one.

List-specific operations

`List` is the most popular type of built-in collection in Kotlin. Index access to the elements of lists provides a powerful set of operations for lists.

Retrieve elements by index

Lists support all common operations for element retrieval: `elementAt()`, `first()`, `last()`, and others listed in Retrieve single elements. What is specific for lists is index access to the elements, so the simplest way to read an element is retrieving it by index. That is done with the `get()` function with the index passed in the argument or the shorthand `[index]` syntax.

If the list size is less than the specified index, an exception is thrown. There are two other functions that help you avoid such exceptions:

- `getOrElse()` lets you provide the function for calculating the default value to return if the index isn't present in the collection.
- `getOrNull()` returns `null` as the default value.

```
fun main() {
    val numbers = listOf(1, 2, 3, 4)
    println(numbers.get(0))
    println(numbers[0])
    //numbers.get(5)                        // exception!
    println(numbers.getOrNull(5))             // null
    println(numbers.getOrElse(5, {it}))       // 5
}
```

Retrieve list parts

In addition to common operations for Retrieving Collection Parts, lists provide the `subList()` function that returns a view of the specified elements range as a list. Thus, if an element of the original collection changes, it also changes in the previously created sublists and vice versa.

```
fun main() {
    val numbers = (0..13).toList()
    println(numbers.subList(3, 6))
}
```

Find element positions

Linear search

In any lists, you can find the position of an element using the functions `indexOf()` and `lastIndexOf()`. They return the first and the last position of an element equal to the given argument in the list. If there are no such elements, both functions return `-1`.

```
fun main() {
    val numbers = listOf(1, 2, 3, 4, 2, 5)
    println(numbers.indexOf(2))
    println(numbers.lastIndexOf(2))
}
```

There is also a pair of functions that take a predicate and search for elements matching it:

- `indexOfFirst()` returns the *index of the first* element matching the predicate or `-1` if there are no such elements.
- `indexOfLast()` returns the *index of the last* element matching the predicate or `-1` if there are no such elements.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4)
    println(numbers.indexOfFirst { it > 2})
    println(numbers.indexOfLast { it % 2 == 1})
}
```

Binary search in sorted lists

There is one more way to search elements in lists – binary search. It works significantly faster than other built-in search functions but *requires the list to be sorted* in ascending order according to a certain ordering: natural or another one provided in the function parameter. Otherwise, the result is undefined.

To search an element in a sorted list, call the `binarySearch()` function passing the value as an argument. If such an element exists, the function returns its index; otherwise, it returns `(-insertionPoint - 1)` where `insertionPoint` is the index where this element should be inserted so that the list remains sorted. If there is more than one element with the given value, the search can return any of their indices.

You can also specify an index range to search in: in this case, the function searches only between two provided indices.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")
    numbers.sort()
    println(numbers)
    println(numbers.binarySearch("two"))  // 3
    println(numbers.binarySearch("z")) // -5
    println(numbers.binarySearch("two", 0, 2))  // -3
}
```

Comparator binary search

When list elements aren't `Comparable`, you should provide a `Comparator` to use in the binary search. The list must be sorted in ascending order according to this `Comparator`. Let's have a look at an example:

```
data class Product(val name: String, val price: Double)

fun main() {
    val productList = listOf(
        Product("WebStorm", 49.0),
        Product("AppCode", 99.0),
        Product("DotTrace", 129.0),
        Product("ReSharper", 149.0))

    println(productList.binarySearch(Product("AppCode", 99.0), compareBy<Product> { it.price }.thenBy
{ it.name }))
}
```

Here's a list of `Product` instances that aren't `Comparable` and a `Comparator` that defines the order: product `p1` precedes product `p2` if `p1`'s price is less than `p2`'s price. So, having a list sorted ascending according to this order, we use `binarySearch()` to find the index of the specified `Product`.

Custom comparators are also handy when a list uses an order different from natural one, for example, a case-insensitive order for `String` elements.

```
fun main() {
    val colors = listOf("Blue", "green", "ORANGE", "Red", "yellow")
    println(colors.binarySearch("RED", String.CASE_INSENSITIVE_ORDER)) // 3
}
```

Comparison binary search

Binary search with *comparison* function lets you find elements without providing explicit search values. Instead, it takes a comparison function mapping elements to `Int` values and searches for the element where the function returns zero. The list must be sorted in the ascending order according to the provided function; in other words, the return values of comparison must grow from one list element to the next one.

```
import kotlin.math.sign
data class Product(val name: String, val price: Double)

fun priceComparison(product: Product, price: Double) = sign(product.price - price).toInt()

fun main() {
    val productList = listOf(
        Product("WebStorm", 49.0),
        Product("AppCode", 99.0),
        Product("DotTrace", 129.0),
        Product("ReSharper", 149.0))

    println(productList.binarySearch { priceComparison(it, 99.0) })
}
```

Both comparator and comparison binary search can be performed for list ranges as well.

List write operations

In addition to the collection modification operations described in Collection write operations, mutable lists support specific write operations. Such operations use the index to access elements to broaden the list modification capabilities.

Add

To add elements to a specific position in a list, use `add()` and `addAll()` providing the position for element insertion as an additional argument. All elements that come after the position shift to the right.

```
fun main() {
    val numbers = mutableListOf("one", "five", "six")
    numbers.add(1, "two")
    numbers.addAll(2, listOf("three", "four"))
    println(numbers)
}
```

Update

Lists also offer a function to replace an element at a given position - `set()` and its operator form `[]`. `set()` doesn't change the indexes of other elements.

```
fun main() {
    val numbers = mutableListOf("one", "five", "three")
    numbers[1] =  "two"
    println(numbers)
}
```

`fill()` simply replaces all the collection elements with the specified value.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4)
    numbers.fill(3)
    println(numbers)
}
```

Remove

To remove an element at a specific position from a list, use the `removeAt()` function providing the position as an argument. All indices of elements that come after the element being removed will decrease by one.

```
fun main() {
    val numbers = mutableListOf(1, 2, 3, 4, 3)
    numbers.removeAt(1)
    println(numbers)
}
```

Sort

In Collection Ordering, we describe operations that retrieve collection elements in specific orders. For mutable lists, the standard library offers similar extension functions that perform the same ordering operations in place. When you apply such an operation to a list instance, it changes the order of elements in that exact instance.

The in-place sorting functions have similar names to the functions that apply to read-only lists, but without the `ed/d` suffix:

- `sort*` instead of `sorted*` in the names of all sorting functions: `sort()`, `sortDescending()`, `sortBy()`, and so on.
- `shuffle()` instead of `shuffled()`.

- `reverse()` instead of `reversed()`.

`asReversed()` called on a mutable list returns another mutable list which is a reversed view of the original list. Changes in that view are reflected in the original list. The following example shows sorting functions for mutable lists:

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four")

    numbers.sort()
    println("Sort into ascending: $numbers")
    numbers.sortDescending()
    println("Sort into descending: $numbers")

    numbers.sortBy { it.length }
    println("Sort into ascending by length: $numbers")
    numbers.sortByDescending { it.last() }
    println("Sort into descending by the last letter: $numbers")

    numbers.sortWith(compareBy<String> { it.length }.thenBy { it })
    println("Sort by Comparator: $numbers")

    numbers.shuffle()
    println("Shuffle: $numbers")

    numbers.reverse()
    println("Reverse: $numbers")
}
```

Set-specific operations

The Kotlin collections package contains extension functions for popular operations on sets: finding intersections, merging, or subtracting collections from each other.

To merge two collections into one, use the `union()` function. It can be used in the infix form `a union b`. Note that for ordered collections, the order of the operands is important. In the resulting collection, the elements of the first operand go before the elements of the second:

```
fun main() {
    val numbers = setOf("one", "two", "three")

    // output according to the order
    println(numbers union setOf("four", "five"))
    // [one, two, three, four, five]
    println(setOf("four", "five") union numbers)
    // [four, five, one, two, three]
}
```

To find an intersection between two collections (elements present in both of them), use the `intersect()` function. To find collection elements not present in another collection, use the `subtract()` function. Both these functions can be called in the infix form as well, for example, `a intersect b`:

```
fun main() {
    val numbers = setOf("one", "two", "three")

    // same output
    println(numbers intersect setOf("two", "one"))
    // [one, two]
    println(numbers subtract setOf("three", "four"))
    // [one, two]
    println(numbers subtract setOf("four", "three"))
    // [one, two]
}
```

To find the elements present in either one of the two collections but not in their intersection, you can also use the `union()` function. For this operation (known as symmetric difference), calculate the differences between the two collections and merge the results:

```
fun main() {
    val numbers = setOf("one", "two", "three")
    val numbers2 = setOf("three", "four")

    // merge differences
    println((numbers - numbers2) union (numbers2 - numbers))
    // [one, two, four]
}
```

You can also apply `union()`, `intersect()`, and `subtract()` functions to lists. However, their result is *always* a `Set`. In this result, all the duplicate elements are merged into one and the index access is not available:

```
fun main() {
    val list1 = listOf(1, 1, 2, 3, 5, 8, -1)
    val list2 = listOf(1, 1, 2, 2, 3, 5)

    // result of intersecting two lists is a Set
    println(list1 intersect list2)
    // [1, 2, 3, 5]

    // equal elements are merged into one
    println(list1 union list2)
    // [1, 2, 3, 5, 8, -1]
}
```

Map-specific operations

In maps, types of both keys and values are user-defined. Key-based access to map entries enables various map-specific processing capabilities from getting a value by key to separate filtering of keys and values. On this page, we provide descriptions of the map processing functions from the standard library.

Retrieve keys and values

For retrieving a value from a map, you must provide its key as an argument of the `get()` function. The shorthand `[key]` syntax is also supported. If the given key is not found, it returns `null`. There is also the function `getValue()` which has slightly different behavior: it throws an exception if the key is not found in the map. Additionally, you have more options to handle the key absence:

- `getOrElse()` works the same way as for lists: the values for non-existent keys are returned from the given lambda function.

- `getOrDefault()` returns the specified default value if the key is not found.

For maps with nullable values, use the following functions instead, which handle missing keys and `null` values explicitly:

- `getOrElseIfNull()` returns the result of the specified default value if the key is missing or has a `null` value.
- `getOrElseIfMissing()` returns the result of the specified default value if the key is missing.

Here's an example that shows the difference between these functions:

```
@OptIn(ExperimentalStdlibApi::class)
fun main() {
    val numbersMap = mapOf("one" to 1, "two" to 2, "three" to 3)
    println(numbersMap.get("one"))
    // 1

    println(numbersMap["one"])
    // 1

    println(numbersMap.getOrDefault("four", 10))
    // 10

    println(numbersMap["five"])
    // null

    val nullableMap = mapOf("one" to 1, "two" to null)
    println(nullableMap.getOrElseIfNull("two") { 0 })
    // 0

    println(nullableMap.getOrElseIfMissing("two") { 0 })
    // null

    // Throws an exception because "six" is missing from the map
    // numbersMap.getValue("six")

}
```

To perform operations on all keys or all values of a map, you can retrieve them from the properties `keys` and `values` accordingly. `keys` is a set of all map keys and `values` is a collection of all map values.

```
fun main() {
    val numbersMap = mapOf("one" to 1, "two" to 2, "three" to 3)
    println(numbersMap.keys)
    println(numbersMap.values)
}
```

Filter

You can filter maps with the `filter()` function as well as other collections. When calling `filter()` on a map, pass to it a predicate with a `Pair` as an argument. This enables you to use both the key and the value in the filtering predicate.

```
fun main() {
    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key11" to 11)
    val filteredMap = numbersMap.filter { (key, value) -> key.endsWith("1") && value > 10}
    println(filteredMap)
}
```

There are also two specific ways for filtering maps: by keys and by values. For each way, there is a function: `filterKeys()` and `filterValues()`. Both return a new map of entries which match the given predicate. The predicate for `filterKeys()` checks only the element keys, the one for `filterValues()` checks only values.

```
fun main() {
    val numbersMap = mapOf("key1" to 1, "key2" to 2, "key3" to 3, "key11" to 11)
    val filteredKeysMap = numbersMap.filterKeys { it.endsWith("1") }
    val filteredValuesMap = numbersMap.filterValues { it < 10 }

    println(filteredKeysMap)
    println(filteredValuesMap)
}
```

Plus and minus operators

Due to the key access to elements, `plus` (`+`) and `minus` (`-`) operators work for maps differently than for other collections. `plus` returns a `Map` that contains elements of its both operands: a `Map` on the left and a `Pair` or another `Map` on the right. When the right-hand side operand contains entries with keys present in the left-hand side `Map`, the result map contains the entries from the right side.

```
fun main() {
    val numbersMap = mapOf("one" to 1, "two" to 2, "three" to 3)
    println(numbersMap + Pair("four", 4))
    println(numbersMap + Pair("one", 10))
    println(numbersMap + mapOf("five" to 5, "one" to 11))
}
```

`minus` creates a `Map` from entries of a `Map` on the left except those with keys from the right-hand side operand. So, the right-hand side operand can be either a single key or a collection of keys: list, set, and so on.

```
fun main() {
    val numbersMap = mapOf("one" to 1, "two" to 2, "three" to 3)
    println(numbersMap - "one")
    println(numbersMap - listOf("two", "four"))
}
```

For details on using `plusAssign` (`+=`) and `minusAssign` (`-=`) operators on mutable maps, see Map write operations below.

Map write operations

Mutable maps offer map-specific write operations. These operations let you change the map content using the key-based access to the values.

There are certain rules that define write operations on maps:

- Values can be updated. In turn, keys never change: once you add an entry, its key is constant.
- For each key, there is always a single value associated with it. You can add and remove whole entries.

Below are descriptions of the standard library functions for write operations available on mutable maps.

Add and update entries

To add a new key-value pair to a mutable map, use `put()`. When a new entry is put into a `LinkedHashMap` (the default map implementation), it is added so that it comes last when iterating the map. In sorted maps, the positions of new elements are defined by the order of their keys.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2)
    numbersMap.put("three", 3)
    println(numbersMap)
}
```

To add multiple entries at a time, use `putAll()`. Its argument can be a `Map` or a group of `Pair`s: `Iterable`, `Sequence`, or `Array`.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2, "three" to 3)
    numbersMap.putAll(setOf("four" to 4, "five" to 5))
    println(numbersMap)
}
```

Both `put()` and `putAll()` overwrite the values if the given keys already exist in the map. Thus, you can use them to update the values of map entries.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2)
    val previousValue = numbersMap.put("one", 11)
    println("value associated with 'one', before: $previousValue, after: ${numbersMap["one"]}")
    println(numbersMap)
}
```

You can also add new entries to maps using the shorthand operator form. There are two ways:

- `plusAssign` (`+=`) operator.
- the `[]` operator alias for `set()`.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2)
    numbersMap["three"] = 3     // calls numbersMap.put("three", 3)
    numbersMap += mapOf("four" to 4, "five" to 5)
    println(numbersMap)
}
```

When called with the key present in the map, operators overwrite the values of the corresponding entries.

Add default values for missing entries

To return an existing value or add a default value when no value is available, use the `.getOrPut()` extension function. If the key is missing or has a `null` value, `.getOrPut()` stores the default value and returns it.

For maps with nullable values, you can use the `.getOrPutIfNull()` and `.getOrPutIfMissing()` functions to control how `null` values are treated:

- `getOrPutIfNull()` behaves like `getOrPut()` and uses the default value if the key is missing or has a `null` value.
- `getOrPutIfMissing()` uses the default value only if the key is missing.

The `getOrPutIfNull()` and `getOrPutIfMissing()` functions are Experimental. To opt in, use the `@OptIn(ExperimentalStdlibApi::class)` annotation.

Here's an example:

```
@OptIn(ExperimentalStdlibApi::class)
fun main() {
    val mapForNull = mutableMapOf<String, Int?>("one" to null)
    val mapForMissing = mutableMapOf<String, Int?>("one" to null)

    // Replaces the value if "one" has a null value
    mapForNull.getOrPutIfNull("one") { 1 }

    println(mapForNull)
    // {one=1}

    // Keeps the null value because "one" exists in the map
    mapForMissing.getOrPutIfMissing("one") { 1 }

    println(mapForMissing)
    // {one=null}
}
```

Remove entries

To remove an entry from a mutable map, use the `remove()` function. When calling `remove()`, you can pass either a key or a whole key-value-pair. If you specify both the key and value, the element with this key will be removed only if its value matches the second argument.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2, "three" to 3)
    numbersMap.remove("one")
    println(numbersMap)
    numbersMap.remove("three", 4)            //doesn't remove anything
    println(numbersMap)
}
```

You can also remove entries from a mutable map by their keys or values. To do this, call `remove()` on the map's keys or values providing the key or the value of an entry. When called on values, `remove()` removes only the first entry with the given value.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2, "three" to 3, "threeAgain" to 3)
    numbersMap.keys.remove("one")
    println(numbersMap)
    numbersMap.values.remove(3)
    println(numbersMap)
}
```

The `minusAssign` (`-=`) operator is also available for mutable maps.

```
fun main() {
    val numbersMap = mutableMapOf("one" to 1, "two" to 2, "three" to 3)
    numbersMap -= "two"
    println(numbersMap)
    numbersMap -= "five"             //doesn't remove anything
    println(numbersMap)
}
```

Plus and minus operators

In Kotlin, `plus` (`+`) and `minus` (`-`) operators are defined for collections. They take a collection as the first operand; the second operand can be either an element or another collection. The return value is a new read-only collection:

- The result of `plus` contains the elements from the original collection *and* from the second operand.
- The result of `minus` contains the elements of the original collection *except* the elements from the second operand. If it's an element, `minus` removes its *first* occurrence; if it's a collection, *all* occurrences of its elements are removed.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")

    val plusList = numbers + "five"
    val minusList = numbers - listOf("three", "four")
    println(plusList)
    println(minusList)
}
```

For the details on `plus` and `minus` operators for maps, see Map specific operations. The augmented assignment operators `plusAssign` (`+=`) and `minusAssign` (`-=`) are also defined for collections. However, for read-only collections, they actually use the `plus` or `minus` operators and try to assign the result to the same variable. Thus, they are available only on `var` read-only collections. For mutable collections, they modify the collection if it's a `val` . For more details, see Collection write operations.

Sequences

Along with collections, the Kotlin standard library contains another type – *sequences* (`Sequence<T>`). Unlike collections, sequences don't contain elements, they produce them while iterating. Sequences offer the same functions as `Iterable` but implement another approach to multistep collection processing.

When the processing of an `Iterable` includes multiple steps, they are executed eagerly: each processing step completes and returns its result – an intermediate collection. The following step executes on this collection. In turn, multistep processing of sequences is executed lazily when possible: actual computing happens only when the result of the whole processing chain is requested.

The order of operations execution is different as well: `Sequence` performs all the processing steps one-by-one for every single element. In turn, `Iterable` completes each step for the whole collection and then proceeds to the next step.

So, the sequences let you avoid building results of intermediate steps, therefore improving the performance of the whole collection processing chain. However, the lazy nature of sequences adds some overhead which may be significant when processing smaller collections or doing simpler computations. Hence, you should consider both `Sequence` and `Iterable` and decide which one is better for your case.

Construct

From elements

To create a sequence, call the `sequenceOf()` function listing the elements as its arguments.

```
val numbersSequence = sequenceOf("four", "three", "two", "one")
```

From an Iterable

If you already have an `Iterable` object (such as a `List` or a `Set`), you can create a sequence from it by calling `asSequence()`.

```
val numbers = listOf("one", "two", "three", "four")
val numbersSequence = numbers.asSequence()
```

From a function

One more way to create a sequence is by building it with a function that calculates its elements. To build a sequence based on a function, call `generateSequence()` with this function as an argument. Optionally, you can specify the first element as an explicit value or a result of a function call. The sequence generation stops when the provided function returns `null`. So, the sequence in the example below is infinite.

```
fun main() {
    val oddNumbers = generateSequence(1) { it + 2 } // `it` is the previous element
    println(oddNumbers.take(5).toList())
    //println(oddNumbers.count())     // error: the sequence is infinite
}
```

To create a finite sequence with `generateSequence()`, provide a function that returns `null` after the last element you need.

```
fun main() {
    val oddNumbersLessThan10 = generateSequence(1) { if (it < 8) it + 2 else null }
    println(oddNumbersLessThan10.count())
}
```

From chunks

Finally, there is a function that lets you produce sequence elements one by one or by chunks of arbitrary sizes – the `sequence()` function. This function takes a lambda expression containing calls of `yield()` and `yieldAll()` functions. They return an element to the sequence consumer and suspend the execution of `sequence()` until the next element is requested by the consumer. `yield()` takes a single element as an argument; `yieldAll()` can take an `Iterable` object, an `Iterator`, or another `Sequence`. A `Sequence` argument of `yieldAll()` can be infinite. However, such a call must be the last: all subsequent calls will never be executed.

```
fun main() {
    val oddNumbers = sequence {
        yield(1)
        yieldAll(listOf(3, 5))
        yieldAll(generateSequence(7) { it + 2 })
    }
    println(oddNumbers.take(5).toList())
}
```

Sequence operations

The sequence operations can be classified into the following groups regarding their state requirements:

- *Stateless* operations require no state and process each element independently, for example, `map()` or `filter()`. Stateless operations can also require a small constant amount of state to process an element, for example, `take()` or `drop()`.
- *Stateful* operations require a significant amount of state, usually proportional to the number of elements in a sequence.

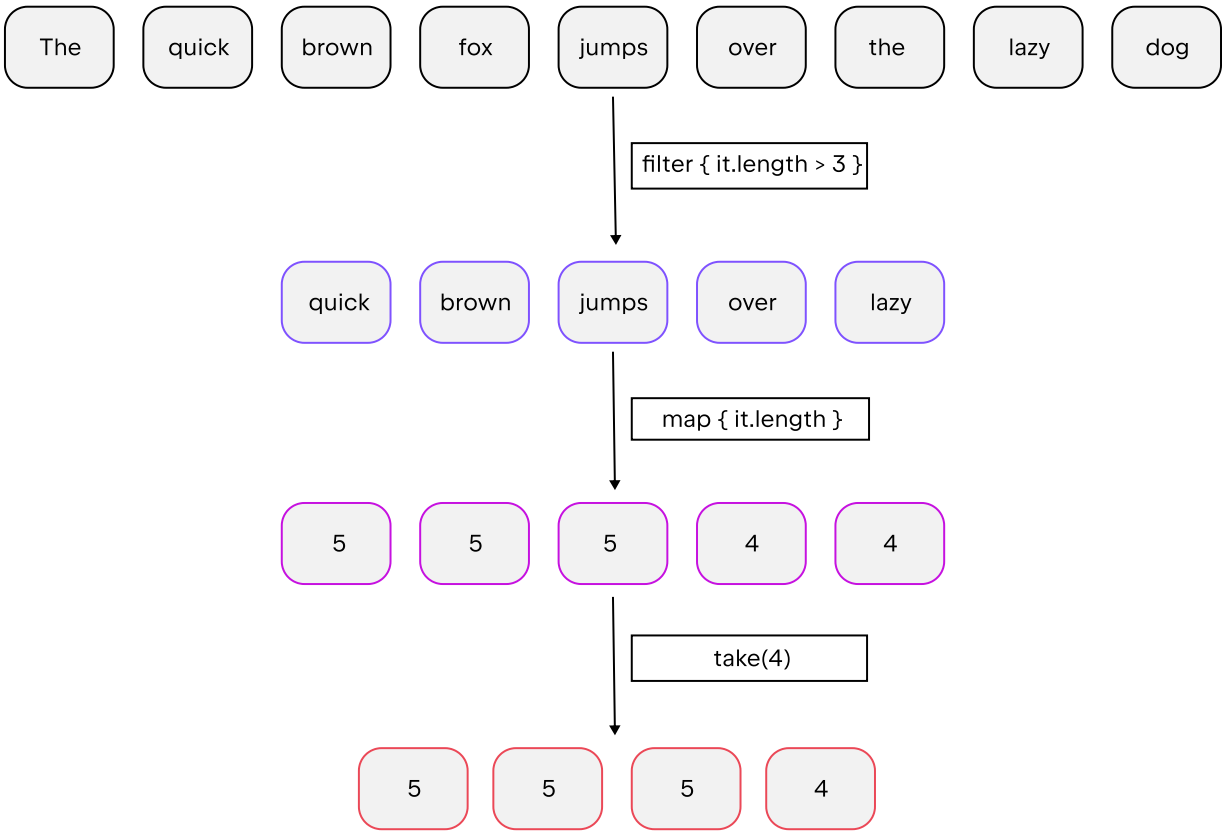
If a sequence operation returns another sequence, which is produced lazily, it's called *intermediate*. Otherwise, the operation is *terminal*. Examples of terminal operations are `toList()` or `sum()`. Sequence elements can be retrieved only with terminal operations.

Sequences can be iterated multiple times; however, some sequence implementations might constrain themselves to be iterated only once. That is mentioned specifically in their documentation.

Sequence processing example

Let's take a look at the difference between `Iterable` and `Sequence` with an example.

Iterable



Assume that you have a list of words. The code below filters the words longer than three characters and prints the lengths of first four such words.

```
fun main() {
    val words = "The quick brown fox jumps over the lazy dog".split(" ")
    val lengthsList = words.filter { println("filter: $it"); it.length > 3 }
        .map { println("length: ${it.length}"); it.length }
        .take(4)

    println("Lengths of first 4 words longer than 3 chars:")
    println(lengthsList)
}
```

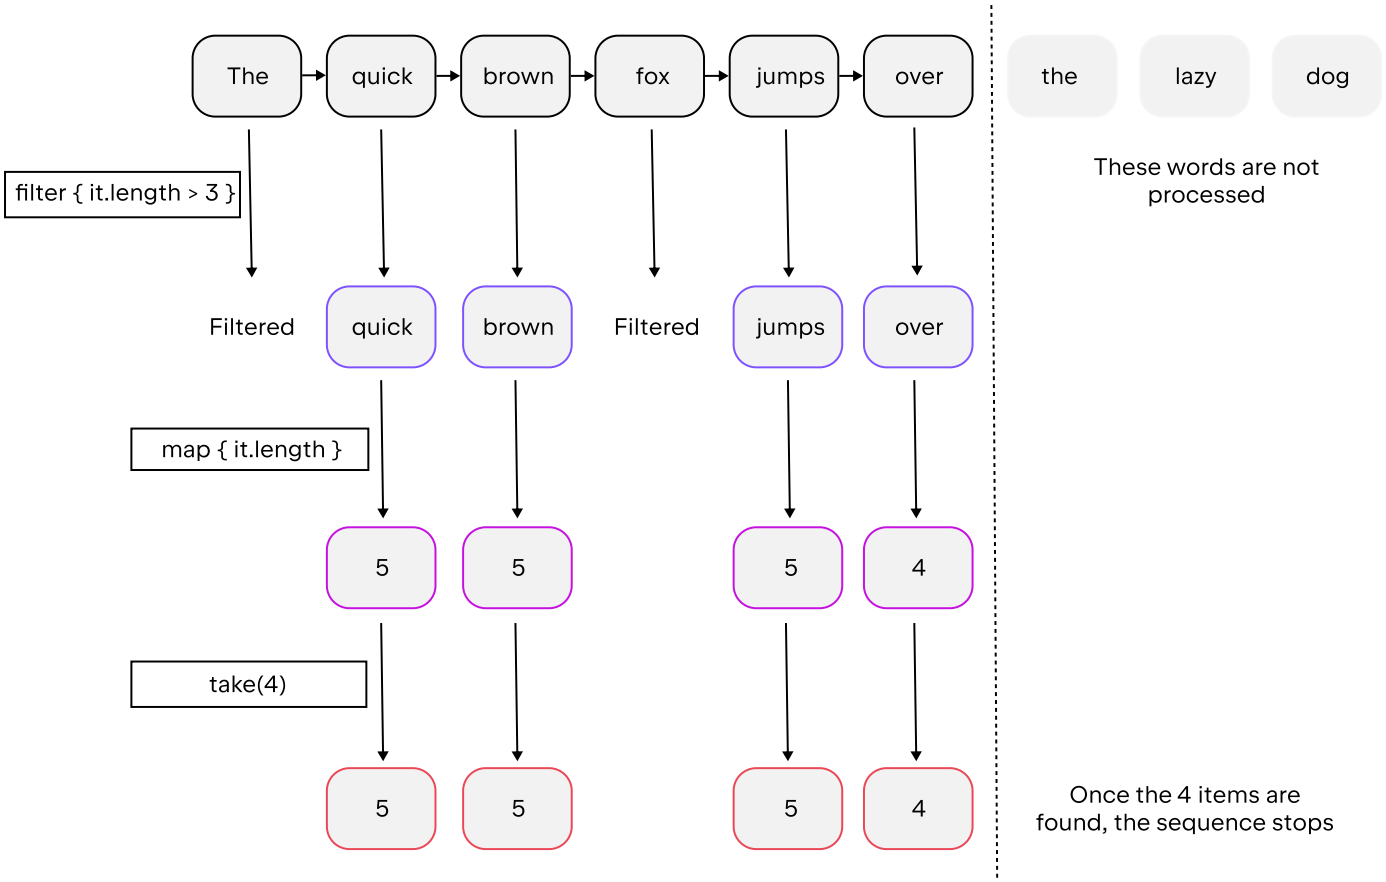
When you run this code, you'll see that the `filter()` and `map()` functions are executed in the same order as they appear in the code. First, you see `filter:` for all elements, then `length:` for the elements left after filtering, and then the output of the two last lines.

This is how the list processing goes:

List processing

Sequence

Now let's write the same with sequences:



```
fun main() {
    val words = "The quick brown fox jumps over the lazy dog".split(" ")
    //convert the List to a Sequence
    val wordsSequence = words.asSequence()

    val lengthsSequence = wordsSequence.filter { println("filter: $it"); it.length > 3 }
        .map { println("length: ${it.length}"); it.length }
        .take(4)

    println("Lengths of first 4 words longer than 3 chars")
    // terminal operation: obtaining the result as a List
    println(lengthsSequence.toList())
}
```

The output of this code shows that the `filter()` and `map()` functions are called only when building the result list. So, you first see the line of text `"Lengths of.."` and then the sequence processing starts. Note that for elements left after filtering, the map executes before filtering the next element. When the result size reaches 4, the processing stops because it's the largest possible size that `take(4)` can return.

The sequence processing goes like this:

Sequences processing

In this example, the lazy processing of elements and stopping after finding four items reduces the number of operations compared to using a list approach.

Ranges and progressions

Ranges and progressions define sequences of values in Kotlin, supporting range operators, iteration, custom step values, and arithmetic progressions.

Ranges

Kotlin lets you easily create ranges of values using the `.rangeTo()` and `.rangeUntil()` functions from the `kotlin.ranges` package.

A range represents an ordered set of values with a defined start and end. By default, it increments by 1 at each step. For example, `1..4` represents the numbers 1, 2, 3, and 4.

To create:

- a closed-ended range, call the `.rangeTo()` function with the `..` operator. This includes both the start and end values.
- an open-ended range, call the `.rangeUntil()` function with the `..<` operator. This includes the start value but excludes the end value.

For example:

```
fun main() {
    // Closed-ended range: includes both 1 and 4
    println(4 in 1..4)
    // true

    // Open-ended range: includes 1, excludes 4
    println(4 in 1..<4)
    // false
}
```

Ranges are particularly useful for iterating over `for` loops:

```
fun main() {
    for (i in 1..4) print(i)
    // 1234
}
```

To iterate numbers in reverse order, use the `downTo` function instead of `..`.

```
fun main() {
    for (i in 4 downTo 1) print(i)
    // 4321
}
```

You can also iterate over numbers with a custom step using the `step()` function, instead of the default increment of 1:

```
fun main() {
    for (i in 0..8 step 2) print(i)
    println()
    // 02468
    for (i in 0..<8 step 2) print(i)
    println()
    // 0246
    for (i in 8 downTo 0 step 2) print(i)
    // 86420
}
```

Progressions

The ranges of integral types, such as `Int`, `Long`, and `Char`, can be treated as arithmetic progressions. In Kotlin, these progressions are defined by special types: `IntProgression`, `LongProgression`, and `CharProgression`.

Progressions have three essential properties: the `first` element, the `last` element, and a non-zero `step`. The first element is `first`, subsequent elements are the previous element plus a `step`. Iteration over a progression with a positive step is equivalent to an indexed `for` loop in Java/JavaScript.

```
for (int i = first; i ⩽ last; i += step) {
  // ...
}
```

When you create a progression implicitly by iterating a range, this progression's `first` and `last` elements are the range's endpoints, and the `step` is 1.

```
fun main() {
    for (i in 1..10) print(i)
    // 12345678910
}
```

To define a custom progression step, use the `step` function on a range.

```
fun main() {
    for (i in 1..8 step 2) print(i)
    // 1357
}
```

The `last` element of the progression is calculated this way:

- For a positive step: the maximum value not greater than the end value such that `(last - first) % step == 0`.
- For a negative step: the minimum value not less than the end value such that `(last - first) % step == 0`.

Thus, the `last` element is not always the same as the specified end value.

```
fun main() {
    for (i in 1..9 step 3) print(i) // the last element is 7
    // 147
}
```

Progressions implement `Iterable<N>`, where `N` is `Int`, `Long`, or `Char` respectively, so you can use them in various collection functions like `map`, `filter`, and other.

```
fun main() {
    println((1..10).filter { it % 2 == 0 })
    // [2, 4, 6, 8, 10]
}
```

Read standard input

Use the `readln()` function to read data from the standard input. It reads the whole line as a string:

```
// Reads and stores the user input in a variable. For example: Hi there!
val myInput = readln()

println(myInput)
// Hi there!

// Reads and prints the user input without storing it in a variable. For example: Hi, Kotlin!
println(readln())
// Hi, Kotlin!
```

You can also read multiline input as one string. Use the `joinToString()` function to combine the lines:

```
val input = generateSequence(::readlnOrNull)
  .joinToString("\n")
```

Use `readlnOrNull()` instead of `readln()` to read input until end-of-file without throwing an exception.

To work with data types other than strings, you can convert the input using conversion functions like `.toInt()`, `.toLong()`, `.toDouble()`, `.toFloat()`, or `.toBoolean()`. It is possible to read multiple inputs of different data types and store each input in a variable:

```
// Converts the input from a string to an integer value. For example: 12
val myNumber = readln().toInt()
println(myNumber)
// 12

// Converts the input from a string to a double value. For example: 345
val myDouble = readln().toDouble()
println(myDouble)
// 345.0

// Converts the input from a string to a boolean value. For example: true
val myBoolean = readln().toBoolean()
println(myBoolean)
// true
```

These conversion functions assume the user enters a valid representation of the target data type. For example, converting "hello" to an integer using `.toInt()` would result in an exception as the function expects a number in the string input.

To read several input elements separated by a delimiter, use the `.split()` function specifying the delimiter. The following code sample reads from the standard input, splits the input into a list of elements based on the delimiter, and converts each element of the list into a specific type:

```
// Reads the input, assuming the elements are separated by spaces, and converts them into integers.
For example: 1 2 3
val numbers = readln().split(' ').map { it.toInt() }
println(numbers)
//[1, 2, 3]

// Reads the input, assuming the elements are separated by commas, and converts them into doubles. For
example: 4,5,6
val doubles = readln().split(',').map { it.toDouble() }
println(doubles)
//[4.0, 5.0, 6.0]
```

For an alternative way to read user input in Kotlin/JVM, see Standard input with Java Scanner.

Handle standard input safely

You can use the `.toIntOrNull()` function to safely convert user input from a string to an integer. This function returns an integer if the conversion is successful. However, if the input is not a valid representation of an integer, it returns `null`:

```
// Returns null if the input is invalid. For example: Hello!
val wrongInt = readln().toIntOrNull()
println(wrongInt)
// null

// Converts a valid input from a string to an integer. For example: 13
val correctInt = readln().toIntOrNull()
println(correctInt)
// 13
```

The `readlnOrNull()` function is also helpful in safely handling the user input. The `readlnOrNull()` function reads from the standard input and returns null if the end of the input is reached, whereas `readln()` throws an exception in such a case.

Opt-in requirements

The Kotlin standard library provides a mechanism for requiring and giving explicit consent to use certain API elements. This mechanism allows library authors to inform users about specific conditions that require opt-in, such as when an API is in an experimental state and is likely to change in the future.

To protect users, the compiler warns about these conditions and requires them to opt in before the API can be used.

Opt in to API

If a library author marks a declaration from their library's API as requiring opt-in, you must give explicit consent before you can use it in your code. There are several ways to opt in. We recommend choosing the approach that best suits your situation.

Opt in locally

To opt in to a specific API element when you use it in your code, use the `@OptIn` annotation with a reference to the experimental API marker. For example, suppose you want to use the `DateProvider` class, which requires an opt-in:

```
// Library code
@RequiresOptIn(message = "This API is experimental. It could change in the future without notice.")
@Retention(AnnotationRetention.BINARY)
@Target(AnnotationTarget.CLASS, AnnotationTarget.FUNCTION)
annotation class MyDateTime

@MyDateTime
// A class requiring opt-in
class DateProvider
```

In your code, before declaring a function that uses the `DateProvider` class, add the `@OptIn` annotation with a reference to the `MyDateTime` annotation class:

```
// Client code
@OptIn(MyDateTime::class)

// Uses DateProvider
fun getDate(): Date {
    val dateProvider: DateProvider
    // ...
}
```

It's important to note that with this approach, if the `getDate()` function is called elsewhere in your code or used by another developer, no opt-in is required:

```
// Client code
@OptIn(MyDateTime::class)

// Uses DateProvider
fun getDate(): Date {
    val dateProvider: DateProvider
    // ...
}

fun displayDate() {
    // OK: No opt-in is required
    println(getDate())
}
```

The opt-in requirement is not propagated, which means others might unknowingly use experimental APIs. To avoid this, it is safer to propagate the opt-in requirements.

Propagate opt-in requirements

When you use API in your code that's intended for third-party use, such as in a library, you can propagate its opt-in requirement to your API as well. To do this, mark your declaration with the same opt-in requirement annotation used by the library.

For example, before declaring a function that uses the `DateProvider` class, add the `@MyDateTime` annotation:

```
// Client code
@MyDateTime
fun getDate(): Date {
    // OK: the function requires opt-in as well
    val dateProvider: DateProvider
    // ...
}

fun displayDate() {
    println(getDate())
    // Error: getDate() requires opt-in
}
```

As you can see in this example, the annotated function appears to be a part of the `@MyDateTime` API. The opt-in propagates the opt-in requirement to users of the `getDate()` function.

If the signature of an API element includes a type that requires opt-in, the signature itself must also require opt-in. Otherwise, if an API element doesn't require opt-in, but its signature includes a type that does, using it triggers an error.

```
// Client code
@MyDateTime
fun getDate(dateProvider: DateProvider = DateProvider()): Date

@MyDateTime
fun displayDate() {
    // OK: the function requires opt-in as well
    println(getDate())
}
```

Similarly, if you apply `@OptIn` to a declaration whose signature includes a type that requires opt-in, the opt-in requirement still propagates:

```
// Client code
@OptIn(MyDateTime::class)
// Propagates opt-in due to DateProvider in the signature
fun getDate(dateProvider: DateProvider = DateProvider()): Date

fun displayDate() {
    println(getDate())
    // Error: getDate() requires opt-in
}
```

When propagating opt-in requirements, it's important to understand that if an API element becomes stable and no longer has an opt-in requirement, any other API elements that still have the opt-in requirement remain experimental. For example, suppose a library author removes the opt-in requirement for the `getDate()` function because it's now stable:

```
// Library code
// No opt-in requirement
fun getDate(): Date {
    val dateProvider: DateProvider
    // ...
}
```

If you use the `displayDate()` function without removing the opt-in annotation, it remains experimental even though the opt-in is no longer needed:

```
// Client code

// Still experimental!
@MyDateTime
fun displayDate() {
    // Uses a stable library function
    println(getDate())
}
```

Opt in to multiple APIs

To opt in to multiple APIs, mark the declaration with all their opt-in requirement annotations. For example:

```
@ExperimentalCoroutinesApi
@FlowPreview
```

Or alternatively with `@OptIn`:

```
@OptIn(ExperimentalCoroutinesApi::class, FlowPreview::class)
```

Opt in a file

To use an API that requires opt-in for all functions and classes in a file, add the file-level annotation `@file:OptIn` to the top of the file before the package specification and imports.

```
// Client code
@file:OptIn(MyDateTime::class)
```

Opt in a module

> The `-opt-in` compiler option is available since Kotlin 1.6.0. For earlier Kotlin versions, use `-Xopt-in`.

If you don't want to annotate every usage of APIs that require opt-in, you can opt in to them for your whole module. To opt in to using an API in a module, compile it with the argument `-opt-in`, specifying the fully qualified name of the opt-in requirement annotation of the API you use: `-opt-in=org.mylibrary.OptInAnnotation`. Compiling with this argument has the same effect as if every declaration in the module has the annotation `@OptIn(OptInAnnotation::class)`.

If you build your module with Gradle, you can add arguments like this:

Kotlin

```
import org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask
// ...

tasks.named<KotlinCompilationTask<*>>("compileKotlin").configure {
    compilerOptions.optIn.add("org.mylibrary.OptInAnnotation")
}
```

Groovy

```
import org.jetbrains.kotlin.gradle.tasks.KotlinCompilationTask
// ...

tasks.named('compileKotlin', KotlinCompilationTask) {
    compilerOptions {
        optIn.add('org.mylibrary.OptInAnnotation')
    }
}
```

If your Gradle module is a multiplatform module, use the `optIn` method:

Kotlin

```
kotlin {
    compilerOptions {
        optIn.add("org.mylibrary.OptInAnnotation")
    }
}
```

Groovy

```
kotlin {
    compilerOptions {
        optIn.add('org.mylibrary.OptInAnnotation')
    }
}
```

For Maven, use the following:

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <version>${kotlin.version}</version>
            <executions>...</executions>
            <configuration>
                <args>
                    <arg>-opt-in=org.mylibrary.OptInAnnotation</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

To opt in to multiple APIs on the module level, add one of the described arguments for each opt-in requirement marker used in your module.

Opt in to inherit from a class or interface

Sometimes, a library author provides an API but wants to require users to explicitly opt in before they can extend it. For example, the library API may be stable for use but not for inheritance, as it might be extended in the future with new abstract functions. Library authors can enforce this by marking open or abstract classes and non-functional interfaces with the `@SubclassOptInRequired` annotation.

To opt in to use such an API element and extend it in your code, use the `@SubclassOptInRequired` annotation with a reference to the annotation class. For example, suppose you want to use the `CoreLibraryApi` interface, which requires an opt-in:

```
// Library code
@RequiresOptIn(
 level = RequiresOptIn.Level.WARNING,
 message = "Interfaces in this library are experimental"
)
annotation class UnstableApi()

@SubclassOptInRequired(UnstableApi::class)
// An interface requiring opt-in to extend
interface CoreLibraryApi
```

In your code, before creating a new interface that inherits from the `CoreLibraryApi` interface, add the `@SubclassOptInRequired` annotation with a reference to the `UnstableApi` annotation class:

```
// Client code
@SubclassOptInRequired(UnstableApi::class)
interface SomeImplementation : CoreLibraryApi
```

Note that when you use the `@SubclassOptInRequired` annotation on a class, the opt-in requirement is not propagated to any inner or nested classes:

```
// Library code
@RequiresOptIn
annotation class ExperimentalFeature

@SubclassOptInRequired(ExperimentalFeature::class)
open class FileSystem {
    open class File
}

// Client code

// Opt-in is required
class NetworkFileSystem : FileSystem()

// Nested class
// No opt-in required
class TextFile : FileSystem.File()
```

Alternatively, you can opt in by using the `@OptIn` annotation. You can also use an experimental marker annotation to propagate the requirement further to any uses of the class in your code:

```
// Client code
// With @OptIn annotation
@OptInRequired(UnstableApi::class)
interface SomeImplementation : CoreLibraryApi

// With annotation referencing annotation class
// Propagates the opt-in requirement further
@UnstableApi
interface SomeImplementation : CoreLibraryApi
```

Require opt-in to use API

You can require users of your library to opt in before they are able to use your API. Additionally, you can inform users about any special conditions for using your API until you decide to remove the opt-in requirement.

Create opt-in requirement annotations

To require opt-in to use your module's API, create an annotation class to use as an **opt-in requirement annotation**. This class must be annotated with `@RequiresOptIn`:

```
@RequiresOptIn
@Retention(AnnotationRetention.BINARY)
@Target(AnnotationTarget.CLASS, AnnotationTarget.FUNCTION)
annotation class MyDateTime
```

Opt-in requirement annotations must meet several requirements. They must have:

- `BINARY` or `RUNTIME` retention.
- No `EXPRESSION`, `FILE`, `TYPE`, or `TYPE_PARAMETER` as a target.
- No parameters.

An opt-in requirement can have one of two severity levels:

- `RequiresOptIn.Level.ERROR`. Opt-in is mandatory. Otherwise, the code that uses marked API won't compile. This is the default level.
- `RequiresOptIn.Level.WARNING`. Opt-in is not mandatory, but advisable. Without it, the compiler raises a warning.

To set the desired level, specify the `level` parameter of the `@RequiresOptIn` annotation.

Additionally, you can provide a `message` to API users. The compiler shows this message to users that try to use the API without opt-in:

```
@RequiresOptIn(level = RequiresOptIn.Level.WARNING, message = "This API is experimental. It can be
incompatibly changed in the future.")
@Retention(AnnotationRetention.BINARY)
@Target(AnnotationTarget.CLASS, AnnotationTarget.FUNCTION)
annotation class ExperimentalDateTime
```

If you publish multiple independent features that require opt-in, declare an annotation for each. This makes using your API safer for your clients because they can use only the features that they explicitly accept. This also means that you can remove the opt-in requirements from features independently, which makes your API easier to maintain.

Mark API elements

To require an opt-in to use an API element, annotate its declaration with an opt-in requirement annotation:

```
@MyDateTime
class DateProvider

@MyDateTime
fun getTime(): Time {}
```

Note that for some language elements, an opt-in requirement annotation is not applicable:

- You can't annotate a backing field or a getter of a property, just the property itself.
- You can't annotate a local variable or a value parameter.

Require opt-in to extend API

There may be times when you want more granular control over which specific parts of your API can be used and extended. For example, when you have some API that is stable to use but:

- **Unstable to implement** due to ongoing evolution, such as when you have a family of interfaces where you expect to add new abstract functions without default implementations.
- **Delicate or fragile to implement**, such as individual functions that need to behave in a coordinated manner.
- **Has a contract that may be weakened in the future** in a backward-incompatible way for external implementations, such as changing an input parameter `T` to a nullable version `T?` where the code didn't previously consider `null` values.

In such cases, you can require users to opt in to your API before they can extend it further. Users can extend your API by inheriting from the API or implementing abstract functions. By using the `@SubclassOptInRequired` annotation, you can enforce this requirement to opt-in for open or abstract classes and non-functional interfaces.

To add the opt-in requirement to an API element, use the `@SubclassOptInRequired` annotation with a reference to the annotation class:

```
@RequiresOptIn(
 level = RequiresOptIn.Level.WARNING,
 message = "Interfaces in this library are experimental"
)
annotation class UnstableApi()

@SubclassOptInRequired(UnstableApi::class)
// An interface requiring opt-in to extend
interface CoreLibraryApi
```

Note that when you use the `@SubclassOptInRequired` annotation to require opt-in, the requirement is not propagated to any inner or nested classes.

For a real-world example of how to use the `@SubclassOptInRequired` annotation in your API, check out the `SharedFlow` interface in the `kotlinx.coroutines` library.

Opt-in requirements for pre-stable APIs

If you use opt-in requirements for features that are not stable yet, carefully handle the API graduation to avoid breaking client code.

Once your pre-stable API graduates and is released in a stable state, remove opt-in requirement annotations from your declarations. The clients can then use them without restriction. However, you should leave the annotation classes in modules so that the existing client code remains compatible.

To encourage API users to update their modules by removing any annotations from their code and recompiling, mark the annotations as `@Deprecated` and provide an explanation in the deprecation message.

```
@Deprecated("This opt-in requirement is not used anymore. Remove its usages from your code.")
@RequiresOptIn
annotation class ExperimentalDateTime
```

Scope functions

The Kotlin standard library contains several functions whose sole purpose is to execute a block of code within the context of an object. When you call such a function on an object with a lambda expression provided, it forms a temporary scope. In this scope, you can access the object without its name. Such functions are called *scope functions*. There are five of them: `let`, `run`, `with`, `apply`, and `also`.

Basically, these functions all perform the same action: execute a block of code on an object. What's different is how this object becomes available inside the block and what the result of the whole expression is.

Here's a typical example of how to use a scope function:

```
data class Person(var name: String, var age: Int, var city: String) {
    fun moveTo(newCity: String) { city = newCity }
    fun incrementAge() { age++ }
}

fun main() {
    Person("Alice", 20, "Amsterdam").let {
        println(it)
        it.moveTo("London")
        it.incrementAge()
        println(it)
    }
}
```

If you write the same without `let`, you'll have to introduce a new variable and repeat its name whenever you use it.

```
data class Person(var name: String, var age: Int, var city: String) {
    fun moveTo(newCity: String) { city = newCity }
    fun incrementAge() { age++ }
}

fun main() {
    val alice = Person("Alice", 20, "Amsterdam")
    println(alice)
    alice.moveTo("London")
    alice.incrementAge()
    println(alice)
}
```

Scope functions don't introduce any new technical capabilities, but they can make your code more concise and readable.

Due to the many similarities between scope functions, choosing the right one for your use case can be tricky. The choice mainly depends on your intent and the consistency of use in your project. Below, we provide detailed descriptions of the differences between scope functions and their conventions.

Function selection

To help you choose the right scope function for your purpose, we provide this table that summarizes the key differences between them.

Function	Object reference	Return value	Is extension function
`let`	`it`	Lambda result	Yes
`run`	`this`	Lambda result	Yes
`run`	-	Lambda result	No: called without the context object
`with`	`this`	Lambda result	No: takes the context object as an argument.
`apply`	`this`	Context object	Yes
`also`	`it`	Context object	Yes

Detailed information about these functions is provided in the dedicated sections below.

Here is a short guide for choosing scope functions depending on the intended purpose:

- Executing a lambda on non-nullable objects: `let`
- Introducing an expression as a variable in local scope: `let`
- Object configuration: `apply`
- Object configuration and computing the result: `run`
- Running statements where an expression is required: non-extension `run`
- Additional effects: `also`
- Grouping function calls on an object: `with`

The use cases of different scope functions overlap, so you can choose which functions to use based on the specific conventions used in your project or team.

Although scope functions can make your code more concise, avoid overusing them: it can make your code hard to read and lead to errors. We also recommend that you avoid nesting scope functions and be careful when chaining them because it's easy to get confused about the current context object and value of `this` or `it`.

Distinctions

Because scope functions are similar in nature, it's important to understand the differences between them. There are two main differences between each scope function:

- The way they refer to the context object.
- Their return value.

Context object: this or it

Inside the lambda passed to a scope function, the context object is available by a short reference instead of its actual name. Each scope function uses one of two ways to reference the context object: as a lambda receiver

(`this`) or as a lambda argument (`it`). Both provide the same capabilities, so we describe the pros and cons of each for different use cases and provide recommendations for their use.

```
fun main() {
    val str = "Hello"
    // this
    str.run {
        println("The string's length: $length")
        //println("The string's length: ${this.length}") // does the same
    }

    // it
    str.let {
        println("The string's length is ${it.length}")
    }
}
```

this

`run` , `with` , and `apply` reference the context object as a lambda receiver - by keyword `this` . Hence, in their lambdas, the object is available as it would be in ordinary class functions.

In most cases, you can omit `this` when accessing the members of the receiver object, making the code shorter. On the other hand, if `this` is omitted, it can be hard to distinguish between the receiver members and external objects or functions. So having the context object as a receiver (`this`) is recommended for lambdas that mainly operate on the object's members by calling its functions or assigning values to properties.

```
data class Person(var name: String, var age: Int = 0, var city: String = "")

fun main() {
    val adam = Person("Adam").apply {
        age = 20                       // same as this.age = 20
        city = "London"
    }
    println(adam)
}
```

it

In turn, `let` and `also` reference the context object as a lambda argument. If the argument name is not specified, the object is accessed by the implicit default name `it` . `it` is shorter than `this` and expressions with `it` are usually easier to read.

However, when calling the object's functions or properties, you don't have the object available implicitly like `this` . Hence, accessing the context object via `it` is better when the object is mostly used as an argument in function calls. `it` is also better if you use multiple variables in the code block.

```
import kotlin.random.Random

fun writeToLog(message: String) {
    println("INFO: $message")
}

fun main() {
    fun getRandomInt(): Int {
        return Random.nextInt(100).also {
            writeToLog("getRandomInt() generated value $it")
        }
    }

    val i = getRandomInt()
    println(i)
}
```

The example below demonstrates referencing the context object as a lambda argument with argument name: `value`.

```
import kotlin.random.Random

fun writeToLog(message: String) {
    println("INFO: $message")
}

fun main() {
    fun getRandomInt(): Int {
        return Random.nextInt(100).also { value ->
            writeToLog("getRandomInt() generated value $value")
        }
    }

    val i = getRandomInt()
    println(i)
}
```

Return value

Scope functions differ by the result they return:

- `apply` and `also` return the context object.
- `let`, `run`, and `with` return the lambda result.

You should consider carefully what return value you want based on what you want to do next in your code. This helps you to choose the best scope function to use.

Context object

The return value of `apply` and `also` is the context object itself. Hence, they can be included into call chains as *side steps*: you can continue chaining function calls on the same object, one after another.

```
fun main() {
    val numberList = mutableListOf<Double>()
    numberList.also { println("Populating the list") }
        .apply {
            add(2.71)
            add(3.14)
            add(1.0)
        }
        .also { println("Sorting the list") }
        .sort()
    println(numberList)
}
```

They also can be used in return statements of functions returning the context object.

```
import kotlin.random.Random

fun writeToLog(message: String) {
    println("INFO: $message")
}

fun main() {
    fun getRandomInt(): Int {
        return Random.nextInt(100).also {
            writeToLog("getRandomInt() generated value $it")
        }
    }

    val i = getRandomInt()
}
```

Lambda result

`let`, `run`, and `with` return the lambda result. So you can use them when assigning the result to a variable, chaining operations on the result, and so on.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three")
    val countEndsWithE = numbers.run {
        add("four")
        add("five")
        count { it.endsWith("e") }
    }
    println("There are $countEndsWithE elements that end with e.")
}
```

Additionally, you can ignore the return value and use a scope function to create a temporary scope for local variables.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three")
    with(numbers) {
        val firstItem = first()
        val lastItem = last()
        println("First item: $firstItem, last item: $lastItem")
    }
}
```

Functions

To help you choose the right scope function for your use case, we describe them in detail and provide recommendations for use. Technically, scope functions are interchangeable in many cases, so the examples show conventions for using them.

let

- **The context object** is available as an argument (`it`).
- **The return value** is the lambda result.

`let` can be used to invoke one or more functions on results of call chains. For example, the following code prints the results of two operations on a collection:

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four", "five")
    val resultList = numbers.map { it.length }.filter { it > 3 }
    println(resultList)
}
```

With `let` , you can rewrite the above example so that you're not assigning the result of the list operations to a variable:

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four", "five")
    numbers.map { it.length }.filter { it > 3 }.let {
        println(it)
        // and more function calls if needed
    }
}
```

If the code block passed to `let` contains a single function with `it` as an argument, you can use the method reference (`::`) instead of the lambda argument:

```
fun main() {
    val numbers = mutableListOf("one", "two", "three", "four", "five")
    numbers.map { it.length }.filter { it > 3 }.let(::println)
}
```

`let` is often used to execute a code block containing non-null values. To perform actions on a nullable object, use the safe call operator `?.` on it and call `let` with the actions in its lambda.

```
fun processNonNullString(str: String) {}

fun main() {
    val str: String? = "Hello"
    //processNonNullString(str)       // compilation error: str can be null
    val length = str?.let {
        println("let() called on $it")
        processNonNullString(it)      // OK: 'it' is not null inside '?.let { }'
        it.length
    }
}
```

You can also use `let` to introduce local variables with a limited scope to make your code easier to read. To define a new variable for the context object, provide its name as the lambda argument so that it can be used instead of the default `it`.

```
fun main() {
    val numbers = listOf("one", "two", "three", "four")
    val modifiedFirstItem = numbers.first().let { firstItem →
        println("The first item of the list is '$firstItem'")
        if (firstItem.length ≥ 5) firstItem else "!" + firstItem + "!"
    }.uppercase()
    println("First item after modifications: '$modifiedFirstItem'")
}
```

with

- **The context object** is available as a receiver (`this`).
- **The return value** is the lambda result.

As `with` is not an extension function: the context object is passed as an argument, but inside the lambda, it's available as a receiver (`this`).

We recommend using `with` for calling functions on the context object when you don't need to use the returned result. In code, `with` can be read as " *with this object, do the following.* "

```
fun main() {
    val numbers = mutableListOf("one", "two", "three")
    with(numbers) {
        println("'with' is called with argument $this")
        println("It contains $size elements")
    }
}
```

You can also use `with` to introduce a helper object whose properties or functions are used for calculating a value.

```
fun main() {
    val numbers = mutableListOf("one", "two", "three")
    val firstAndLast = with(numbers) {
        "The first element is ${first()}," +
        " the last element is ${last()}"
    }
    println(firstAndLast)
}
```

run

- **The context object** is available as a receiver (`this`).
- **The return value** is the lambda result.

`run` does the same as `with` but it is implemented as an extension function. So like `let`, you can call it on the context object using dot notation.

`run` is useful when your lambda both initializes objects and computes the return value.

```
class MultiportService(var url: String, var port: Int) {
    fun prepareRequest(): String = "Default request"
    fun query(request: String): String = "Result for query '$request'"
}

fun main() {
    val service = MultiportService("https://example.kotlinlang.org", 80)

    val result = service.run {
        port = 8080
        query(prepareRequest() + " to port $port")
    }

    // the same code written with let() function:
    val letResult = service.let {
        it.port = 8080
        it.query(it.prepareRequest() + " to port ${it.port}")
    }
    println(result)
    println(letResult)
}
```

You can also invoke `run` as a non-extension function. The non-extension variant of `run` has no context object, but it still returns the lambda result. Non-extension `run` lets you execute a block of several statements where an expression is required. In code, non-extension `run` can be read as " *run the code block and compute the result.* "

```
fun main() {
    val hexNumberRegex = run {
        val digits = "0-9"
        val hexDigits = "A-Fa-f"
        val sign = "+-"

        Regex("[$sign]?[$digits$hexDigits]+")
    }

    for (match in hexNumberRegex.findAll("+123 -FFFF !%*& 88 XYZ")) {
        println(match.value)
    }
}
```

apply

- **The context object** is available as a receiver (`this`).
- **The return value** is the object itself.

As `apply` returns the context object itself, we recommend that you use it for code blocks that don't return a value and that mainly operate on the members of the receiver object. The most common use case for `apply` is for object configuration. Such calls can be read as " *apply the following assignments to the object.* "

```
data class Person(var name: String, var age: Int = 0, var city: String = "")

fun main() {
    val adam = Person("Adam").apply {
        age = 32
        city = "London"
    }
    println(adam)
}
```

Another use case for `apply` is to include `apply` in multiple call chains for more complex processing.

also

- **The context object** is available as an argument (`it`).
- **The return value** is the object itself.

`also` is useful for performing some actions that take the context object as an argument. Use `also` for actions that need a reference to the object rather than its properties and functions, or when you don't want to shadow the `this` reference from an outer scope.

When you see `also` in code, you can read it as " *and also do the following with the object.* "

```
fun main() {
    val numbers = mutableListOf("one", "two", "three")
    numbers
        .also { println("The list elements before adding new one: $it") }
        .add("four")
}
```

takeIf and takeUnless

In addition to scope functions, the standard library contains the functions `takeIf` and `takeUnless` . These functions let you embed checks of an object's state in call chains.

When called on an object along with a predicate, `takeIf` returns this object if it satisfies the given predicate. Otherwise, it returns `null` . So, `takeIf` is a filtering function for a single object.

`takeUnless` has the opposite logic of `takeIf` . When called on an object along with a predicate, `takeUnless` returns `null` if it satisfies the given predicate. Otherwise, it returns the object.

When using `takeIf` or `takeUnless` , the object is available as a lambda argument (`it`).

```
import kotlin.random.*

fun main() {
    val number = Random.nextInt(100)

    val evenOrNull = number.takeIf { it % 2 == 0 }
    val oddOrNull = number.takeUnless { it % 2 == 0 }
    println("even: $evenOrNull, odd: $oddOrNull")
}
```

When chaining other functions after `takeIf` and `takeUnless` , don't forget to perform a null check or use a safe call (`?.`) because their return value is nullable.

```
fun main() {
    val str = "Hello"
    val caps = str.takeIf { it.isNotEmpty() }?.uppercase()
   //val caps = str.takeIf { it.isNotEmpty() }.uppercase() //compilation error
    println(caps)
}
```

`takeIf` and `takeUnless` are especially useful in combination with scope functions. For example, you can chain `takeIf` and `takeUnless` with `let` to run a code block on objects that match the given predicate. To do this, call `takeIf` on the object and then call `let` with a safe call (`?`). For objects that don't match the predicate, `takeIf` returns `null` and `let` isn't invoked.

```
fun main() {
    fun displaySubstringPosition(input: String, sub: String) {
        input.indexOf(sub).takeIf { it ≥ 0 }?.let {
            println("The substring $sub is found in $input.")
            println("Its start position is $it.")
        }
    }

    displaySubstringPosition("010000011", "11")
    displaySubstringPosition("010000011", "12")
}
```

For comparison, below is an example of how the same function can be written without using `takeIf` or scope functions:

```
fun main() {
    fun displaySubstringPosition(input: String, sub: String) {
        val index = input.indexOf(sub)
        if (index ≥ 0) {
            println("The substring $sub is found in $input.")
            println("Its start position is $index.")
        }
    }

    displaySubstringPosition("010000011", "11")
    displaySubstringPosition("010000011", "12")
}
```

Time measurement

The Kotlin standard library gives you the tools to calculate and measure time in different units. Accurate time measurement is important for activities like:

- Managing threads or processes
- Collecting statistics
- Detecting timeouts
- Debugging

By default, time is measured using a monotonic time source, but other time sources can be configured. For more information, see Create time source.

Calculate duration

To represent an amount of time, the standard library has the `Duration` class. A `Duration` can be expressed in the following units from the `DurationUnit` enum class:

- `NANOSECONDS`
- `MICROSECONDS`

- `MILLISECONDS`
- `SECONDS`
- `MINUTES`
- `HOURS`
- `DAYS`

A `Duration` can be positive, negative, zero, positive infinity, or negative infinity.

Create duration

To create a `Duration`, use the extension properties available for `Int`, `Long`, and `Double` types: `nanoseconds`, `microseconds`, `milliseconds`, `seconds`, `minutes`, `hours`, and `days`.

> Days refer to periods of 24 hours. They are not calendar days.

For example:

```
import kotlin.time.*
import kotlin.time.Duration.Companion.nanoseconds
import kotlin.time.Duration.Companion.milliseconds
import kotlin.time.Duration.Companion.seconds
import kotlin.time.Duration.Companion.minutes
import kotlin.time.Duration.Companion.days

fun main() {
    val fiveHundredMilliseconds: Duration = 500.milliseconds
    val zeroSeconds: Duration = 0.seconds
    val tenMinutes: Duration = 10.minutes
    val negativeNanosecond: Duration = (-1).nanoseconds
    val infiniteDays: Duration = Double.POSITIVE_INFINITY.days
    val negativeInfiniteDays: Duration = Double.NEGATIVE_INFINITY.days

    println(fiveHundredMilliseconds) // 500ms
    println(zeroSeconds)             // 0s
    println(tenMinutes)              // 10m
    println(negativeNanosecond)      // -1ns
    println(infiniteDays)            // Infinity
    println(negativeInfiniteDays)    // -Infinity
}
```

You can also perform basic arithmetic with `Duration` objects:

```
import kotlin.time.*
import kotlin.time.Duration.Companion.seconds

fun main() {
    val fiveSeconds: Duration = 5.seconds
    val thirtySeconds: Duration = 30.seconds

    println(fiveSeconds + thirtySeconds)
    // 35s
    println(thirtySeconds - fiveSeconds)
    // 25s
    println(fiveSeconds * 2)
    // 10s
    println(thirtySeconds / 2)
    // 15s
    println(thirtySeconds / fiveSeconds)
    // 6.0
    println(-thirtySeconds)
    // -30s
    println((-thirtySeconds).absoluteValue)
    // 30s
}
```

Get string representation

It can be useful to have a string representation of a `Duration` so that you can print, serialize, transfer, or store it.

To get a string representation, use the `.toString()` function. By default, the time is reported using each unit that is present. For example: `1h 0m 45.677s` or `-(6d 5h 5m 28.284s)`

To configure the output, use the `.toString()` function with your desired `DurationUnit` and number of decimal places as function parameters:

```
import kotlin.time.Duration
import kotlin.time.Duration.Companion.milliseconds
import kotlin.time.DurationUnit

fun main() {
    // Print in seconds with 2 decimal places
    println(5887.milliseconds.toString(DurationUnit.SECONDS, 2))
    // 5.89s
}
```

To get an ISO-8601-compatible string, use the `toIsoString()` function:

```
import kotlin.time.Duration.Companion.seconds

fun main() {
    println(86420.seconds.toIsoString()) // PT24H0M20S
}
```

Convert duration

To convert your `Duration` into a different `DurationUnit`, use the following properties:

- `inWholeNanoseconds`
- `inWholeMicroseconds`

- `inWholeSeconds`
- `inWholeMinutes`
- `inWholeHours`
- `inWholeDays`

For example:

```
import kotlin.time.Duration
import kotlin.time.Duration.Companion.minutes

fun main() {
    val thirtyMinutes: Duration = 30.minutes
    println(thirtyMinutes.inWholeSeconds)
    // 1800
}
```

Alternatively, you can use your desired `DurationUnit` as a function parameter in the following extension functions:

- `.toInt()`
- `.toDouble()`
- `.toLong()`

For example:

```
import kotlin.time.Duration.Companion.seconds
import kotlin.time.DurationUnit

fun main() {
    println(270.seconds.toDouble(DurationUnit.MINUTES))
    // 4.5
}
```

Compare duration

To check if `Duration` objects are equal, use the equality operator (`==`):

```
import kotlin.time.Duration
import kotlin.time.Duration.Companion.hours
import kotlin.time.Duration.Companion.minutes

fun main() {
    val thirtyMinutes: Duration = 30.minutes
    val halfHour: Duration = 0.5.hours
    println(thirtyMinutes == halfHour)
    // true
}
```

To compare `Duration` objects, use the comparison operators (`<` , `>`):

```
import kotlin.time.Duration.Companion.microseconds
import kotlin.time.Duration.Companion.nanoseconds

fun main() {
    println(3000.microseconds < 25000.nanoseconds)
    // false
}
```

Break duration into components

To break down a `Duration` into its time components and perform a further action, use the overload of the `toComponents()` function. Add your desired action as a function or lambda expression as a function parameter.

For example:

```
import kotlin.time.Duration
import kotlin.time.Duration.Companion.minutes

fun main() {
    val thirtyMinutes: Duration = 30.minutes
    println(thirtyMinutes.toComponents { hours, minutes, _, _ -> "${hours}h:${minutes}m" })
    // 0h:30m
}
```

In this example, the lambda expression has `hours` and `minutes` as function parameters with underscores (`_`) for the unused `seconds` and `nanoseconds` parameters. The expression returns a concatenated string using string templates to get the desired output format of `hours` and `minutes` .

Measure time

To track the passage of time, the standard library provides tools so that you can easily:

- Measure the time taken to execute some code with your desired time unit.
- Mark a moment in time.
- Compare and subtract two moments in time.
- Check how much time has passed since a specific moment in time.
- Check whether the current time has passed a specific moment in time.

Measure code execution time

To measure the time taken to execute a block of code, use the `measureTime` inline function:

```
import kotlin.time.measureTime

fun main() {
    val timeTaken = measureTime {
        Thread.sleep(100)
    }
    println(timeTaken) // e.g. 103 ms
}
```

To measure the time taken to execute a block of code **and** return the value of the block of code, use inline function `measureTimedValue` .

For example:

```
import kotlin.time.measureTimedValue

fun main() {
    val (value, timeTaken) = measureTimedValue {
        Thread.sleep(100)
        42
    }
    println(value)     // 42
    println(timeTaken) // e.g. 103 ms
}
```

By default, both functions use a monotonic time source.

Mark moments in time

To mark a specific moment in time, use the `TimeSource` interface and the `markNow()` function to create a `TimeMark`:

```
import kotlin.time.*

fun main() {
   val timeSource = TimeSource.Monotonic
   val mark = timeSource.markNow()
}
```

Measure differences in time

To measure differences between `TimeMark` objects from the same time source, use the subtraction operator (`-`).

To compare `TimeMark` objects from the same time source, use the comparison operators (`<`, `>`).

For example:

```
import kotlin.time.*

fun main() {
   val timeSource = TimeSource.Monotonic
   val mark1 = timeSource.markNow()
   Thread.sleep(500) // Sleep 0.5 seconds.
   val mark2 = timeSource.markNow()

   repeat(4) { n ->
       val mark3 = timeSource.markNow()
       val elapsed1 = mark3 - mark1
       val elapsed2 = mark3 - mark2

       println("Measurement 1.${n + 1}: elapsed1=$elapsed1, elapsed2=$elapsed2, diff=${elapsed1 -
elapsed2}")
   }

   println(mark2 > mark1) // This is true, as mark2 was captured later than mark1.
   // true
}
```

To check if a deadline has passed or a timeout has been reached, use the `hasPassedNow()` and `hasNotPassedNow()` extension functions:

```
import kotlin.time.*
import kotlin.time.Duration.Companion.seconds

fun main() {
    val timeSource = TimeSource.Monotonic
    val mark1 = timeSource.markNow()
    val fiveSeconds: Duration = 5.seconds
    val mark2 = mark1 + fiveSeconds

    // It hasn't been 5 seconds yet
    println(mark2.hasPassedNow())
    // false

    // Wait six seconds
    Thread.sleep(6000)
    println(mark2.hasPassedNow())
    // true

}
```

Time sources

By default, time is measured using a monotonic time source. Monotonic time sources only move forward and are not affected by variations like timezones. An alternative to monotonic time is elapsed real time, which is also known as wall-clock time. Elapsed real time is measured relative to another point in time.

Default time sources per platform

This table explains the default source of monotonic time for each platform:

Platform	Source
Kotlin/JVM	`System.nanoTime()`
Kotlin/JS (Node.js)	`process.hrtime()`
Kotlin/JS (browser)	`window.performance.now()` or `Date.now()`
Kotlin/Native	`std::chrono::high_resolution_clock` or `std::chrono::steady_clock`

Create time source

There are some cases where you might want to use a different time source. For example, in Android, `System.nanoTime()` only counts time while the device is active. It loses track of time when the device enters deep sleep. To keep track of time while the device is in deep sleep, you can create a time source that uses `SystemClock.elapsedRealtimeNanos()`:

```
object RealtimeMonotonicTimeSource : AbstractLongTimeSource(DurationUnit.NANOSECONDS) {
    override fun read(): Long = SystemClock.elapsedRealtimeNanos()
}
```

Then you can use your time source to make time measurements:

```
fun main() {
    val elapsed: Duration = RealtimeMonotonicTimeSource.measureTime {
        Thread.sleep(100)
    }
    println(elapsed) // e.g. 103 ms
}
```

For more information about the `kotlin.time` package, see our standard library API reference.

UUIDs

The `Uuid` class represents Universally Unique Identifiers (UUIDs), also known as Globally Unique Identifiers (GUIDs).

A `Uuid` is a 128-bit value used to uniquely identify an entity without relying on a central system that assigns IDs. This makes UUIDs useful in distributed applications, databases, client-generated records, or Kotlin Multiplatform applications.

Use the `Uuid` class to work with UUID values. Unlike plain strings, a dedicated UUID type makes your code more explicit and prevents accidental use of invalid values.

To use UUIDs in your project, import the `Uuid` class from the `kotlin.uuid` package:

```
import kotlin.uuid.Uuid
```

Generate UUIDs

To generate a random version 4 UUID for regular identifiers, such as user or database IDs, use the `Uuid.random()` function:

```
import kotlin.uuid.Uuid

fun main() {
//sampleStart
    val id = Uuid.random()
    println(id)
}
```

You can also generate specific versions of UUIDs with the following Experimental functions:

- The `Uuid.generateV4()` function generates the same type of UUID as the `Uuid.random()` function but explicitly states that the value is a version 4 UUID.
- The `Uuid.generateV7()` function generates a version 7 UUID with a timestamp that you can use for UUID sorting.
- The `Uuid.generateV7NonMonotonicAt()` function generates a version 7 UUID for a specific moment in time.

These UUID generation functions are Experimental. To opt in, use the `@OptIn(ExperimentalUuidApi::class)` annotation or add the following compiler option to your build file:

Gradle

```
kotlin {
    compilerOptions {
        freeCompilerArgs.add("-opt-in=kotlin.uuid.ExperimentalUuidApi")
    }
}
```

Maven

```
<build>
    <plugins>
        <plugin>
            <groupId>org.jetbrains.kotlin</groupId>
            <artifactId>kotlin-maven-plugin</artifactId>
            <configuration>
                <args>
                    <arg>-opt-in=kotlin.uuid.ExperimentalUuidApi</arg>
                </args>
            </configuration>
        </plugin>
    </plugins>
</build>
```

Here's an example that generates version-specific UUIDs:

```
import kotlin.time.Instant
import kotlin.time.ExperimentalTime
import kotlin.uuid.Uuid

@OptIn(kotlin.uuid.ExperimentalUuidApi::class, ExperimentalTime::class)
fun main() {
    // Generates a version 4 UUID
    val idVersion4 = Uuid.generateV4()
    println(idVersion4)

    // Generates a version 7 UUID
    val idVersion7 = Uuid.generateV7()
    println(idVersion7)

    // Generates a version 7 UUID for the specified timestamp
    val timestamp = Instant.fromEpochMilliseconds(1757440583000L)
